Background: Chronic kidney disease (CKD), and hemodialysis in particular, is thought to be a hypercoagulable state, which may contribute to increased cardiovascular risks. Given the limitations of current available coagulation testing in assessing thrombotic risks, we aim to evaluate the changes of global coagulation assays in patients with CKD undergoing haemodialysis.

Methods: This prospective observational study recruited patients undergoing hemodialysis. Fasting blood samples were collected prior to starting hemodialysis for baseline investigations such as full blood evaluation, coagulation studies and lipid studies, in addition to experimental testing via thromboelastography (TEG® 5000S) utilising citrated whole blood. Additional samples were double-centrifuged to obtain platelet-poor plasma for later assessment with calibrated automated thrombogram (CAT) and overall haemostasis potential (OHP).

Results: Twenty-six patients were recruited and the results were compared to age-matched normal controls previously collected. Hemodialysis patients had lower platelet count with increased fibrinogen, VWF antigen and factor VIII levels (p<0.01). They also had more hypercoagulable TEG® profile when compared to normal controls, with increased maximal amplitude (69.6 vs 60.0 mm, p<0.001) and reduced clot lysis (0.0% vs 0.4%, p=0.001). Interestingly, there was no significant difference in the thrombin generation parameters. In addition, D-dimer was markedly increased in hemodialysis patients independent of age (860 vs 189 ng/mL, p<0.001) but this did not correlate with fibrin generation parameters.

Conclusions: Hemodialysis patients appear to have a more hypercoagulable state characterised by increased fibrinogen, VWF antigen and factor VIII levels, as well as TEG parameters. D-dimer was markedly increased, which brings into question the clinical usefulness of D-dimer in predicting venous thromboembolism in haemodialysis patients. The lack of correlation with fibrinolytic potential may signify reduced renal clearance of D-dimer.

	Control (n=41)	Haemodialysis (n=26)	p-value
Haemoglobin (g/dL)	143.2 ± 11.7	110.0 ± 9.2	**p<0.001**
Platelet (x10^9/L)	238 (± 49)	192 (± 56)	**p=0.014**
Fibrinogen (g/L)	3.2 (± 0.6)	4.1 (± 0.9)	**p<0.001**
vWF Antigen (%)	118 (86 – 168)	155 (120 – 187)	**p=0.006**
Factor VIII (%)	121 (± 35)	161 (± 45)	**p=0.002**
TEG parameters			
R time (min)	6.3 (5.4 – 7.5)	8.2 (8.0 – 8.9)	**p<0.001**

D-dimer	189 (149 – 310)	860 (565 – 1300)	**p<0.001**

SA-PO1004

Characterization of the Effects of a Vacuolar H+-ATPase (V-ATPase) Mutation Linked to Distal Renal Tubular Acidosis (dRTA)

Jordan J. Juarez,[1] Jessica Pham,[1] Pei-Yin Ho,[1] Valeria Mancino,[1] Vivek Bhalla,[2] Nuria M. Pastor-Soler.[1] *[1]Keck School of Medicine of USC, Los Angeles, CA; [2]Stanford University, Stanford, CA.*

Background: Distal renal tubular acidosis (dRTA) Type I is a disease affecting the kidney's ability to secrete non-volatile acid. This disease can lead to severe kidney and systemic sequelae. Improper functioning of collecting duct (CD) intercalated cells (ICs) due to autoimmune or infectious conditions can lead to dRTA. More recently, single point mutations in transport proteins in ICs have been found to result Type I dRTA. One such mutation is the 1231G>T in ATP6V0A4, the a4 isoform of the V_0domain of the V-ATPase. This mutation results in a D411Y (Aspartate to Tyrosine) variant. Carriers of this mutation are seemingly healthy and therefore this mutation likely acts in an autosomal recessive fashion. We identified a 26 year-old man with refractory dRTA that was homozygous for this mutation by a NextGen dRTA sequencing panel. One of his half-siblings has presented with metabolic acidosis and hypokalemia, consistent with dRTA. Published reports from Brazil and Mexico identify this mutation as causative for dRTA. However, the exact effects of this mutation on the expression and activity of the V-ATPase has yet to be determined. We hypothesized that this mutation in a reportedly non-transmembrane region of the a4 subunit would have effects on the subcellular localization of the subunit as the underlying mechanism for decreased V-ATPase membrane function.

Methods: We performed transfections of FLAG-Tagged wild-type (WT) vs. D411Y pTracer plasmids into HEK and Clone C cells (of IC origin), followed by immunoblot and immunofluorescent labeling and confocal imaging.

Results: Our results demonstrate low expression of both WT- and D411Y ATP6V0A4 in Clone-C cells, although an anti-FLAG antibody detected a band at ~100 kDa by immunoblot in transfected Clone-C lysates. By immunolabeling and confocal microscopy we detected the WT subunit at the apical domain of transfected Clone-C polarized

monolayers on transwell filters. In contrast, the D411Y mutant subunits were detected in a cytosolic distribution.

Conclusions: Our preliminary findings indicate that the D411Y mutation interferes with normal accumulation of the V-ATPase at the apical membrane of ICs, thus offering a potential mechanism for defective V-ATPase function and dRTA patients with this mutation.

A Novel I551F Mutant of Na+/HCO3- Cotransporter NBCe1 Has Cytosolic Retention and Diminishes Transport Activity

Osamu Yamazaki,[1,2] Maho Yamashita,[1] Jinping Li,[2] Tadashi Yoshida,[1] Junichi Hirahashi,[1] Shigeru Shibata,[2] Matsuhiko Hayashi.[3,1] *[1]Department of General Medicine, Center of Apheresis and Dialysis, Keio University of Medicine, Tokyo, Japan; [2]Teikyo University School of Medicine, Tokyo, Japan; [3]Kawakita General Hospital, Suginami-ku, Japan.*

Background: Homozygous mutations in SLC4A4 encoding the electrogenic Na^+/HCO_3^- cotransporter cause proximal renal tubular acidosis associated with ocular abnormalities. Although up to 14 SLC4A4 mutations have been identified, the mechanism of NBCe1 inactivation due to the individual mutations has not been completely clarified.

Methods: In the present study we investigated the impact of SNP (Single Nucleotide Polymorphism) mutations on NBCe1 function. We identified 14 mutations in NBCe1A, resulting in the single amino acid substitutions, A425T, F461L, A465S, L494F, N503H, A518T, A518G, I523V, V533D, Y535H, I551F, Y554H, M753V, and L785I.

Results: Immunohistological analysis with confocal microscopy revealed that almost all of SNP mutants except I551F were predominantly expressed in the plasma membrane of HEK293 cells and MDCK cells. On the other hand, I551F mutant was expressed only in the cytoplasm of HEK 293 cells and MDCK cells. Functional analysis using *Xenopus* oocytes revealed that I551F mutant had a significantly reduced activity corresponding to 52% of that of wild-type ($p<0.01$). Western blotting in HEK293 cells confirmed that the surface expression of I551F mutant was significantly reduced and showed immaure band. To examine the role of I551 in more details, we also examined the properties of artificial mutants I551A, I551P, I551K, I551R, I551D and I551E in HEK293 cells. Artificial mutants were properly expressed in the plasma membrane. By contrast, only I551F mutant was predominantly expressed in cytoplasmic regions.

Conclusions: These results indicate that I551F mutation inactivates the NBCe1 function with cytoplasmic retention. Because NBCe1 plays a major role in renal proximal sodium and bicarbonate reabsorption, I551F SNP may be associated with the disturbance in systemic acid-base balance or the changes in blood pressure.

SA-PO1006

NFAT5 Regulates Endothelin Gene Expression: Possible Common Pathway in Skin and Kidney Responses to High Na+ Intake

Jayalakshmi Lakshmipathi,[1] Will Wheatley,[1] Nirupama Ramkumar,[3] Donald E. Kohan.[1,2] *[1]University of Utah Health Sciences Center, Salt Lake City, UT; [2]Salt Lake VA Medical Center, Salt Lake City, UT; [3]University of Utah, Salt Lake City, UT.*

Background: High Na^+ intake stimulates collecting duct endothelin-1 (ET-1) production which in turn promotes a natriuresis. High Na^+ intake induced ET-1 involves several factors, however increasing extracellular osmolality, as occurs in the renal medulla during Na^+loading, stimulates ET-1 by inner medullary collecting duct (IMCD3 cells) more potently than any other known stimulus. In addition, following a Na^+ load, the skin stores Na^+ leading to increased local osmolality; release of skin Na^+ into the circulation (facilitating renal elimination) partly depends upon ET-1. The current studies were undertaken to determine how osmolality augments ET-1 in IMCD and skin.

Methods: Cultured IMCD3 and dermal microvascular endothelial cells (DMVEC) were studied. Osmolality was increased for 2-4 hr using 50 mOsm/L mannitol. ET-1/GAPDH mRNA were measured. ET-1 promoter/reporter constructs were transfected into cells and secreted luciferase/alkaline phosphatase assayed. NFAT content and subcellular distribution were analyzed by western analysis.

Results: Increasing osmolality increased IMCD3 ET-1 mRNA associated with an increase in nuclear fraction NFAT5 protein content. Osmolality-stimulated ET-1 was markedly reduced by NFAT5 siRNA. Transfection of 1, 2 or 3 kb (5' to transcription start site) ET-1 promoter/reporter constructs revealed maximal osmolality induced activity in the 1 kb fragment. This region contains two NFAT5 consensus binding sites; mutation of both sites (TGGAAA to TCACGA) completely prevented hyperosmolality induced promoter activity. Increasing osmolality also increased DMVEC ET-1 mRNA content; initial studies suggest this is also NFAT5 dependent.

Conclusions: These studies identify for the first time that NFAT5 directly regulates ET-1 promoter activity. Both the skin and IMCD NFAT5/ET-1 may be involved in the Na^+ homeostatic response to high Na^+ intake. Thus, there may be a remarkably common system used by the skin and the kidney to regulate body Na^+content.

Large-Scale Meta-Analysis in European Ancestry Identifies 114 Independent Signals for Serum Urate

Adrienne Tin,[1] Jonathan Marten.[2] CKDGen Consortium *[1]Epidemiology, Johns Hopkins University, Baltimore, MD; [2]MRC IGMM, University of Edinburgh, Edinburgh, United Kingdom.*

Background: High serum urate levels are a cause of gout, an excruciating disease with suboptimal treatment affecting ~4% of the adult population in many developed countries. Patients with kidney disease have higher risk for gout. Genome-wide association studies (GWAS) of serum urate in European ancestries have identified 28 loci. Together the index SNPs at these loci explain <10% of the phenotypic variance, suggesting that additional loci remain to be identified.

Methods: We performed meta-analyses of serum urate GWAS among 288,649 individuals of European ancestry from 60 studies and of gout among 753,884 individuals of European ancestry from 17 studies using fixed-effect inverse variance weighting. To reveal independent signals of serum urate, we used GCTA model selection to identify independent variants ($r2<0.01$) in genome-wide significant urate loci ($p<5x10^{-8}$). To prioritize significant urate-associated variants, we conducted finemapping by calculating posterior probabilities in each independent region based on the Wakefield Bayes factor and constructed credible sets with 99% probability of containing driver variants.

Results: Meta-analyses identified 123 genome-wide significant 1-Mb intervals associated with serum urate (genomic control factor: 1.04). Of these, 87 were not annotated to known serum urate loci, and 98% were associated with gout in the same direction. GCTA model selection identified 114 independent signals of urate in 99 genomic regions, which were merged from the 123 intervals when index SNPs in adjacent intervals were correlated ($r2 > 0.2$). Of these 114 independent signals, half of the 99% credible sets had <17 variants, and 25% had only one variant.

Conclusions: We identified 114 independent signals associated with serum urate among European ancestry individuals. The concordance in effect direction of urate index variants for gout are consistent with established causal role of urate in gout pathophysiology. Following up on these GWAS findings with functional studies will generate novel insight in serum urate regulation and potential treatment targets for lowering urate levels for the prevention of gout.

Calcium-Dependent Contraction of Renal Tubules

Samuel L. Svendsen,[1] Alexis Hofherr,[2] Michael Kottgen,[3] Jens G. Leipziger.[1] *[1]Aarhus University, Aarhus C, Denmark; [2]University of Freiburg - Medical Center, Freiburg im Breisgau, Germany; [3]University Medical Center Freiburg, Freiburg, Germany.*

Background: Over several years, we have observed, that perfused renal tubules show "odd movements" when exposed to extracellular ATP. Whether this observation was merely an artefact or a relevant biological observation remained elusive. It is well known that renal tubules express a contractile machinery localized closely to the apical membrane. The functionality of this structure is enigmatic. Plate grown kidney cells show a pattern on their apical membrane consistent with active contraction of the luminal membrane domain. Here we test if isolated perfused renal tubules can contract.

Methods: We measured the effect on tubular diameter in isolated murine thick ascending limbs (TAL), when inducing a cytosolic $[Ca^{2+}]$ ($[Ca^{2+}]_i$) increase with uncaging ATP/stimulation of the apical P2Y2 receptors.

Results: Uncaging luminal ATP elicited a marked increase of $[Ca^{2+}]_i$, which could be fully blocked by intracellular Ca^{2+} chelation following BAPTA-AM loading. Remarkably, within 40 seconds following apical P2Y2 receptor stimulation, both the inner and outer diameter of the perfused TAL were significantly reduced. The inner and outer diameter decreased by 0.236μm (SEM ±0.041, n=5) and 0.170 μm (SEM ±0.022, n=5), respectively. This reduction could be largely prevented either blocking the $[Ca^{2+}]_i$ increase with BAPTA or by hindering actin-myosin interaction with highly specific antagonists.

Conclusions: We report the remarkable observation that renal tubules in a $[Ca^{2+}]_i$ -dependent manner can contract. This suggests that the diameter of renal tubules is a subject to active and acute regulation.

MR Modulator AZD9977 Causes Reduced Plasma Potassium Elevation Compared to Eplerenone After Potassium Challenge in CKD Model

Krister Bamberg,[1] Lena William-Olsson,[1] Soumaya El moghrabi,[2] Frederic Jaisser,[3] Judith Hartleib-Geschwindner.[1] *[1]AstraZeneca, Molndal, Sweden; [2]INSERM U1138 - Centre de Recherche des Cordeliers, Paris, France; [3]INSERM U1138, Paris Cedex 13, France.*

Background: Hyperkalemia is a potential side effect of mineralocorticoid receptor (MR) antagonists since they cause renal Na^+ excretion and K^+ retention. MR antagonist dependent renal Na^+ excretion can be studied acutely in rodents and translates well to man. However, rodents are largely refractory to plasma K^+ elevations and hence the potential reduced liability of novel MR modulators to cause hyperkalemia is difficult to explore in rodent models.

Methods: Acute effects on 7 hours urine electrolyte excretion were studied after single dose administration of 30, 100 or 200 mg/kg eplerenone or AZD9977 to mice fed a low

salt (0.02%) diet for 3 days prior to dosing. Effects on plasma K^+ elevations were studied in 5/6 nephrectomised mice with developed chronic kidney disease (CKD) treated for 5 days with 100 mg/kg bid eplerenone or AZD9977 followed by a KCl load over night before measuring plasma K^+.

Results: 100 and 200 mg/kg eplerenone treatment caused an increased urinary Na^+/K^+ ratio (0.57±0.11, p=0.0022 and 0.68±0.08, p<0.0001, respectively) compared to vehicle (0.06±0.09). AZD9977 exposure did not alter urinary Na^+/K^+ ratio. Subchronic treatment with eplerenone or AZD9977 in CKD at exposures 14x above in vitro IC_{50} did not alter plasma K^+ levels. Eplerenone vs vehicle treatment followed by K^+ challenge led to a robust elevation of plasma K^+ (6.5±0.2 vs 5.4±0.2 mM, p<0.001). The plasma K^+ elevation after AZD9977 treatment and K+ challenge (5.9±0.2 mM, p=0.042 vs vehicle) was significantly lower compared to eplerenone (p=0.0045).

Conclusions: AZD9977 is a novel MR modulator developed to yield maximal efficacy on organ protection and minimal effects on plasma K^+. AZD9977 did not cause the typical acute urinary Na^+ excretion in mice observed with MR antagonists. Lack of effect on urinary electrolytes translated to a reduced plasma K^+ elevation in a mouse CKD model after potassium challenge. Whether the reduced effect on plasma K^+ observed with AZD9977 vs eplerenone will translate into a clinically meaningful differentiation will be explored in clinical studies.

Dietary K-Induced Temporal Changes in mRNA Encoding Proteins Associated with Renal K Secretion in Mouse

Daniel Flores,[1] Joshua L. Rein,[1] Rolando Carrisoza-Gaytan,[1] Arohan R. Subramanya,[2] Thomas R. Kleyman,[2] Lisa M. Satlin.[1] *[1]Icahn School of Medicine at Mount Sinai, New York, NY; [2]University of Pittsburgh, Pittsburgh, PA.*

Background: Flow-induced K secretion in the cortical collecting duct (CCD) of the distal nephron is mediated by Ca^{2+}/stretch-activated BK channels, which also contribute to the renal adaptation to a high K diet (HKD). We reported that CCDs from rabbits fed a HKD for 10 d exhibit an increase in steady-state abundance of BK channel subunit-specific mRNAs and expression of immunodetectable BKα and L-WNK1 expression in the apical membrane of β-type intercalated cells (ICs). Overexpression of L-WNK1 increases BKα whole cell abundance and functional channel expression in HEK cells suggesting that an increase in L-WNK1 in ICs may mediate enhanced BK channel expression and K secretion in K-adapted CCDs. We sought to examine the temporal changes in mRNA abundance of BK channel subunits and L-WNK1 as well as other major CCD transport and regulatory proteins in mouse kidney following initiation of HKD or low K diet (LKD).

Methods: C57BL/6 mice on a control K diet were switched to either a HKD or LKD for up to 11 days. On the day of sacrifice, spot blood and urine samples were collected for measurement of [Na] and [K] by flame photometry. qPCR primers and probes specific for BKα, β1, β4, and γ subunits and for regulatory kinases L-WNK1, KS-WNK1, and WNK4 were used to assess message abundance in renal cortical homogenates.

Results: Steady state expression of BKα mRNA increased >3-fold by day 7 of HKD (n=4, p<0.05) but did not significantly change during LKD. No significant changes were observed for message encoding BK β1, β4, γ subunits or L-WNK1, KS-WNK1, and WNK4 during either diet. Plasma [Na] and [K] remained unchanged under HKD and LKD, while urine [K] increased during HKD and decreased during LDK.

Conclusions: HKD increased steady state abundance of message encoding BKα. The failure to detect an increase in message encoding WNK1, a regulatory protein known to increase BK channel expression during HKD, may reflect post-translational modification.

SA-PO1011

Sexual Dimorphic Responses of Renal Transporters to High Salt Diet Favor More Diuresis in Females

Diana L. Torres, Luciana C. Veiras, Donna Ralph, Zoya Khalil, Hector R. Lisboa, Alicia A. McDonough. *Keck School of Medicine of USC, Los Angeles, CA.*

Background: Previous studies have shown that there are distinct sexual dimorphic patterns of transporters along the nephron. Compared to males (M), female (F) rats and mice at baseline have less proximal tubule sodium transporters (NHE3, NaPi2) and more activated distal NCC and collecting duct epithelial sodium channels (ENaC). Also, F are reported to have a have more robust pressure natriuretic response than M. This study aimed to test the hypothesis that, in F vs. M C57Bl/6 mice, high salt diet regulates renal Na^+ transporters, claudins (Cld) and the regulatory kinase (SPAK) in a pattern that facilitates more natriuresis in females.

Methods: For 2 wk, mice (n=7/group) received a normal salt diet (0.26% NaCl, NSD) or a high salt diet (4.0% NaCl, HSD). Urine Na^+ and K^+ were measured by flame photometry and osmolality with an osmometer. Renal transporter and channel abundance was determined by quantitative immunoblot, and subcellular distribution by confocal immunohistochemistry.

Results: At baseline, F exhibit lower urinary volume (UV), Na^+ (UNaV), K^+ (UKV), and osmoles (UosmV); F also had lower abundance of the PT NHE3, NHE3p and Cld2 and higher DCT NCC and SPAK compared to M. In response to HSD, F vs. M exhibit greater fold increases in UV (5- vs. 1.6-fold), UNaV (25- vs. 8-fold), UKV (2.3-fold vs. no increase) and UosmV (6 vs. 2-fold) and no change in plasma [Na^+] or [K^+]. During HSD NHE3p, a marker for less activity, increased in M but not F. During HSD, abundance of NKCCp, NCCp, and cleaved ENaC alpha decreased in both sexes, evidence of less activity of these transporters from loop through collecting duct. SPAK and Cld7 were unchanged. At baseline, NHE3 and NHE3p were located in the villi in M and at the base of the villi in F; with HSD NHE3, NHE3p redistributed to the villar base in M and were unchanged in F. NCCp remained localized to the apical membranes in both sexes.

Conclusions: The renal responses to a high salt diet are sex dependent: redistribution of NHE3 and NHE3p in males, and reduced NKCC2p, NCC, NCCp and α ENaC cleavage in both sexes contribute to natriuresis. Females exhibit more robust natriuresis and diuresis during HSD which we hypothesize is due, at least in part, to the lower baseline PT NHE3 and Cld2.

SA-PO1012

Notch Signaling and Adam10 in Lithium-Induced Collecting Duct Remodeling in Mouse Kidney

Yue Zhang,[1,3] Janos Peti-Peterdi,[2] Marshall R. Roedel,[1] Tao Liu,[1] Anne Riquier-brison,[2] Noel G. Carlson,[1] Bellamkonda K. Kishore.[1] *[1]Univ. of Utah and VA Medical Center, Salt Lake City, UT; [2]University of Southern California, Los Angeles, CA; [3]Nanjing Medical University, Nanjing, China.*

Background: The cell biology of lithium (Li) induced collecting duct (CD) remodeling, whereby the percent of AQP2-positive principal cells (PC) is decreased with a proportionate increase in [H^+]-ATPase-positive intercalated cells (IC), is not well defined. It has been reported that genetic suppression of Notch signaling or Adam10 interferes with the development of CD resulting in off-spring with very low percentage of PC in the kidney. Hence, here we evaluated whether these two play a similar role in Li-induced CD remodeling in adult mice.

Methods: Groups of mice (B6D2; N = 5/group) were fed either a regular or LiCl-containing chow for 30 days and humanely euthanized. Using confocal immunofluorescence microscopy and double labeling, kidney sections were examined for the percent of AQP2 or [H^+]-ATPase positive cells. cDNA prepared from the medulla was subjected to Notch signaling PCR Array, and expression of selected genes was further confirmed by real-time PCR on all samples.

Results: Li treatment caused significant polyuria associated with a significant decrease in percentage of PC in the medulla (88.2 ± 3.4 vs. 69.2 ± 0.8, $P < 0.05$), and a proportionate increase in the percentage of IC (11.3 ± 3.4 vs. 30.0 ± 0.8, $P < 0.05$). Several genes were under or over expressed in Li-treated mice (Table).

Conclusions: Similar to its role during embryonic life, Notch signaling plays a role in Li-induced CD remodeling. However, our results do not support a role for Adam10 in Li-induced CD remodeling in adult mice. The roles of Nr4a2, Neurla1A and Figf in CD remodeling need to be further defined.

Metformin Has Natriuretic Effects Through Reduction of the Sodium-Chloride Cotransporter Phosphorylation

Hiroko Hashimoto, Naohiro Nomura, Wakana Shoda, Kiyoshi Isobe, Hiroaki Kikuchi, Kohei Yamamoto, Takuya Fujimaru, Fumiaki Ando, Takayasu Mori, Tomokazu Okado, Tatemitsu Rai, Shinichi Uchida, Eisei Sohara. *Tokyo Medical and Dental University, Tokyo, Japan.*

Background: Metformin is an antidiabetic drug that is widely used to treat patients with type 2 diabetes mellitus. Recent studies have reported that treatment with metformin not only improved blood glucose levels but also reduced blood pressure. However, it remains unclear how metformin reduces blood pressure. We hypothesized that metformin affects sodium reabsorption in the kidneys.

Methods: We firstly examined urinary sodium excretion and expression of renal sodium transporters in 8-week-old male C57BL/6 mice with acute and chronic treatment of metformin. In addition, we examined metformin effects using *ex vivo* preparations of mice kidney slices. We also performed experiments using the spontaneously hypertensive rat (SHR).

Results: In this study, we demonstrated that metformin increased urinary sodium excretion by reducing phosphorylation of the thiazide-sensitive Na-Cl cotransporter (NCC) in acute and chronic metformin administration. We also confirmed reduction of phosphorylated NCC in an *ex vivo* study. Expression levels of other renal sodium transporters, such as NKCC2, ENaC, and NHE3 did not show significant changes. WNK-OSR1/SPAK kinase signal was not involved in this effect of metformin on NCC. We finally performed experiments using SHR, whose blood pressure is well known to be decreased by metformin. We observed decreased phosphorylated NCC in SHR by metformin treatment,

suggesting that this decreased NCC phosphorylation is involved in the mechanisms of metformin-induced blood pressure reduction.

Conclusions: Metformin increased urinary sodium excretion by reducing phosphorylation of NCC. Considering that metformin could have natriuresis effect, metformin could be an ideal drug for excessive salt intake, in addition to excessive calorie intake.

SA-PO1014

Urinary Exosomes Quantitation of Renal Transporter Abundance Correlates with Function

Cameron J. Menezes, Kristin J. Bergsland, Elaine M. Worcester, Fredric L. Coe, Benjamin S. Ko. *University of Chicago, Chicago, IL.*

Background: Urinary exosomes have the potential to provide considerable insight into renal tubular function. However, estimates of urinary exosomes been qualitative or semi-qualitative using Western blotting. Therefore, we sought develop approaches to measure several relevant sodium and calcium transporters simultaneously in the urine from humans and then correlate them to function in humans.

Methods: 4 healthy males were studied in a CRC setting. Fasting and fed urine and blood samples were collected hourly. Serum ultrafiltrate and urine calcium, magnesium, sodium, potassium, creatinine, and urine volume were measured. Lithium was measured in deproteinated serum and urine by atomic emission spectroscopy. Urinary exosomes were isolated via ultracentrifugation. NHE3, SLC26A6, NKCC2, NCC, TRPV5 and prostasin abundance were measured via ELISA at each collection point in triplicate and these values were compared with metabolic parameters of tubule function at each time point.

Results: The presence of enriched amounts of ALIX, CD63, and TSG-101 protein in the exosomal fraction compared to the various wash fractions was verified via Western blotting. NHE3, SLC26A6, NKCC2, NCC, TRPV5 and prostasin abundance were measured. NHE3 and fractional excretion of lithium are significantly correlated, indicating that proximal tubule function is related to the exosomal abundance of NHE3 (-0.66, p=0.001). Fully corrected for multiple comparisons, significant inverse correlations between the fractional excretion of distally delievered Ca and TRPV5 (-0.76, p=0.001) and FEDNa and prostasin (-0.78, p=0.001) were demonstated.

Conclusions: Our findings represent reliable and precise methods for quantitation of urinary exosomal abundance of the transport proteins NHE3, SLC26A6, NKCC2, NCC, TRPV5, and prostasin. The quantitation of urinary exosome renal transporter protein abundance allows for greater insight into human renal transport, allowing for direct measurements of markers of molecular solute transport. In this way, this system has the potential to further our understanding of molecular electrolyte physiology and disease in humans by confirming previous theories and finding new connections.

Urinary Exosomes as a Novel Tool to Study the NaCl Cotransporter in Hypertension

René J. Bindels,[2] Omar Tutakhel,[3] Joost Hoenderop.[1] *[1]Radboud university medical center, Nijmegen, Netherlands; [2]Radboud University Medical Center, Nijmegen, Netherlands; [3]Radboud University Medical Centre, Nijmegen, Netherlands.*

Background: The NaCl cotransporter (NCC) is located at the apical membrane of epithelial cells lining the distal convoluted tubule of the kidney, and plays an instrumental role in blood pressure regulation by fine-tuning renal sodium excretion. Renal salt transporters such as NCC are excreted in urinary exosomes (uEs) after internalization into multivesicular bodies. The aims of this study were to investigate the effect of thiazides on the abundance of NCC in uEs of patients with hypertension, and to assess whether NCC abundance in exosomes can predict the blood pressure response to thiazides.

Methods: The NCC abundance was compared in uEs both before and after treatment in patients with hypertension (n=41) who did or did not respond to thiazides. Responders to treatment were defined as patients with a significant anti-hypertensive response to thiazides (≥5 mmHg, n=24), while non-responders had a minimal or no response (<5 mmHg in blood pressure, n=17). To analyze whether normalization by urinary creatinine resulted in a similar number of uEs loaded on a gel, the abundance of the exosomal-marker CD9 was measured.

Results: Despite the inhibitory action of thiazide on NCC, immunoblot analysis of exosomes showed increased abundance of NCC (>2.5-fold, $P<0.05$). The increase in NCC abundance in uEs after thiazide treatment correlated with the blood pressure response and change in plasma potassium levels ($R^2=0.22$, $P<0.05$; $R^2=0.19$, $P<0.05$, respectively). The abundance of NCC in uEs before treatment was significantly higher in responders compared to non-responders (>6-fold,$P<0.05$). Moreover, after thiazide treatment, the increase in abundance of NCC in uEs and decrease in plasma potassium levels was stronger in responders compared to non-responders ($P<0.05$). No significant differences in CD9 abundance were observed between the two experimental groups, suggesting comparable urinary exosomal numbers.

Conclusions: Our studies highlight that NCC is upregulated by thiazides and this increase correlates with the blood pressure response to thiazides and the change in plasma potassium levels. Additionally, we show that higher abundance of NCC prior to treatment with thiazides predicts the blood pressure response to thiazides. This implies that assessment of NCC in uEs could represent novel method to guide anti-hypertensive therapy in hypertensive patients.

Parathyroid Hormone (PTH) Increases Paracellular Permeability to Na and Ca in the Cortical Thick Ascending Limb (CTAL)

Caroline Prot-Bertoye,[2,3] Lucile Figueres,[2] Elsa Ferriere,[2] Gaëlle Brideau,[4,2] Tilman Breiderhoff,[5] Dominik Müller,[5] Pascal Houillier.[1,3] *[1]Paris Descartes University / INSERM, UMRS1138, Paris, France; [2]INSERM, UMRS1138, Centre de Recherche des Cordeliers, Paris, France; [3]Renal and Metabolic Diseases Unit, Georges Pompidou Hospital, Paris, France; [4]CNRS- ERL8228, Paris, France; [5]Pediatric Nephrology, Charité - Universitätsmedizin Berlin, Berlin, Germany.*

Background: Ca absorption in the CTAL is passive along the paracellular pathway and requires the expression of claudin-16 at tight junction that increases the paracellular permeability to Ca (PCa). In vivo, Na is passively secreted along the paracellular pathway due to the transepithelial Na gradient, and to the permeability to Na of the tight junction that requires the expression of claudin-10b. In the CTAL, the lumen-positive transepithelial voltage (Vte) gradient that depends on claudin-10b expression and back diffusion of Na is critical for driving passive Ca reabsorption. PTH increases Ca transport across the CTAL but the mechanisms involved are imprecise. We aim to elucidate if claudin-16, which determines PCa, and claudin-10b, which determines Vte and PNa, are involved in the effects of PTH on the CTAL and to identify the underlying mechanisms.

Methods: Murine CTAL were microperfused *in vitro* to measure transepithelial Ca and Na absorption under symmetrical conditions and ionic paracellular permeabilities under asymmetrical conditions with 0.1 mM furosemide in the lumen. All measures were made under control and experimental conditions. The ratio of permeabilities PNa/PCl was calculated according to the Goldman-Hodgkin-Katz equation.

Results: PTH (10^{-10}M) significantly increased Ca reabsorption in CTAL from claudin $16^{+/+}$(+44 %) and claudin $16^{-/-}$(+60 %) mice; Vte did not change, indicating that PTH increased PCa. PTH increased Na reabsorption (+15 %) and PNa/PCl (+22 %) in CTAL from wild type mice. Dibutyryl cAMP (5.10^{-4}M), ionomycin (10^{-7}M), thapsigargin (10^{-6}M), but not phorbol 12-Myristate 13-Acetate (10^{-6}M), significantly increased PNa/PCl. Dibutyryl cAMP and ionomycin had additive effects on PNa/PCl. H-89 (PKA inhibitor, 10^{-5}M) partly inhibited the effect of PTH on PNa/PCl.

Conclusions: We conclude that, in the mouse CTAL, PTH - increases PCa independently of the presence of claudin-16 - increases PNa via cAMP- and cytosolic calcium-dependent signaling pathways. Our results show that properties of intercellular tight junctions can be directly and rapidly controlled by intracellular signaling pathways in intact tissue.

Systems-Level Identification of PKA-Independent Vasopressin Signaling in Renal Epithelial Cells

Arnab Datta, Chin-Rang Yang, Viswanathan Raghuram, Mark A. Knepper. *NHLBI, NIH, Bethesda, MD.*

Background: Vasopressin signaling in the renal collecting duct is believed to be mediated predominantly by the activation of protein kinase A (PKA). The recent generation of mouse cell lines ("PKA dKO" cells), derived from mpkCCD cells, in which both PKA catalytic subunit genes have been deleted via CRISPR-Cas9 affords us an opportunity to identify PKA-independent signaling.

Methods: We used protein mass spectrometry to profile proteome-wide phosphorylation changes in response to vasopressin (dDAVP, 0.1 nM, 30 min) in PKA dKO cells and in control mpkCCD cells. dDAVP-treated and vehicle-treated cells were metabolically labeled using the SILAC method to allow quantification of dDAVP-induced changes in tryptic phospho-peptide abundances in an Orbitrap Fusion Lumos Tribrid mass spectrometer. Experiments were done in triplicate.

Results: Overall, >13,000 unique phosphopeptides were quantified in both PKA dKO and control cells. In control cells, 691 distinct phosphopeptides were altered in abundance in response to dDAVP. In contrast, in PKA dKO cells, only 73 phosphopeptides were altered in abundance, indicating that a large component of the vasopressin response is PKA dependent. However, altered phosphorylation in response to dDAVP in PKA dKO cells is indicative of substantial PKA-independent signaling. Notably, phosphorylation of Ser256 of AQP2 (thought to be a PKA site) increased in response to dDAVP in PKA dKO cells, indicating that other kinases can phosphorylate this site. The upregulated phosphorylation sites in PKA dKO cells mapped to an X-R-(A/S/T)-X-S*-X motif, consistent with activation of other basophilic kinases such as SGK, PKG, CAMK2B or PAK2. Interestingly, cAMP measurements showed that baseline cAMP levels in PKA dKO cells, were ~10-fold higher than in control mpkCCD cells, although both PKA dKO and control cells showed significant increases in response to dDAVP. This indicates that there is likely to be a PKA-dependent feedback on some component of the Avpr2-G_{α}s-Adcy6 signaling pathway responsible for cAMP generation.

Conclusions: In cultured mouse principal cells: (1) the signaling response to vasopressin is largely PKA-dependent; (2) a smaller component of the vasopressin response is PKA-independent; (3) Ser256 of AQP2 can be phosphorylated by kinases other than PKA; (4) PKA is responsible for a feedback inhibition of cAMP generation.

Ticagrelor Reduces Urinary Concentration and Arginine Vasopressin (AVP) Levels: Potential Use in AVP Excess States

Bellamkonda K. Kishore,[1] Kenny M. Hansson,[2] Noel G. Carlson,[1] Yue Zhang.[1] *[1]Univ. of Utah and VA Medical Center, Salt Lake City, UT; [2]AstraZeneca, Cardiovascular, Renal and Metabolism iMED, Mölndal, Sweden.*

Background: Previously we showed that blockade of $P2Y_{12}$ receptor by thienopyridine anti-thrombotic drugs (clopidogrel or prasugrel) increases urinary concentration and AVP levels. However, it is not clear whether non-thienopyridine drugs, such as ticagrelor, have similar effects on urine concentration and AVP levels.

Methods: Groups of B6D2 mice (N = 5/group) were fed regular chow containing different concentrations of ticagrelor (0.15, 0.20 and 0.25%) for 14 or 21 days and euthanized. Urine output, osmolality and AVP levels were determined prior to and at the end of treatment. Terminal plasma ticagrelor levels were assayed by LC-MS/MS. The effect of ticagrelor (0.5, 2 or 10 μM) added in vitro on dDAVP (synthetic analog of AVP; 20 nM)-induced AQP2 and AQP3 mRNA expression in primary cultures of rat inner medullary collecting duct (IMCD) cells was assessed.

Results: Administration of ticagrelor to mice caused increased urine output associated with decreased urine osmolality and AVP levels. (see Table). There was significant negative correlation between the plasma ticagrelor and urinary AVP ($P < 0.04$). But, blockade of $P2Y_{12}$ receptor in cultured IMCD cells by ticagrelor caused dose dependent enhancement of AQP2 and APQ3 mRNA expression.

Conclusions: The observed decrease in urinary AVP excretion appears to be due to an unexpected off-target effect on hypothalamic AVP production/secretion. However, the in vitro effect on IMCD cells was an expected one based on our previous studies on $P2Y_{12}$ receptor blockade. Hence, it appears that the *off-target* effect of ticagrelor on AVP production in vivo has apparently overridden its *targeted* effect on IMCD cells. Thus, our results suggest that the off-target effect of ticagrelor may find potential use in conditions associated with AVP excess, such as ADPKD, congestive heart failure, cirrhosis of liver, diabetic ketoacidosis, and cardiorenal syndrome, among others.

Decreased Release of Aquaporin-2 in Urinary Extracellular Vesicles in Rats Subjected to Allogenic Kidney Transplantation

Hiroko Sonoda,[1] Tomonori Nakanishi,[2] Tomoyuki Kabayama,[1] Sayaka Oshikawa,[1] Masahiro Ikeda.[1] *[1]Veterinary Pharmacology, University of Miyazaki, Miyazaki, Japan; [2]Chemistry and Technology of Animal Products, University of Miyazaki, Miyazaki, Japan.*

Background: Diuresis has been observed within a week following renal transplantation. Aquaporin-2 (AQP2) plays an important role in the regulation of urinary concentration. Recently, AQP2 has been shown to be predominantly localized to urinary extracellular vesicles (uEVs). However, the release pattern of AQP2-bearing uEVs (uEV-AQP2) in an early phase after renal transplantation is largely unknown. In this study, we examined the release pattern of uEV-AQP2 in the recipient animals after allogenic kidney transplantation.

Methods: All animal studies were approved by the committee on the Care and Use of Laboratory Animals at the University of Miyazaki. Male SD rats were used as recipients and male Wistar rats were used as donors. The donor right kidney was transplanted into the recipient whose right kidney had been removed, and thereafter the remaining left kidney was removed (Tpx group). For the control group, a simple left kidney nephrectomy was performed. Urine and renal samples were collected at 5 days after the surgery. uEVs were isolated by differential centrifugation.

Results: Urine output was increased and urine osmolality was decreased in Tpx group in comparison with the control group. The level of renal AQP2 expression was significantly decreased in Tpx group. The release of uEV-AQP2 was significantly lower in Tpx group. Correlation analysis showed that the release of uEV-AQP2 was related to urine osmolality. When we examined marker proteins for uEVs, such as TSG101 and Alix, the release of both proteins in uEVs increased in Tpx group.

Conclusions: These data indicate that the release of uEV-AQP2 was associated with its renal expression. Furthermore, uEV-AQP2 might be an indicator for urinary concentration ability in the case of renal transplantation.

SA-PO1020

Contribution of Collecting Duct NOS1 in the Regulation of Urine Flow in Hydrated and Dehydrated States

Kelly A. Hyndman, Luciano D. Mendoza. *University of Alabama at Birmingham, Birmingham, AL.*

Background: We previously determined that collecting duct (CD) nitric oxide synthase-1 (NOS1) was critical for maintaining fluid-electrolyte balance during high Na^+ intake. Mice with genetic deletion of all NOS1 splice variants from the principal cells of the CD (CDNOS1KO), have reduced urine flow after a single high Na^+ meal compared to control mice even though food and water intake was similar. This suggests that CD NOS1 may regulate CD water permeability during high Na^+ challenges. The purpose of this study was to determine if CD NOS1 is a regulator of water permeability during chronic hydration or water deprivation.

Methods: Male and female (n=6 per sex/genotype/treatment) CDNOS1KO and littermate $NOS1^{flox/flox}$(control) mice were randomly assigned to the hydration or 24 h dehydration protocols. All mice were placed on 5% sucrose water to encourage hydration. After 3 days, half of the mice were switched to water deprivation. Urine was collected diurnally matching the 12 h light schedule of the room.

Results: In male mice, both genotypes drank similar amounts while hydrated, and produced similar amounts of urine. With water deprivation, CDNOS1KO male mice produced significantly more urine than controls during their active period (182±0.04 vs 40±0.03 μl/12 h, $p = 0.02$), and urine from CDNOS1KO male mice was very concentrated (UOsm= 4632±193 mOsm/kg H_2O). Plasma osmolality rose similarly in both control (300±3 vs 315±2 mOsm/kg H_2O) and CDNOS1KO (301±2 vs 314±3 mOsm/kg, $P_{genotype}$=0.53 $P_{hydration}$<0.01, P_{gxh}= 0.3) during dehydration. In the females, fluid intake was significantly reduced in the CDNOS1KO mice during their active period compared to controls (7.2±1.6 vs 15.2±2.6 ml/day, p=0.01), and likewise there was a reduction in urine volume (3.1±1.2 vs 8.2±2.0 ml/day, p= 0.03). With dehydration, female control and CDNOS1KO mice both produced very little urine and concentrated urine (125±0.05 and 105±0.04 μl/12h, $p = 0.99$). Plasma osmolality following dehydration was increased in the controls (from 300±3 to 308±2 mOsm/kg H_2O) and further exacerbated in CDNOS1KO (from 309±4 to 319±6 mOsm/kg, $P_{genotype}$=0.02 $P_{hydration}$ = 0.03, P_{gxh} = 0.8).

Conclusions: In conclusion, CD NOS1 does contribute to the urine concentrating mechanisms of the kidney in both sexes, although it is a minor component. Interestingly, CD NOS1 is crucial in female mice to properly regulate plasma osmolality.

Effects of TGF-β1 on the Activity of NFAT5, an Osmoprotective Transcription Factor

Yuichiro Izumi,[1] Naomi Matsuo,[1] Koji Eguchi,[1] Akiko Hara,[1] Makoto Ono,[1] Yushi Nakayama,[1] Hideki Inoue,[1] Hiroshi Nonoguchi,[2] Yutaka Kakizoe,[1] Takashige Kuwabara,[1] Masashi Mukoyama.[1] *[1]Department of Nephrology, Kumamoto University Graduate School of Medicine, Kumamoto, Japan; [2]Kitasato University Medical Center, Kitamoto, Japan.*

Background: NFAT5 (nuclear factor of activated T-cells 5, or TonEBP) is a transcription factor that stimulates the expression of osmoprotective genes in response to extracellular hypertonicity, resulting in cell survival even in extremely hypertonic conditions. Activated NFAT5 is translocated from the cytoplasm to nucleus, and then binds to the osmotic response element (ORE) to induce transcription. Not only hypertonicity but also hypoxia, oxidative stress, and toll-like receptor signaling, which promote fibrogenesis in the kidney, have been suggested to increase the NFAT5 activity. Transforming growth factor-β1 (TGF-β1) is an important factor that stimulates fibrogenesis, but little is known about the interaction between TGF-β and NFAT5. We evaluated the effects of TGF-β1 on the NFAT5 activity.

Methods: For *in vivo* experiments, mice were subjected to unilateral ureteral obstruction (UUO). After 14 days, the expression of NFAT5 and TGF-β1 in the kidney was examined by real-time PCR. For *in vitro* experiments, we used human embryonic kidney 293 (HEK 293) ORE-X cells which stably express the ORE-X-luciferase reporter gene. Cells were incubated in 300 mOsm/kg or 500 mOsm/kg (NaCl added) for 24 hrs, and then the luciferase activity was measured to evaluate the NFAT5 transcriptional activity. Protein expression of NFAT5 was examined by Western blotting. To examine the effect of TGF-β on nuclear translocation of NFAT5, whole cell lysate was fractionated to nucleus and cytoplasm.

Results: The expression of NFAT5 and TGF-β1 mRNAs was 2.5 and 12 times greater in the kidney in UUO mice than that in sham-operated mice, respectively. TGF-β1 suppressed tonicity-induced NFAT5 transcriptional activity and protein expression in HEK293 cells. Nuclear translocation of NFAT5 was inhibited by TGF-β1. These results suggest that TGF-β1 directly inhibits the activation and expression of NFAT5.

Conclusions: TGF-β1 inhibits NFAT5 in the kidney, which might exacerbate renal fibrogenesis during fibrotic renal disorders.

Dog and Human Zip10 (SLC39A10) Localization Is More Than Proximal Tubule, Helping to Explain Role in Nephrolithiasis

Michael F. Romero,[1] Heather L. Holmes,[1] Greg M. Landry,[2,1] Mukesh K. Pandey,[1] Huailei Jiang,[1] Aditya Bansal,[1] Marie-Christine Franz,[4,1] Nicolas Montalbetti,[5,1] Pablo Cabrero,[3] Julian A. Dow,[3] Eva Furrow.[6] *[1]Mayo Clinic College of Medicine, Rochester, MN; [2]Massachusetts College of Pharmacy & Health Sciences, Boston, MA; [3]University of Glasgow, Glasgow, United Kingdom; [4]CSL Behring AG, Bern, Switzerland; [5]University of Pittsburgh, Pittsburgh, PA; [6]University of Minnesota, Falcon Heights, MN.*

Background: In the past several years, we and others have implicated zinc (Zn^{2+}) and Zn^{2+} transporters, e.g., SLC39A10 / ZIP10, to have a role in dog and human nephrolithiasis using a *Drosophila* model. As for other ions and solutes, Zn^{2+} is moved into and out of cells by specific membrane transporters: ZnT, ZIP, and NRAMP/DMT proteins. In rodents, ZIP10 has been localized at the apical membrane of renal proximal tubules (PT), where it is believed to play a role in Zn^{2+} import.

Methods: Our group has used *Drosophila* as a model of calcium oxalate kidney stones We expressed ZIP10 from dog, human, and *Drosophila* (*CG10006*), tested clones for Zn^{2+} uptake, electrogenicity (voltage clamp) and ability to change intracellular pH (pH_i) in *Xenopus* oocytes. Finally using immunofluorescence, we localized the ZIP10 protein in mouse, dog, human and fly renal structures.

Results: *CG10006*, rather than *foi* (fear-of-intimacy, *CG6817*) is the primary ZIP10 homolog found in *Drosophila* Malpighian tubules. All of these ZIP10-proteins were found to transport $^{63}Zn^{2+}$ (PET isotope) in oocytes; however, we were unable to elicit membrane currents or pH_i changes with addition of Zn^{2+}. The ZIP10 antibody recognizes recombinant and native rodent, dog, human and *Drosophila* ZIP10 proteins. Immunohistochemistry reveals that Zip10 in higher mammals is found not only in the PT but also in AQP2-positive tubules (collecting duct, CD).

Conclusions: 1) CG10006 is the likely ortholog of ZIP10; 2) ZIP10 transport is not electrogenic; 3) ZIP10 transport is not HCO_3^- coupled; 4) ZIP10 in dogs and humans has both PT and CD localization. Together these studies reveal ZIP10 has multiple roles in renal Zn^{2+} transport and may provide additional insights to the role of Zn^{2+} in calcium oxalate nephrolithiasis.

SA-PO1023

Acetazolamide Inhibits Ammoniagenesis and Prevents the Correction of Metabolic Acidosis in Rat

Hassane Amlal, Sihame Amlal, Perwez Alam. *University of Cincinnati, Cincinnati, OH.*

Background: Acetazolamide (ACTZ), a potent inhibitor of carbonic anhydrases (CA), increases renal bicarbonate wasting and causes metabolic acidosis. Intracellular acidic pH, *per se*, upregulates the glutamine transporter SNAT3 and the ammoniagenic enzymes (glutaminase or GA and glutamate dehydrogenase or GDH). CAII binds to the basolateral Na^+:HCO_3^- cotransporter (NBCe1) and facilitates HCO_3^- reabsorption across the proximal tubule. However, whether ACTZ alters NBCe1 activity and interferes with the ammoniagenesis pathway during the onset of ACTZ-induced metabolic acidosis remains elusive.

Methods: We compared male Sprague Dawley rats treated with ACTZ or its vehicle (control) to those subjected to NH_4Cl loading inthe drinking water. The animals were housed in metabolic cages for daily measurements of urine volume, Na^+ excretion, NH_4^+ excretion and urine pH. The animals were sacrificed after 6 days or 2 weeks. Blood composition was analyzed and the protein abundance of SNAT3, GA and GDH in the kidney cortex was examined.

Results: ACTZ-treated rats exhibited a significant increase in urine flow, natriuresis and bicarbonaturia (urine pH = 8.1 vs. 6.8 in controls). NH_4Cl-loaded rats showed a significant decrease in urine pH (5.6 vs. 6.7 in controls) with no change in Na^+ excretion or urine flow. ACTZ caused a significant and sustained metabolic acidosis for up to 2 weeks (serum $[HCO_3^-]$ = 20 and 21 mM for 6 days and 2 weeks, respectively, vs. 30mM in controls). Whereas in NH_4Cl loaded rats, metabolic acidosis was developed in 6 days but was fully corrected after 2 weeks of treatment (serum $[HCO_3^-]$ = 20 and 28 mM for 6 days and 2 weeks, respectively, vs. 29 mM in controls). NH_4^+ excretion increased by 4-fold in NH_4Cl-loaded rats but only slightly (0.6-flod) in ACTZ-treated rats for 6 days despite similar degree of metabolic acidosis. Immunoblotting studies showed that the protein abundance of GA (4-fold), GDH (06-fold) and SN1 (8-fold) increased significantly in NH_4Cl-loaded rats, but remained unchanged in ACTZ-treated animals.

Conclusions: 1- We propose that ACTZ binds to CAII and inactivates NBCe1. This alkalinizes proximal tubule cells and therefore suppresses the ammoniagenesis pathway despite systemic metabolic acidosis. 2- Metabolic acidosis of ACTZ is generated by renal HCO_3^- wasting and maintained by the inhibition of ammoniagenesis pathway in the proximal tubule.

SA-PO1024

Co-Localization of NKCC2 with AQP2 in the Collecting Duct Principal Cells Contributes to the Acute Diuretic Effects of Furosemide and Overall Water Handling by the Kidney

Hassane Amlal, Sihame Amlal, Charuhas V. Thakar, Perwez Alam, Rafeeq Ahmed. *University of Cincinnati, Cincinnati, OH.*

Background: The activity of $Na^+/K^+/2Cl^-$ cotransporter (NKCC2) in the thick ascending limb (TAL) plays an important role in the process of urinary concentrating mechanism and the control of water balance by the kidney. Acute furosemide (NKCC2 inhibitor) administration to both human and animals is associated with a rapid (minutes) diuresis, natriuresis, diluted and acidified urine. This raises the question as to whether NKCC2 is co-localized with AQP2 in the collecting duct (CD) principal cells.

Methods: Male rats housed in metabolic cages were injected with furosemide (FURO, 5mg/kg BW) and urine was collected every hour for 2 hours and after 7 days of daily treatment. Urine of vehicle-injected rats (control) was collected over a 3-hour period and after 7 days. Urine volume, urine osmolality, Na^+ excretion and urine pH were measured. Rat and human kidney tissues were used to examine the localization of NKCC2 and AQP2 and ENaC by immunofluorescence labeling technique.

Results: Compared to control group, furosemide-treated rats exhibited an increase in urine output and Na+ excretion by 9- and 33-fold, respectively, during the first hour of treatment. Urine osmolality decreased to 439 mosm/kg H2O during the first hour and remained low (450~ mosm/kg H2O) after 7 days vs. 1373 (3 hours) or 1635 (7 days) mosm/kg in control group. Urine pH decreased significantly (from 6.56 to 6.04, $P<0.04$) during the second hour of furosemide treatment. The later effect is inhibited in the presence of low dose of amiloride (ENaC inhibitor). Merged images of double immunofluorescence labeling of rat and human kidney tissues with AQP2 and NKCC2 or with AQP2 and ENaC showed NKCC2 expression in the apical membrane of both AQP-free (TAL), as well as AQP2 expressing cells; whereas ENaC is exclusively co-expressed with AQP2 in the CD principal cells of both rat and human kidneys.

Conclusions: We demobnstarte for the first time that NKCC2, ENaC and AQP2 are co-expressed in the apical membrane of principal cells in the cortical and outer medullary CD of both rat and human kidneys. The co-localization of NKCC2 with AQP2 contributes to the acute diuretic and natriuretic effects of furosemide, and the co-localization of NKCC2 with ENaC in the CD is responsible for furosemide-induced urinary acidification.

Urinary Uromodulin Is Increased in Magnesium Deficiency and Stimulates Tubular Magnesium Absorption via TRPM6

Matthias Wolf,[2] Manjot S. Bal,[2] Carolina Rivera,[2] René J. Bindels,[1] Joost Hoenderop,[1] Denise K. Marciano,[2] Mingzhu Nie.[2] *[1]Radboud University Medical Center, Nijmegen, Netherlands; [2]University of Texas Southwestern Medical Center, Dallas, TX.*

Background: Uromodulin (UMOD) is the most abundant urinary protein in humans. We describe a novel role for Uromodulin in renal magnesium homeostasis. Mild to moderate chronic hypomagnesemia occurs in up to 15% of the population and is associated with type 2 diabetes mellitus, hypertension, and chronic kidney disease.

Methods: Whole-animal experiments for urinary excretion of magnesium and UMOD, and response to furosemide were performed in nine months-old wild-type (WT) and Uromodulin knockout (*Umod*$^{-/-}$) mice. Kidneys from both strains were studied for qRT-PCR studies and immunofluorescent TRPM6 expression. Whole-cell patch-clamp recording and biotinylation assays were performed in HEK293 cells to determine TRPM6 whole-cell current density and cell surface abundance.

Results: *Umod*$^{-/-}$ mice, compared to WT, excreted more urinary magnesium (WT 18 ± 3 μmol/24h vs. *Umod*$^{-/-}$ 34 ± 5 μmol/24h; $p<0.05$) and displayed upregulation of genes promoting renal magnesium absorption, confirming magnesium deficiency in *Umod*$^{-/-}$ mice. The thick ascending limb in both strains responded the same to furosemide, indicating appropriate function. Fine-tuning of magnesium absorption occurs in the distal convoluted tubule (DCT) via the apical magnesium channel TRPM6. We found decreased apical TRPM6 staining in the DCT of *Umod*$^{-/-}$ mice. Applying *in vitro* biotinylation assays and whole-cell patch-clamp recording we found that UMOD enhanced TRPM6 cell surface abundance and current density from the extracellular space (42 ± 6 vs 196 ± 10 *p*A/*p*F for control vs UMOD; $p<0.0001$). Co-immunoprecipitation studies showed that UMOD physically interacted with TRPM6, and thereby impaired dynamin-dependent TRPM6 endocytosis. UMOD depended on the urinary lectin galectin-1 to form a lattice together with a novel extracellular TRPM6 N-glycan to increase TRPM6 current density. To examine if a low magnesium state could modify urinary UMOD secretion we fed WT mice with a low magnesium diet and detected almost two-fold increased urinary UMOD excretion compared to the same mice on a regular diet.

Conclusions: Our data suggest that increased urinary UMOD secretion in low magnesium states defends against further urinary magnesium losses through upregulation of TRPM6 cell surface abundance by impairing TRPM6 endocytosis.

Molecular Mechanism of High-Potassium Induced Na-Cl Cotransporter Dephosphorylation

Wakana Shoda, Naohiro Nomura, Fumiaki Ando, Kiyoshi Isobe, Takayasu Mori, Eisei Sohara, Tatemitsu Rai, Shinichi Uchida. Tokyo Medical and Dental University Department of Nephrology *Tokyo Medical and Dental University, Tokyo, Japan*.

Background: Sodium-chloride cotransporter (NCC), expressed in distal convoluted tubules (DCT), is a key molecule in the regulation of urinary potassium (K^+) excretion. We previously reported that tacrolimus (a calcineurin inhibitor) and W7 (a calmodulin inhibitor) inhibited the K^+-induced NCC dephosphorylation and the increase in urinary K^+ excretion in mouse kidneys. These results suggest that calmodulin and calcineurin (CaN) were activated by calcium (Ca^{2+}) signal in response to the increase in extracellular K^+ concentration ($[K^+]_{ex}$) in DCT. However, the precise mechanism of K^+-induced CaN activation in DCT cells remains unknown.

Methods: Flp-in NCC HEK293 cells were transfected with constitutively active CaN-A (CA-CaN-A), CaN-A, and -B plasmids to determine the role of CaN in NCC dephosphorylation. Intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) were analyzed by live cell imaging using fluo-4 AM. SEA0400 (an NCX reverse-mode inhibitor) and ω-agatoxin (a P/Q type Ca^{2+} channel inhibitor) were injected to C57BL/6 mice 1 hour before K^+ oral gavage.

Results: We confirmed that CA-CaN-A over-expression clearly dephosphorylated NCC in HEK293 cells. In the following experiments, we used HEK293 cells in which both CaN-A and CaN-B were transiently overexpressed. In these cells, K^+-induced NCC dephosphorylation was inhibited by tacrolimus and EGTA treatment. The rapid increase in $[Ca^{2+}]_i$ after high K^+ stimulation was not observed with EGTA treatment, suggesting that the increase in $[Ca^{2+}]_i$ after K^+ stimulation was caused by Ca^{2+} influx. To determine the influx pathway, we treated the cells with several Ca^{2+} transporter inhibitors, and identified that SEA0400 and ω-agatoxin inhibited the K^+-induced $[Ca^{2+}]_i$ increase and NCC dephosphorylation. Furthermore, we found that both SEA0400 and ω-agatoxin inhibited K^+-induced NCC dephosphorylation in mouse kidneys.

Conclusions: This study showed that the K^+-induced NCC dephosphorylation by CaN was mediated by high-$[K^+]_{ex}$-induced influx of Ca^{2+} through reverse-mode NCX and/or P/Q type Ca^{2+} channel.

SA-PO1027

Involvement of CaSR, Claudin-14, and 16 in the Development of Hypermagnesiuria Associated with Tubulo-Interstitial Nephropathy

Taisuke Shimizu, Kaori Takayanagi, Takatsugu Iwashita, Akira Kurosawa, Yuka Kitamura, Hiroaki Hara, Masaaki Terao, Toru Hida, Tatsuro Sano, Tomonari Ogawa, Koichi Kanozawa, Hajime Hasegawa. *Saitama Medical Center, Saitama Medical University, Kawagoe, Japan*.

Background: Hypermagnesiuria is well known clinical feature of tubulo-interstitial nephropathy (TIN), and would be a diagnostic tool for TIN. We studied the changes in the expression of renal magnesium transporting molecules with the development of TIN in rats with unilateral ureter obstruction (UUO).

Methods: Left ureter of male SD rats was ligated, and the left kidney was sampled at day-0 (control), day-1 (early phase) and day-7 (late phase). Just before sampling, urine from the ureter-ligated kidney was collected by catheter insertion into the ureter. Immunohistochemistry, immunoblotting and RT-PCR were applied to this study.

Results: Fractional Mg excretion was significantly increased in the late phase but not in the early phase (FEMg: 3.13±0.81 at day-0, 4.72±0.54 at day-1, 10.7±0.81% at day-7). Immunohistochemistry and RT-PCR for fibrosis related gene indicated that TIN was developed in the late phase but not in the early phase. Expression of claudin-16, Mg reabsorption pathway in the thick ascending limb, was significantly decreased in the late phase but not in the early phase (100.2±2.9% at day-0, 90.3±6.3% at day-1, 36.4±1.6% at day-7). The results were confirmed by immunohistochemistry and immunoblotting. However, mRNA expression of TRPM6, Mg pathway of distal tubule, was significantly down-regulated even in the early phase (0.94±0.14% at day-0, 0.50±0.06% at day-1, 0.05±0.01% at day-7). Claudin-14 which is known to be an inhibitory regulator of claudin-16 was remarkably up-regulated. Because calcium sensing receptor (CaSR) signal is reported to function as an inhibitory regulator of claudin-14, we finally studied the expression of CaSR. CaSR mRNA was significantly down-regulated in the late phase (100.5±4.7 at day-0, 42.5±13.0 at day-1, 7.5±1.8% at day-7), and immunohistochemistry showed remarkable reduction of CaSR signal in the late phase.

Conclusions: Our findings may indicate that the characteristic hypermagnesiuria in TIN is principally caused by a dysfunction of magnesium reabsorption in the thick ascending limb of Henle resulting from a significant decrease in the claudin-16 expression. The down-regulation may be closely related to the development of TIN through CaSR-claudin-14-claudin-16 regulatory network.

SA-PO1028

MAGE-D2 Regulated Na-Cl Cotransporter Through Chaperon-Dependent ERAD

Sung-Sen Yang,[1] Chien-Ming Lin,[1] Martin Kömhoff,[2] Shih-Hua P. Lin.[1] *[1]Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan; [2]University Children's Hospital, Philipps University Marburg, Marburg, Germany*.

Background: Mutations in MAGE-D2 gene, encoded in X-chromosome, was reported to associate with transient antenatal Batter's syndrome with severe polyhydramnios. Reduced Na-K-2Cl cotransporter 2 (NKCC2) and Na-Cl cotransporter (NCC) was observed in the renal tubules of affected male patients.

Methods: To explore the role of mutant MAGE-D2 in the kidney, we created mutant Mage-d2 knock-in (KI) mice and examined the possible molecular mechanisms in vitro.

Results: Three strains of disease-mutant Mage-d2 (c274dupA, Y346X and A495G) KI mice were generated and only female A495G/+ mice could be produced from chimera mouse. By sonography, some embryos with polyhydramnios were found in A495G/+ female mice at E15.5D. Compared with the WT embryos, more amniotic fluid amount in male A495G/+ embryos but not female A495G/+ embryos was observed. The osmolarity of the amniotic fluid was not significant between female or male WT and A495G/+ embryos. When the different types of Mage-d2 cDNA [WT, c274dupA (truncated protein), Y346X (truncated protein) and A495G (missense full-length protein)] was transfected into the HEK293 cells, Y346X and A495G Mage-d2 showed interruption of the cell cycles in the G2/M phase and reduction of the abundance of NCC. Immunoprecipitation study revealed NCC could interact with WT and A495G Mage-D2 instead of truncated c274dupA and Y346X Mage-D2 proteins. Y346X and A495G Mage-d2 also reduce the expression of HSP40, HSP90 and CHIP. These chaperon proteins were reported to form a complex and play a role in the ER-associated degradation (ERAD) of the NCC.

Conclusions: These results suggested that Mage-D2 might affect the cell cycles of renal tubular cells and the NCC expression through regulating ERAD chaperon proteins.

SA-PO1029

SLC41A1 Mediates Magnesium Reabsorption in the Kidney

Joost Hoenderop, Francisco J. Arjona, René J. Bindels, Jeroen H. De Baaij. *Department of Physiology, Radboud Institute for Molecular Life Sciences, Radboud university medical center, Nijmegen, Netherlands*.

Background: Solute carrier family 41 member A1 (SLC41A1) has been suggested to mediate magnesium (Mg^{2+}) transport and to maintain Mg^{2+} homeostasis in humans. However, the function of SLC41A1 in the kidney, the main organ maintaining Mg^{2+} homeostasis, remains to be elucidated.

Methods: In this study, cellular Mg^{2+} transport assays combined with zebrafish *slc41a1* knockdown experiments were performed to disclose SLC41A1 function in the kidney.

Results: The gene *slc41a1* is ubiquitously expressed in zebrafish tissues and is regulated by water and dietary Mg^{2+} availability. Knockdown of *slc41a1* resulted in renal Mg^{2+} wasting in zebrafish larvae and elicited compensatory mechanisms to cope with the renal Mg^{2+} leakage induced. These compensatory mechanisms were illustrated by an up-regulation of the gene expression of the zebrafish orthologs of human magnesiotropic genes expressed in the distal convoluted tubule (*TRPM6*, *SLC12A3*, *SLC41A3* and *CNNM2*). Importantly, the renal Mg^{2+} wasting phenotype is rescued when mouse SLC41A1 is expressed in *slc41a1*-knockdown zebrafish. This proved the specificity of the knockdown approach used, as well as the functional equivalence of zebrafish Slc41a1 with the mammalian SLC41A1. Conversely, expression of mammalian SLC41A1-p.Asp262Ala, harbouring a mutation in the ion-conducting SLC41A1 pore, did not reverse the renal Mg^{2+} wasting observed in *slc41a1*-knockdown zebrafish. $^{25}Mg^{2+}$ transport assays in human embryonic kidney 293 (HEK293) cells overexpressing SLC41A1 demonstrated that SLC41A1 mediates cellular Mg^{2+} extrusion independently of sodium (Na^+). In contrast, SLC41A1-p.Asp262Ala expressing HEK293 cells displayed similar Mg^{2+} extrusion activities than control (mock) cells. In polarized Madin-Darby Canine Kidney cells, SLC41A1 localized to the basolateral cell membrane.

Conclusions: Our results demonstrate that SLC41A1 facilitates renal Mg^{2+} reabsorption in the zebrafish model. Furthermore, our data suggest that SLC41A1 extrudes Mg^{2+} across the basolateral membrane by a mechanism that is independent of Na^+. Based on the SLC41A1 function disclosed, patients with hereditary hypomagnesemia should be screened for *SLC41A1* mutations.

Disruption of a C-Terminal Di-Leucine Motif Directs NKCC1 to the Apical Membrane and Lysosomes in Polarized Epithelia

Rainelli Koumangoye, Eric J. Delpire. *Anesthesiology, Vanderbilt University Medical Center, Nashville, TN*.

Background: Delivery of NKCC1 cotransporter to the basolateral membranes play in crucial rule in ions homeostasis in epithelia. We recently reported the first known SLC12A2 (NKCC1) mutation that causes epithelial dysfunction in an undiagnosed clinical case. The 11 bp deletion resulted in a *non-functional* transporter with a shorter cytosolic COOH-terminal tail. NKCC1-DFX maintains its ability to interact with wild-type NKCC1, leads to increase dimerization of the cotransporter, and causes mis-tafficking of the NKCC1-DFX mutant and wild-type transporters to the apical/subapical region of polarized epithelia.

Methods: In this study, we used sequential truncation and site-directed mutagenesis within NKCC1 COOH domain and immunofluorescence to examine the trafficking of wild-type and mutants NKCC1 cotransporters in polarized MDCK cells.

Results: Our results show that truncation of NKCC1 COOH domain uncouple the co-transporter from the lateral membrane. We also targeted a di-leucine motif ($DxxxLL^{1193-1194}$) part of a previously described tetrad in the extreme C-terminus of NKCC1 as well as a di-leucine motif ($DxxxLL^{1036-1037}$) located upstream. Disruption of the $DxxxLL^{1036-1037}$ motif led to some increase localization in the cytoplasm, although most the cotransporter remained at the plasma membrane. In contrast, mutation of the terminal $DxxxLL^{1193-1194}$ motif led to cotransporter accumulation in the cytoplasm and mis-trafficking to the apical/sub-apical region of polarized epithelial; recapitulating the phenotype observed in NKCC1-DFX mutant. This observation indicates that the $DxxxLL^{1193-1194}$ motif is important for trafficking and maintenance of NKCC1 to the basolateral membrane. Truncation deletion and LL substitution mutants are trafficked out of the Trans-Golgi network and ER but accumulates in early endosomes and late endosomes where they are degraded. Whether they reach the endosomes by trafficking transiently through the plasma membrane is currently under investigation.

Conclusions: Our data demonstrate that NKCC1 basolateral trafficking is regulated by a conserved di-leucine motif in its C-terminal domain. Loss of $DxxxLL^{1193-1194}$ leads to mis-trafficking of NKCC1 to the apical membrane and accumulation in late endosomes in the subapical region of the polarized epithelia.

The Inhibitory Role of ERK1 Signaling in Renal Sodium Handling and Blood Pressure Through Affecting Sodium Chloride Co-Transporter

Shan Chen,[3] Xiuyan Feng,[7] Yixiao Xu,[1] Yunman Wang,[5] Jia Xiao,[6] Xinxin Chen,[4] Ruidian Li,[8] Saier Shen,[9] Hui Cai.[1,2] *[1]Medicine/Renal, Emory University, Atlanta, GA; [2]Nephrology, Atlanta VA Medical Center, Decatur, GA; [3]Medicine/Renal, Emory University, Atlanta, GA; [4]Medicine/Renal, Emory University, Atlanta, GA; [5]Medicine/Renal, Emory University, Atlanta, GA; [6]Medicine/Renal, Emory University, Atlanta, GA; [7]Pathology, LSU Shreveport, Shreveport, LA; [8]Medicine/Renal, Emory University, Atlanta, GA; [9]Medicine/Renal, Emory University, Atlanta, GA.*

Background: Sodium chloride cotransporter (NCC) plays a key role in regulating blood pressure and electrolyte homeostasis. Our previous study showed that WNK4 inhibits NCC by activating ERK1/2 signaling. Although ERK1 and ERK2 share 80% amino acid sequences, roles of ERK1 and ERK2 were reported to be different. Our preliminary studies showed that NCC was decreased in the inducible renal tubular specific ERK2 knockout (KO) mice, suggesting that the ERK1 and ERK2 pathways modulate NCC differently. Thus, we hypothesized that ERK1 signaling pathway plays an inhibitory role in regulating renal sodium excretion and blood pressure through NCC.

Methods: ERK1 global KO mice, western blot analysis, cell culture, siRNA knock-down, metabolic cage study, and tail-cuff blood pressure (BP) measurement were used in this study.

Results: To determine whether ERK1 involves in NCC regulation *in vivo*, we first did western blot experiments. We found that NCC abundance was increased in ERK1 KO mice. To investigate whether ERK1 affects NCC protein expression *in vitro*, we did ERK1 siRNA knock-down experiments in Cos-7 cells cotransfected with NCC and siRNA ERK1. We found that ERK1 knockdown increased NCC protein expression. To explore whether ERK1 signaling pathway involves in sodium excretion**,** we collected 24-h urine using metabolic cage. We found that 24-h urinary sodium excretion / body weight was significantly lower in ERK1 KO mice compared to WT control mice (0.0088 ± 0.0009 vs 0.0107± 0.0014 mmol/g, n=6, $p < 0.05$). To further investigate the role of ERK1 signaling on NCC function, we did metabolic cage study in ERK1 KO mice administrated with either control vehicle or hydrochlorothiazide (HCTZ), a specific NCC inhibitor. We found that ERK 1 mice have more exaggerated response to HCTZ treatment (25mg/kg wt, i.p.) compared to WT mice in urinary sodium excretion (0.49 ± 0.10 vs 0.28 ± 0.14 mmol, $p < 0.05$, n=3), indicating a higher NCC activity in ERK 1 KO mice. Furthermore, we found that systolic BP was higher in ERK1 KO mice than that in WT mice (127.2 ± 4.7 vs 112.9 ± 9.8, n= 4, $p < 0.05$) by tail-cuff method.

Conclusions: Taken all above data together, we concluded that ERK1 signaling pathway plays an inhibitory role in NCC function and NCC protein expression, which affects renal sodium handling and blood pressure.

Cyclosporin A Aggravates Hypomagnesemia and Hypercalciuria in Claudin 16-Deficient Mice

Kerim Mutig,[1] Hoora Drewell,[2] Michael Fähling,[3] Tilman Breiderhoff,[2] Dominik Müller,[2] Sebastian Bachmann.[3] *[1]Charite-Universitaetsmedizin Berlin, Berlin, Germany; [2]Charité-Universitätsmedizin Berlin, Berlin, Germany; [3]Charité - Universitätsmedizin Berlin, Berlin, Germany.*

Background: Calcineurin inhibitors are instrumental for immunosuppression in patients after organ transplantation but renal side effects such as hypomagnesemia and hypercalciuria often limit their therapeutic benefits. The tight junctions protein claudin 16 (Cldn16) is essential for paracellular reabsorption of calcium and magnesium along the cortical thick ascending limb (cTAL). In this study we treated wild-type (WT) and Cldn16-deficient (Cldn16-/-) mice with a calcineurin inhibitor cyclosporin A (CsA) to identify the role of Cldn16 in calcineurin inhibitor-induced abnormalities of renal divalent cation handling.

Methods: Kidney performance was evaluated in metabolic cages. Key paracellular and transcellular distal calcium and magnesium transport proteins were assessed by quantitative PCR, immunoblotting and immunofluorescence.

Results: Labeling of Cldn16 produced strong signal in cTAL tight junctions of WT but not of Cldn16-/- kidneys. Physiological analysis showed baseline hypomagnesaemia and hypercalciuria in Cln16-/- mice compared to controls. CsA administration (25 mg/kg i.p. for 7 days) induced hypomagnesaemia and hypercalciuria in WT and aggravated calcium and magnesium wasting in Cldn16-/- mice. Analysis of Cldn10, Cldn14, Cldn16, and Cldn19 isoforms did not reveal any CsA-dependent changes of their expression or protein abundance. In contrast, expression and abundance levels of relevant transcellular divalent cation transporters including the transient receptor potential channel TRPM6, calbindin, parvalbumin, and divalent metal cation transporter CNNM2 were significantly reduced upon CsA in both genotypes with stronger decreases in Cldn16-/- mice.

Conclusions: In summary, our data suggest that calcineurin inhibitors cause renal calcium and magnesium loss via suppression of transcellular reabsorption pathways, rather than via inhibition of the Cldn16-mediated paracellular transport.

SA-PO1033

Intracellular Chloride Depletion Promotes WNK4-RRXS Phosphorylation by a PKC/PKA Dependent Mechanism

Adrian R. Murillo-de-Ozores,[2,1] Leoneli I. Grajeda-Medina,[2] Gerardo Gamba,[2,1] Maria Castañeda-Bueno.[2] *[1]Universidad Nacional Autónoma de México, Mexico City, Mexico; [2]Nephrology and Mineral Metabolism, INCMNSZ, Mexico City, Mexico.*

Background: Mutations in *WNK4* gene cause Familial Hyperkalemic Hypertension (FHHt) due to increased salt reabsorption by the Na^+:Cl^- cotransporter (NCC). While WNK4 activity is inhibited by chloride, this kinase can be activated by angiotensin II or CaSR-induced PKC or PKA-mediated phosphorylation in different WNK4-RRXS motifs. This is essential for full activation of WNK4. NCC activity is inversely proportional to plasma K^+ concentration and evidence suggests that modulation of WNK4 by chloride underlies this phenomenon. Here we analyzed if WNK4 phosphorylation in its RRXS motifs is also modulated by intracellular chloride concentration ($[Cl^-]_i$).

Methods: We used a mouse model of hypokalemia generated by feeding WT mice with low K^+ diet for 7 days. WNK4-RRXS phosphorylation was analyzed by Western Blot and immunofluorescence in hypokalemic mice and in WNK4-transfected HEK293 cells incubated with different media and pharmacological inhibitors. ELISA was used to determine PKC activity.

Results: WNK4 phosphorylation at RRXS motifs S64 and S1196 increased in mice fed with low K^+ diet compared to controls. Interestingly, this was only observed in NCC positive tubules. Incubation of transfected HEK293 cells with low K^+ medium also resulted in WNK4-RRXS phosphorylation. Furthermore, two different maneuvers that decrease $[Cl^-]_i$ (low chloride hypotonic stress or NEM-incubation) in HEK293 cells also caused an increase in WNK4-RRXS phosphorylation. This was prevented by PKC inhibitor BIM and PKA inhibitor H89, as well as by intracellular Ca^{2+} chelation by BAPTA-AM. Accordingly, we found that PKC activity was increased upon $[Cl^-]_i$ depletion. Given that WNKs are the only kinases known to be regulated by $[Cl^-]_i$, we hypothesized that WNK activity was involved in the PKC/A-induced WNK4-RRXS phosphorylation. However, the specific WNK inhibitor WNK463 did not ablate low K^+-induced WNK4-RRXS phosphorylation. Instead, WNK463 increased WNK4-RRXS phosphorylation, probably due to the expected $[Cl^-]_i$ decrease.

Conclusions: WNK4 is phosphorylated in its RRXS motifs during reduction of $[Cl^-]_i$ by a mechanism that involves PKC or PKA activation. This process seems to be independent of WNK activity and was also observed *in vivo* since low potassium diet resulted in WNK4-RRXS phosphorylation in mouse DCT.

High Chloride Silences Aldosterone Signaling in the Distal Nephron

Heimo Ehmke,[1,2] Catherine Meyer-Schwesinger,[1] Helga Vitzthum.[3] *[1]University Medical Centre Hamburg-Eppendorf, Hamburg, Germany; [2]Partner Site Hamburg/Kiel/Lübeck, DZHK (German Centre for Cardiovascular Research), Hamburg, Germany; [3]University Medical Center Hamburg-Eppendorf (UKE), Hamburg, Germany.*

Background: The adrenal steroid hormone aldosterone plays a primary role in maintaining normal body electrolyte homeostasis. Physiologically, aldosterone secretion from the adrenal glands is under the control of angiotensin II and plasma $[K^+]$. Surprisingly, high aldosterone levels due to high K^+ intake are normally not associated with renal salt retention and disturbances of systemic Na^+ and Cl^- homeostasis. K^+ supplementation consistently enhances renal Na^+ excretion in animals as well as in humans particularly during NaCl loading when Na^+ delivery to the distal nephron is high. We therefore questioned whether a further mechanism may exist which in the context of a high NaCl and high K^+ intake attenuates the aldosterone-MR-ENaC pathway.

Methods: We analyzed the effects of a normal or high K^+ diet on Na^+ excretion, MR localization, ENaC mRNA and protein expression, and ENaC activity in salt replete mice. The effects of high extracellular chloride concentration $[Cl^-]$ on MR localization and ENaC expression was also determined in mCCD cells, a cellular model of principal cells in the collecting duct.

Results: The canonical cellular responses to aldosterone, encompassing translocation of the mineralocorticoid receptor (MR), transcription and activation of epithelial sodium channel ENaC, and ENaC-dependent Na^+ reabsorption, were undetectable in mice receiving a high K^+ /high NaCl diet in spite of increased plasma aldosterone concentrations. Elevating extracellular chloride concentration [Cl^-] was sufficient to suppress the aldosterone-induced MR translocation and ENaC protein expression in vitro and in vivo. Functionally and biochemically, the aldosterone response was rescued in vivo when the extracellular [Cl^-] increase was prevented during the high K^+ diet.

Conclusions: These findings show that aldosterone signaling in the kidney is silenced by increased extracellular [Cl^-] and provide an explanation for the natriuretic effect of a high K^+ intake in the presence of a high NaCl consumption characteristic for the Western diet.

SCAMP4, a New Player in the Regulation of NKCC2 Surface Expression

Sylvie Demaretz,[2] Kamel Laghmani.[1] *[1]Cordeliers Research Centre, Sorbonne University, INSERM-U1138, CNRS-ERL8228, Paris, France; [2]Cordeliers Research Centre, Sorbonne University, INSERM-U1138, CNRS-ERL8228, Paris, France.*

Background: The apically located Na-K-2l cotransporter is the pacemaker of NaCl reabsorption in the thick ascending limb (TAL) of the loop of Henle. We have previously shown that secretory carrier membrane protein 2 (SCAMP2) regulates exocytic insertion of NKCC2 into the cell membrane. The aim of the present study was to investigate the effect of SCAMP4, a member of the SCAMPs family that lacks the highly conserved N-terminal NPF repeats, on NKCC2 surface expression.

Methods: To examine the expression of SCAMP4 in TAL, we checked for the presence of its transcript in native TAL cells using real-time RT-PCR. Protein-protein interaction was assessed by co-immunopreciptation assay. NKCC2 surface expression was monitored in transiently transfected OKP and HEK cells, using protein biotinylation, immunoblot and confocal imaging.

Results: Real time PCR on renal microdissected tubules demonstrated the expression of SCAMP4 in TAL. Co-immunoprecipitation experiments showed robust interaction between SCAMP4 and the complex-glycosalyed form of NKCC2 in cultured renal cells, suggesting that the interaction takes a place at the post-Golgi level. Consistent with this notion, co-immunolocalization experiments revealed that similar to SCAMP2, SCAMP4 co-localizes with NKCC2 in recycling endosomes. However, in contrast to SCAMP2, SCAMP4 co-expression promoted NKCC2 surface expression, whereas SCAMP4 knock-down had the opposite effect. Interestingly, deleting the deleting N-terminal NPF repeats from SCAMP2, abolished its negative effect on NKCC2 surface expression, suggesting that this highly conserved domain plays a crucial in the differential regulation of NKCC2 surface expression by SCAMP2 and SCAMP4.

Conclusions: We identified SCAMP4 as a novel NKCC2 binding partner that plays a key role in the modulation of NKCC2 surface expression. Most importantly, our results are consistent with SCAMP2 and SCAMP4 having differential and antagonistic effects with regard to NKCC2 transit through recycling endosomes, thereby revealing a new regulatory mechanism governing the co-transporter intracellular trafficking.

SA-PO1036

Dietary Mg2+ Restriction Downregulates NCC Through a SPAK-Independent Pathway

Mohammed Z. Ferdaus, Lauren N. Miller, James A. McCormick. *Oregon Health & Science University, Portland, OR.*

Background: Hypomagnesemia is often observed in critically ill patients and is associated with lower kidney function and life-threatening complications. The distal convoluted tubule (DCT) is the major site of active Mg^{2+} reabsorption, determining the final urinary Mg^{2+} excretion. The Na^+-Cl^- cotransporter (NCC), expressed along the DCT, plays a key role in ion homeostasis. Dietary interventions have a strong effect on NCC.

Methods: We studied the effect of dietary Mg^{2+} manipulation on NCC in C57BL/6J mice by assessing levels of total NCC (tNCC), phospho-NCC (pNCC) and other relevant proteins with blood electrolyte analysis.

Results: We observed that abundances of tNCC and pNCC, a surrogate for NCC activity, were lower following acute (3 days) and chronic dietary Mg^{2+} (14 days) restriction, compared with normal and high Mg^{2+} diets. However, pNCC:tNCC was unchanged, suggesting the primary effect is on tNCC abundance. It is well-established that low blood [K^+] induces NCC phosphorylation. We observed that while tNCC was still downregulated by combined K^+ and Mg^{2+} restriction, pNCC abundance was strongly increased compared with normal and Mg^{2+} deficient diets. These data suggest that distinct signaling pathways mediate the effects of dietary Mg^{2+} and K^+ restriction on NCC. STE20 (Sterile 20)/SPS-1 related proline/alanine-rich kinase (SPAK) directly phosphorylates NCC, and SPAK knockout (KO) mice have ~90% lower tNCC abundance compared with wild type mice. Dietary Mg^{2+} restriction of SPAK KO mice further decreased tNCC, suggesting a strong effect of dietary Mg^{2+} restriction on tNCC abundance, and showing that SPAK was not involved in mediating the effect of dietary Mg^{2+} restriction. The E3 ubiquitin-protein ligase neural precursor cell expressed developmentally downregulated gene 4-like (Nedd4-2) induces tNCC degradation on a high Na^+ diet, but targets the epithelial sodium channel (ENaC) during K^+ restriction. As activated Nedd4-2 promotes self-degradation, its abundance reflects its activity. We found that Nedd4-2 abundance was lower on Mg^{2+} deficient diet compared with normal diet, suggesting activation of Nedd4-2 by Mg^{2+} restriction. However, abundances of ENaC subunits were unaffected.

Conclusions: Overall, our data suggest that dietary Mg^{2+} deficiency may alter NCC function by downregulating total abundance of NCC by activating Nedd4-2 selectively along the DCT.

Association Between Estimated Dietary Acid Load and Albuminuria in Japanese Adults

Keiko Kabasawa,[1] Michihiro Hosojima,[2] Yumi Ito,[1] Hideyuki Kabasawa,[2] Ribeka Takachi,[3] Kazutoshi Nakamura,[4] Akihiko Saito,[5] Junta Tanaka,[1] Ichiei Narita.[6] *[1]Health Promotion Medicine, Niigata University, Niigata, Japan; [2]Clinical Nutrition Science, Niigata University, Niigata, Japan; [3]Food Science and Nutrition, Nara Women's University, Niigata, Japan; [4]Preventive Medicine, Niigata University, Niigata, Japan; [5]Applied Molecular Medicine, Niigata University, Niigata, Japan; [6]Clinical Nephrology and Rheumatology, Niigata University, Niigata, Japan.*

Background: Acid-base imbalance might promote the progression of chronic kidney disease (CKD). Albuminuria is a risk factor for cardiovascular disease and mortality even in the high normoalbuminuric range and is also one of the diagnostic markers for CKD. However, the exact relationship between dietary acid load and albuminuria is unclear. In this study, we assessed the association of dietary acid load with albuminuria in Japanese adults.

Methods: Subjects were a Japanese cohort comprising 3,202 men and 3,429 women (age range 40-97 years); subjects with a urine albumin-to-creatinine ratio (UACR) ≥ 300 mg/g or eGFR < 15 mL/min/1.73 m^2 were excluded. We performed a cross-sectional analysis of net endogenous acid production (NEAP) score and the presence of low-grade albuminuria. NEAP score was derived from nutrient intake based on food frequency questionnaire assessment. Low-grade albuminuria, evaluated using UACR from spot urine samples, was defined as high normoalbuminuria (UACR: 10-29 mg/g) or microalbuminuria (UACR: 30-299 mg/g).

Results: Median NEAP was 43.3 (interquartile range: 34.2, 53.4) mEq/d in men and 35.1 (27.7, 43.7) mEq/d in women. Median UACR and eGFR were 9.6 (5.0, 22.0) mg/g and 73.8 (64.1, 84.3) mL/min/1.73 m^2 in men and 13.0 (7.2, 25.0) mg/g and 73.7 (64.7, 83.7) mL/min/1.73 m^2 in women, respectively. High normoalbuminuria and microalbuminuria were found in 976 and 616 men and 1,449 and 703 women, respectively. After adjusting for potential confounders, such as diabetes mellitus, the odds ratio of the highest versus lowest NEAP quartile for the presence of high normoalbuminuria and microalbuminuria was 1.28 (95% CI: 1.04–1.58) in men and 1.34 (95% CI: 1.08–1.65) in women. Among the subjects without microalbuminuria, the odds ratio of the highest versus lowest NEAP quartile for the presence of high normoalbuminuria was 1.21 (95% CI: 0.96–1.53) in men and 1.30 (95% CI: 1.04–1.63) in women.

Conclusions: NEAP score was associated with the presence of low-grade albuminuria in a Japanese adult population. Further studies are needed to confirm whether dietary acid load influences the development and progression of albuminuria.

SA-PO1038

A Diet Rich in Vegetables and Fruits and Incident CKD: Community-Based Prospective Cohort Study

Yooju Nam, Arum Choi, Seon yeong Lee, Joohwan Kim, Ki Heon Nam, Tae-Hyun Yoo, Seung Hyeok Han. *Yonsei University College of Medicine, Seodaemun-gu, SEOUL, Republic of Korea.*

Background: A diet rich in vegetables and fruits can lower blood pressure (BP) and reduce cardiovascular risk. However, it is unknown on the association between this diet and incident chronic kidney disease (CKD) in general population.

Methods: Using the database from the Korean Genome and Epidemiology Study, we analyzed 9487 subjects with normal renal function. Habitual diet survey was performed using a validated food frequency questionnaire at baseline. The study subjects were classified into tertiles according to the consumption of raw and fermented vegetables, and fruits. The primary outcome was incident CKD defined as an estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m^2. The secondary endpoint was incident proteinuria determined by dipstick test ≥ 1+.

Results: At baseline, BP, C-reactive protein levels and estimated net endogenous acid production were significantly lower in the highest tertile of raw vegetable intake. During a mean follow-up of 8.2 years, 1741 (18.4%) subjects had incident CKD. Compared to the lowest tertile of raw vegetable intake (19.3%), CKD occurred less in the middle (18.8%) and the highest (16.9%) tertile groups (P<0.001). Incidence rate of proteinuria was also lower in the latter two groups. In multivariable Cox analysis, the highest tertile of raw vegetable intake was associated with a 14% lower risk of CKD development compared to the lowest tertile (P < 0.001). The highest tertile also conferred a 28% lower risk of proteinuria development than the lowest tertile (P < 0.001). There were no associations between fermented vegetable and fruit intake and CKD development. However, both highest tertiles of fermented vegetable and fruit intake were associated with 14% and 45% lower risk of incident proteinuria compared to the lowest tertiles, respectively (P < 0.001 for both).

Conclusions: This study suggests that a diet rich in vegetables and fruits may have beneficial effects on the prevention of kidney disease.

SA-PO1039

Comparison of Mixed-Based vs Animal-Based Low Phosphorus Diet on Hyperphosphatemia in Dialysis Patients: Randomized Clinical Trial

Ximena Atilano carsi,[1] Juan Carlos Ramirez-Sandoval,[2] Jorge A. Sánchez,[3] Celene V. Arce santander,[4] Cristinoc Cruz,[5] Luis Tamez Pedroza,[6] Miguel Angel Garcia de Leon,[9] Angeles Espinosa-Cuevas,[8] Ricardo Correa-Rotter.[7] *[1]Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Ciudad de México, Mexico; [2]Instituto Nacional de Ciencias Medicas y Nutricion Salvador Zubiran, México city, Mexico; [3]Instituto Nacional de Ciencias Medicas y Nutricion Salvador Zubiran, Ciudad de México, Mexico; [4]Lapi Unidad de Hemodiálisis, Ciudad de México, Mexico; [5]INCMNSZ, Mexico city, Mexico; [6]Universidad Autonoma de Baja California, Ciudad de M?xico, Mexico; [7]Institutor Nacional de la Nutricion, Mexico City, Mexico; [8]Nacional Medical Science and Nutrition Institute, Mexico, Mexico; [9]Instituto Mexicano del Seguro Social, Distrito Federal, Mexico.*

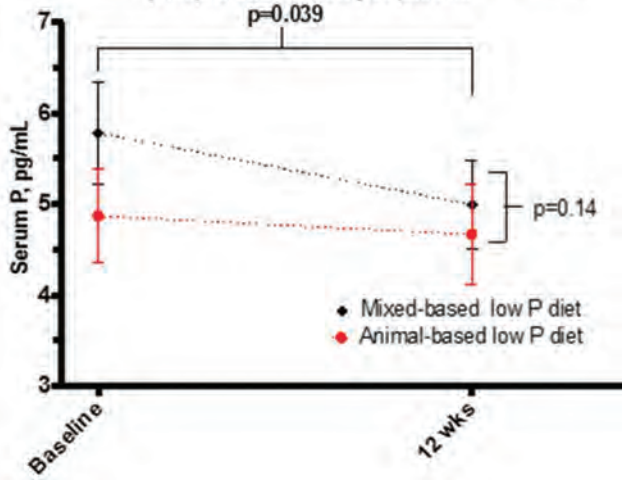
Background: Dietary P restriction is major component of hyperphosphatemia treatment in dialysis. Bioavailability of vegetable and animal P sources is not taken in consideration. KDIGO recommends to conduct clinical trials with different sources of dietary P. Aim:assess the effect on serum P of 2 low-Pdiets(<1000mg/day;Animal Vs.vegetal+animal) in dialysis patients.

Methods: Randomized, multicenter, open-label clinical trial. Subjects on dialysis for>6 mo and P>4.5mg/dL were randomized into a mixed-based(3oz equivalent animal protein+3oz equivalent legumes)vs.animal-based(6oz equivalent animal protein) low P diet with equivalent nutrients (protein=1.3 g/kg/d). Primary outcome was the change in serum P after 12 wks. We excluded patients who modified their dialysis dose, phosphate binder or vitamin D prescription during trial.

Results: 56 subjects(38HD,18PD) were randomized. Age, sex, phosphate-binders use and other baseline characteristics were similar between groups. Baseline P values were 5.6±1.6 and 4.9±1.2 in mixed-based and animal-based groups respectively(p=0.06). Mixed-based group had a significant decrease in P after 12 wks of intervention(5.6±1.6 to 5.0±1.3, p=0.04). Animal-based group did not change P significantly(4.9±1.2 to 4.7±1.4, p=0.46). Serum P in the mixed-based and animal-based declined by -0.66(95%CI:-1.39 to -0.04)mg/dL and -0.21(95%IC:-0.81 to 0.38) respectively(p=0.14, Fig). There were no differences between groups in the change of other biochemical parameters.

Conclusions: Dietary P restriction with animal or mixed-based P sources had a similar efficacy to achieve and maintain P concentration in dialysis. Mixed-based group had a non-statistically significant trend to achieve a higher decrease in serum P.

Figure. Serum P changes after *mixed-based* Vs. *animal-based* low phosphorus diet in dialysis patients



SA-PO1040

Effect of Low-Protein Rice on Progression of CKD

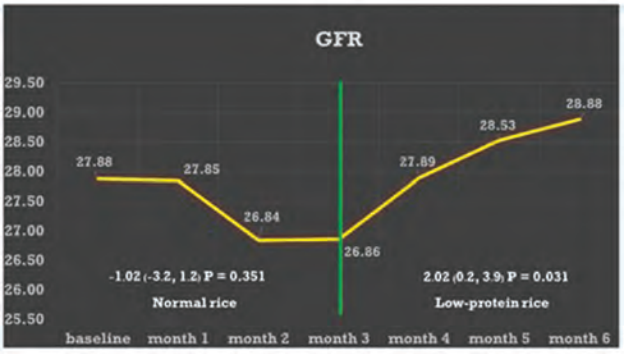
Worawon Chailimpamontree, Anupong Thananphuwasit, Pongsathorn Gojaseni, Anutra Chittinandana. *Bhumibol Adulyadej hospital, Bangkok, Thailand.*

Background: CKD is a worldwide public health problem. Protein restriction is effective in slowing the progression of kidney disease. Rice is the main staple foods in Thailand. However, besides carbohydrates, rice also consists of low biological value proteins. Since it is not easy to control dietary protein intake in patients who eat normal-protein rice(protein content 8g/rice100g), low protein rice(protein content 1.6g/rice100g) has been developed to counter these problems. As it is, the data on low-protein rice's effect on CKD progression is limited. This pilot study was done to determine the impact of low-protein rice on CKD progression.

Methods: This involved a controlled before-and-after study in patients with stage 3-4 CKD who had protein intake of> 0.8 g/kg/day. The study covered a total duration of 6 months: the first 3 months when patients ate normal-protein riceand the second 3 months when they ate low protein-rice. All patients received multidisciplinary team care and were advised to have 0.6-0.8 gram/kg/day of protein intake along the study.

Results: 32 patients were included in this study. Majority of patients were male (56.3%): 62.5% have diabetes and 81.3%have CKD stage 4. Mean age of patients is 55.9 years. After eating low-protein rice for 3 months, we noted that the GFR increased from baseline by 2.0 ± 3.1 ml/min/1.73m^2(P=0.031). The nPNA reduced from baseline by 0.1 g/kg (95%CI: -0.2, 0.1, P = 0.04). In addition, eating low-protein rice significantly decreased waist circumference.

Conclusions: Low protein-rice has an impact on improving kidney function. It is also helping patients controlling dietary protein intake and improved there's body composition. Further studies are required before applied to all CKD patients who eating rice as a main cultural cuisine.



SA-PO1041

Dietary Pattern Modifies the Association of APOL1 Variants with CKD: The Jackson Heart Study

Stanford Mwasongwe,[1] Bessie A. Young,[2] Julia J. Scialla,[3] Clementina A. Davenport,[4] Adolfo Correa,[5] Solomon K. Musani.[5] *[1]Jackson Heart Study, Jackson, MS; [2]Uniiversity of Washington, Seattle, WA; [3]Duke University, Durham, NC; [4]Duke University Medical Center, Durham, NC; [5]University of Mississippi Medical Center, Jackson, MS.*

Background: Apolipoprotein L1 (*APOL1*) variants are associated with increased risk of chronic kidney disease (CKD), however, not everyone with high risk *APOL1* genotypes develops overt kidney disease. We evaluated the modifying effects of dietary pattern on the association between *APOL1* risk variants and prevalent CKD among African Americans (AAs).

Methods: We conducted a cross-sectional analysis of 2,841 AAs from the Jackson Heart Study (JHS) with genotyped *APOL1* variant data. Three dietary patterns, designated "southern", "fast food" and "prudent" were derived from a validated regional specific food frequency questionnaire (Deep South) using factor analysis. The factor scores for each pattern were divided into tertiles labelled low, moderate and high levels, respectively. CKD was defined at baseline as an estimated glomerular filtration rate <60 mL/min/1.73 m^2. First, we assessed the association between *APOL1* Variants and prevalent CKD using multivariate logistic regression model, controlling for demographic, clinical factors to and population stratification. We then added diet and *APOL1* x diet interaction terms to assses the effect modification of each diet pattern.

Results: The mean (± standard deviation) age of included participants was 55±13 years, 62% were female, 5.5 % had CKD. Of the total participants studied, 13% had two *APOL1* risk variants. We observed that the models accounting for *APOL1*× diet interactions fitted the data significantly (P<0.001) better than the main effects model. In multivariable adjusted main effects model, two *APOL1* risk variants were significantly associated (Odds Ratios, OR [95% confidence Interval, CI]; p-value) with prevalent CKD 1.87 (1.16-2.96); p=0.0102. In individuals consuming high levels of fast food diet, 2 *APOL1* risk variants were significantly associated (OR, 95% CI) with greater odds, 3.66 (1.43, 9.39), p=0.007 of prevalent CKD compared to low and moderate levels of fast food diet (Figure 1). Similarly, in individuals consuming high levels of southern diet, the OR were 2.92 (1.16, 2.96); p=0.02.

Conclusions: In a large community-based study of AAs, all dietary patterns studied modified the association between *APOL1* two-risk alleles and increased CKD prevalence.

SA-PO1042

Dietary Protein Intake, Protein Energy Wasting, and Progression of CKD

Eunjeong Kang,[1] Sung Woo Lee,[2] Curie Ahn,[1] Kook-Hwan Oh.[1] *[1]Seoul National University Hospital, Seoul, Republic of Korea; [2]Eulji General Hospital, Seoul, Republic of Korea.*

Background: There have been a paucity of literatures regarding on the effect of dietary protein intake (DPI) on the progression of chronic kidney disease (CKD), in conjunction with the potential hazard of protein-energy wasting (PEW).

Methods: The database of a large-scaled multicenter prospective study in Korea of 2238 patients enrolled from 2011–2016 was reviewed. After excluding 319 with missing data to define DPI and PEW, and 347 with collecting 24-hour urine incompletely, the study included 1572 non-dialysis CKD patients. CKD progression was defined by a >50%

estimated glomerular filtration rate (eGFR) decline, serum creatinine doubling, or dialysis initiation.

Results: During mean 41.6 months' follow-up period, 296 CKD patients (18.8%) progressed. Cross-sectionally, increased DPI was significantly associated with increased eGFR. Similarly, increased DPI tertile was significantly associated with increased renal survival in Kaplan-Meier curve analysis (Log-rank P <0.001). In multivariate Cox proportional hazard regression analysis, the hazard ratio (95% confidence interval) of the third vs. first tertile was 0.685 (0.495-0.948, P = 0.022). However, the statistical significance of DPI tertile group on CKD progression was lost when variables related to PEW were added as covariates. In penalized spline curve analysis, the adjusted odds ratio of PEW was significantly increased as DPI increased.

Conclusions: DPI per se was not a major determinant of CKD progression. Instead, intimate association between reduced DPI and PEW may be more important than DPI per se to predict CKD progression.

SA-PO1043

Prevalence and Impact of Food Insecurity in Children with ESRD

Michelle C. Starr, Aaron G. Wightman, Raj P. Munshi, Sangeeta R. Hingorani. *Seattle Children's Hospital, Seattle, WA.*

Background: Food insecurity (FI) affects 1 in 6 children in America. Children with kidney disease, especially those with End-Stage Renal Disease (ESRD) may be at higher risk, due to their complex care needs, medication burden, and dietary restrictions. Adults with kidney disease and FI progress more quickly to ESRD. The prevalence and impact of FI in pediatric ESRD patients is largely unknown. We sought to determine the prevalence of FI among children with ESRD receiving dialysis and to examine the relationship between FI and clinical factors, healthcare utilization, and quality of life.

Methods: We assessed food insecurity among families of dialysis patients age <21 years seen for ESRD at an academic pediatric center. The primary predictor was household FI status, determined using the Hunger Vital sign, a validated 2 question-screening tool. We compared demographic features, clinical factors, and outcomes including health care utilization between families identified as FI versus those not. We defined unplanned healthcare utilization as unscheduled admission to the hospital, Emergency Department visit, or dialysis related infection.

Results: A total of 43 families were enrolled in this study; 24 (55%) were on peritoneal dialysis (PD) and 19 (45%) were on hemodialysis (HD). 27 of 43 (65%) of children with ESRD lived in food insecure households, with a larger percentage of children on HD reporting FI compared to those on PD (73.7 vs. 54.2%). Food insecure children were more likely to have an unplanned healthcare utilization event (96.3 vs. 75.0%, p = 0.035), including hospitalization (p=0.008) and intensive care unit admissions (p=0.03). Children with FI had a trend towards more dialysis related infections (48.1 vs. 25.0%). Clinically, children with FI were less likely to have adequate Kt/V for the last 3 months (63.0 vs. 93.4%, p=0.03). Both child and parent proxy quality of life scores tended to be lower in those with FI on all subscales, particularly the worry subscale.

Conclusions: FI is common among children on dialysis therapy and negatively impacts clinical care, healthcare utilization, and quality of life. Further exploration into how FI and other social determinants of health influence management of and impact outcomes for children with ESRD is warranted as are interventions to decrease rates of FI.

SA-PO1044

Association Between Estimated Protein Intake and Single-Nephron Glomerular Filtration Rate in Healthy Adults

Rina Oba, Takaya Sasaki, Go Kanzaki, Kotaro Haruhara, Yusuke Okabayashi, Kentaro Koike, Akimitsu Kobayashi, Izumi Yamamoto, Nobuo Tsuboi, Takashi Yokoo. The Jikei University School of Medicine, Division of Nephrology and Hypertension, Department of Internal Medicine. *The Jikei University School of Medicine, Minato-ku, Japan.*

Background: High protein intake can increase renal plasma flow and glomerular filtration rate (GFR) in response to excretory overload, which may exacerbate kidney disease progression. Glomerular hypertrophy has been shown to be closely associated with sclerosis at the level of a single nephron in experimental models. However, the mechanisms by which an excessive protein diet causes glomerular hyperfiltration and increases single-nephron GFR (SNGFR) have not been fully elucidated in humans. The present study aimed to calculate SNGFR by estimating the number of nephrons in living kidney donors and to evaluate the clinicopathological findings associated with SNGFR.

Methods: We identified 33 living kidney donors with a normotensive status who underwent enhanced computed tomography (CT) and kidney biopsy at donation in the Jikei University School of Medicine Hospital from 2007 to 2017. The number of nephron was calculated according to the cortical volumes of both kidneys as assessed on CT and the 1-hour post-transplant renal biopsy-determined glomerular density. Effective renal plasma flow (ERPF) was assessed as ^{99m}Tc-MAG3 clearance, and SNGFR was calculated as the 24-hour creatinine clearance (24hCCr) divided by the total number of non-sclerosed glomeruli. The sodium intake and protein intake of the donors were estimated through a 24-hour urine collection test.

Results: Among the 33 subjects, 13 (39.3%) were males, and the mean age was 53.7 ± 8.7 years. Additionally, the mean arterial pressure (MAP) was 84.4 ± 9.2 mmHg, and the mean 24hCCr was 112.8 ± 25.5 ml/min/1.73 m^2. Urinalysis findings were normal. The estimated total nephron number was 698,308 ± 218,740/kidney, and the mean SNGFR was 90.3 ± 33.7 nl/min/1.73 m^2. SNGFR was strongly and directly associated with the estimated sodium and protein intake (EPI) (P = 0.0365 and 0.0048, respectively) but was not associated with the donor age, BMI, MAP, ERPF, glomerulosclerosis index, or tubular injury level. Interestingly, SNGFR was only associated with EPI as assessed by multivariate analysis.

Conclusions: In healthy adults, we noted a strong positive correlation between SNGFR and EPI. Our study findings indicate that high protein intake might increase SNGFR and cause glomerular hyperfiltration.

SA-PO1045

Dietary Phosphorus and Protein Intake in a Diverse Cohort of Hemodialysis Patients

Amanda R. Tortorici,[2] Connie Rhee,[1] Kamyar Kalantar-Zadeh,[3] Elani Streja,[4] Kimberly M. Juarez,[1] Alejandra Novoa,[5] Tracy Nakata,[6] Amy S. You.[7] *[1]University of California Irvine, Huntington Beach, CA; [2]UC Irvine Medical Center, Irvine, CA; [3]University of California Irvine, School of Medicine, Orange, CA; [4]Harold Simmons Center for Kidney Disease Research and Epidemiology, Orange, CA; [5]UC Irvine Health, Orange, CA; [6]UC Irvine, Orange, CA; [7]University of California, Irvine, Orange, CA.*

Background: We sought to determine whether dietary phosphorus (P) and protein intake in hemodialysis (HD) patients varies across race/ethnicity.

Methods: We identified 407 patients from the "Malnutrition, Diet, and Racial Disparities in Chronic Kidney Disease" (MADRAD) study, a racially/ethnically diverse prospective hemodialysis cohort who underwent food frequency questionnaire assessment. We compared baseline daily dietary intake of P, protein, and ratios of P/protein, P/kcal, as well as protein/kcal across racial/ethnic groups using one-way ANOVA and Bonferroni post hoc analyses.

Results: Blacks had the highest average daily intake of dietary P (882.7±765.7mg) and protein (62.8±54.5g), while patients of other race/ethnicities had the highest ratio of protein/kcal (0.049±0.01g/kcal). The differences in P/protein intake across racial/ethnic groups were significant, such that Hispanics had significantly higher ratios than Blacks and others: 17.2±5.3, 14.4±2.7, and 13.6±2.9mg/g, respectively; p<0.01. Hispanics also had the highest ratio of P/kcal (0.71±0.16mg/kcal). The differences in dietary protein/kcal ratios across racial/ethnic groups were also significant, such that Hispanics had significantly lower intake than Blacks and those of other race/ethnicity: 0.043±0.01, 0.048±0.01, 0.049±0.01, respectively; p<0.01.

Conclusions: These data suggest that, compared to other racial/ethnic groups, Hispanic HD patients' dietary P intake relative to protein intake is higher, whereas their dietary protein intake relative to their total caloric intake is lower. Further studies are needed to determine the specific dietary sources of P among HD patients of varying race/ethnicity, and whether these variations may have a differential impact on their health and survival.

SA-PO1046

Safety and Impact of Low Protein Diet and Ketosteril Before ESRD

Chih-Hsiang Chang. *Chang Gung Memorial Hospital, Taoyuan, Taiwan.*

Background: Low protein diet with ketoacid analogue supplement (LPD-KA) remained under employed in patients with chronic kidney disease (CKD) because of safety issue and low compliance. This study aims to evaluate the sepsis and cardiovascular outcome in patient who received LPD-KA before end stage kidney disease (ESKD).

Methods: The study analyzed encrypted datasets from Taiwan's National Health Insurance Research Database. The exposure group was the patients received LPD and ketoacid analogue over 6 months before ESKD and the comparison group was patients who did not received LPD. Outcomes included mortality cardiovascular event, sepsis and in follow up.

Results: The data of 2607 patients in the LPD group and 10428 propensity score matched patients without LPD between January 1, 2001 and December 31, 2013 were analyzed. Patients on LPD-KA had lower mortality (23.1% vs. 27.6%; hazard ratio [HR] 0.77, 95% confidence interval [CI] 0.70-0.84), lower composite cardiovascular events (19.2% vs. 21.5%; HR 0.86, 95% CI 0.78-0.94), and sepsis death (6.6% vs. 8.5%; HR 0.74, 95% CI 0.63-0.87).

Conclusions: LPD might be a safe therapy for patient of CKD. Overall mortality, cardiovascular event and sepsis death are less in LPD-KA group.

SA-PO1047

Diet and Renal Function in the ELSA-Brasil Cohort: A Mediation Analysis

Geraldo B. Silva Junior,[1] Rosa malena Fagundes xavier,[2] Estela Aquino,[2] Leticia Cardoso,[3] Rosa maria Salani mota,[4] Antonio alberto Lopes,[2] José geraldo Mill,[5] Maria del carmen Bisi molina,[5] Sandhi Barreto,[6] Dora Chor,[3] Carlos Teles santos,[2] Paulo Lotufo,[7] Sheila Alvim matos.[2] *[1]University of Fortaleza, Fortaleza, Brazil; [2]Federal University of Bahia, Salvador, Brazil; [3]Fundacao Oswaldo Cruz, Rio de Janeiro, Brazil; [4]Federal University of Ceara, Fortaleza, Brazil; [5]Federal University of Espirito Santo, Vitoria, Brazil; [6]Federal University of Minas Gerais, Belo Horizonte, Brazil; [7]University of Sao Paulo, Sao Paulo, Brazil.*

Background: Previous studies suggest the influence of diet on renal function. The aim of this study was to investigate the associations between diet and renal function among adults in Brazil.

Methods: The Brazilian Longitudinal Study of Adult Health (ELSA-Brasil) is the largest cohort study in Latin America, with 15,105 participants from 6 cities in Brazil. We have identified 4 dietary patterns in this cohort: 1) Traditional Brazilian, 2) Low sugar/low fat, 3) Fruits and vegetables, and 4) Bakery. Renal function was based on microalbuminuria and glomerular filtration rate (GFR) estimated through CKD-EPI formula. Association between dietary patterns and renal function was investigated through mediation analysis.

Results: Participants mean age was 52±9 years, with 54% female. Dietary patterns found were: traditional (45.7%), fruits/vegetables (25.5%), bakery (24.4%), low sugar/low fat (4.3%). For men, the patterns "bakery" and "fruits and vegetables" had significant effects on GFR and microalbuminuria. The "fruits and vegetables" pattern had only indirect effect on both GFR and microalbuminuria. For women, the "bakery products" pattern presented total effect on GFR and microalbuminuria. The "fruits and vegetables" pattern had the same effect, except for also presenting direct effect on GFR without adjustment (Figure 1).

Conclusions: There is association between dietary patterns and renal function. The "bakery" diet seem to have negative effect on renal function. The "fruits and vegetables" pattern have association with renal function possible due to epidemiological reverse causality effect.

Nutritional Assessment in Dialysis Patients: Are We Missing Something from Subjective Assessment?

Rachana H. Jasani,[1] Rajesh B. Kumar,[1] Shrirang Bichu,[2] J. Kothari,[3] Viswanath Billa,[4] Paras Dedhia.[1] *[1]Apex Kidney Care, Mumbai, India; [2]Bombay Hospital Near Liberty Theater New Marine Lines, Mumbai, India; [3]Hinduja Hospital, Healthcare & Apex Kidney Foundation, Mumbai, India; [4]Bombay Hospital, Mumbai, India.*

Background: Malnutrition is very common in dialysis patients and is associated with increased mortality and morbidity. It is not clear whether subjective assessment can accurately identify malnourished dialysis patients. Also, handgrip strength and body composition analysis are not incorporated in nutritional assessment scoring system.

Methods: Nutritional assessment was carried out by subjective and objective parameters on subjects undergoing thrice a week maintenance hemodialysis. Subjective assessment was done using Subjective Global Assessment (SGA) and Dialysis Malnutrition Score (DMS). Objective assessment was done using handgrip strength and body composition analysis. Subjects with albumin less than 3.5 g/dl were considered as malnourished. Handgrip strength analysis was performed by handgrip dynamometer (CAMRY, model EH101) while body composition analysis was performed by Body Composition Monitor (BCM) (Fresenius Medical Care).

Results: Nutritional assessment was conducted on 81 subjects (46 males and 35 females) undergoing thrice a week hemodialysis. The average age was 54.8 ± 12.7 years and average BMI was 24.8 ± 4.3. The average serum albumin was 3.2 ± 0.3 g/dl. Malnutrition was observed in 76.5% subjects by albumin <3.5 g/dl criteria. On subjective assessment, 55 % and 69.3% subjects were found to be malnourished by SGA and DMS scores respectively. Handgrip strength and BCM (objective assessment), categorized 89% subjects as malnourished.

Conclusions: Subjective assessment is not accurate in identifying malnourished dialysis patients. Simple, bedside tools like handgrip strength and body composition monitor may help to better characterize nutritional assessment and early intervention in dialysis patients.

SA-PO1049

Use of Medical Nutrition Therapy Is Low Among US Veterans with Stage 3-5 Non-Dialysis Dependent CKD

Holly J. Kramer,[2,3] Talar Markossian,[2,3] Nick Burge,[3] Ivan M. Pacold,[3,1] David J. Leehey,[3,1] Kevin Stroupe.[3] *[1]Loyola University Medical Center, Maywood, IL; [2]Loyola University Chicago, Maywood, IL; [3]Hines VA Medical Center, Hines, IL.*

Background: Once chronic kidney disease (CKD) is established, dietary modifications such as decreasing intake of animal protein and salt and increasing intake of fresh fruits and vegetables may slow CKD progression. However, dietary modifications require patient education and close monitoring due to risks of malnutrition and hyperkalemia. Medical Nutrition Therapy (MNT), the individualized nutrition assessment, care planning and dietary education provided by a registered dietitian nutritionist remains an effective intervention for slowing CKD progression and delaying end-stage renal disease (ESRD). We examined MNT utilization among U.S. Veterans with established non-dialysis dependent stage 3-5 chronic kidney disease (CKD-ND) during calendar year 2015. We hypothesized that utilization of MNT may be low and requires more attention.

Methods: We used data from the VA Corporate Data Warehouse which includes demographics, inpatient and outpatient encounter diagnosis and procedure codes and Current Procedural Terminology (CPT) codes] and patient labs. Since a percentage of Veterans receive their care from non-VA sources, we linked data from the Center for Medicare & Medicaid Services Medicare administrative databases to capture non-VA health care use. CKD status was based on presence of at least two estimated glomerular filtration rate (eGFR) values < 60 ml/min/1.73 m^2 in outpatient laboratory data spaced 90+ days apart.

Results: There were 242,865 Veterans age ≧50 years with at least two eGFR <60 ml/min/1.73 m^2 spaced 90+ days apart during calendar year 2014 with no history of dialysis or transplantation. Mean age was 76.4 years (standard deviation 9.6) and 96.7% were male and most were white with 14.9% reporting black race. During calendar year 2015, only 9.6% of Veterans with stage 3-5 CKD-ND saw a VA dietician and 0.1% saw a Medicare reimbursed dietician. MNT utilization overall was significantly higher among black vs. whites (13.9% vs. 9.0%, p<0.001). Only 1.7% of Veterans with stage 3-5 CKD-ND were enrolled in the VA MOVE! program designed to increase exercise.

Conclusions: Utilization of MNT is very low in U.S. Veterans with stage 3-5 CKD-ND. Increasing utilization of MNT for patients with CKD-ND should be a priority for health systems in order to delay ESRD.

SA-PO1050

Temporal Changes in Nutritional Markers and Their Association with Mortality in Non-Dialysis Dependent CKD

Abhishek J. Patel,[1] Mahmoud A. Mahmoud,[3] Jawed Akhtar,[1] Barry M. Wall,[2] Csaba P. Kovesdy.[2] *[1]University of Tennessee Health Science Center, Memphis, TN; [2]Veterans Affairs Medical Center, Memphis, TN; [3]University of Teneessee Health Science Center, Memphis, TN.*

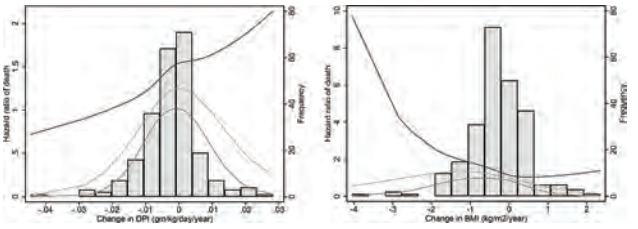
Background: The pathophysiology of protein-energy wasting (PEW) involves both decreased nutrient intake and increased catabolism. The temporal changes of different PEW components and their association with mortality in CKD are not well characterized.

Methods: We examined 234 US veterans with CKD stages 3-5. We assessed serially body weight (BW)/body mass index (BMI), and spot urine urea nitrogen creatinine ratio to estimate 24-hour urine urea nitrogen excretion and daily protein intake (DPI) using the Maroni formula. We estimated the slopes of DPI, BMI and eGFR vs. time in mixed effects models. The association of the slopes of DPI and BMI with all-cause mortality was examined in Cox models adjusted for age, gender, race, diabetes, eGFR and baseline DPI and BMI, respectively.

Results: Patients were 68.6±9.5 years old, 97% male, 38% African-American and 41% diabetic. Mean baseline eGFR, DPI and BMI were 33.1±12.1 ml/min/1.73m^2, 0.41±0.15 g/kgBW/day and 30.3±7.1 kg/m^2, respectively. Patients had a median (25th-75th percentile) of 5 (3-8) measurements over a median follow-up time of 3.2 years, and 64 patients died (mortality rate 93/1000 patient-years, 95%CI: 73-119). Patients experienced modest but statistically significant decreases in eGFR and BMI over time, but no significant average change in DPI (Table). The slope of DPI was not associated with multivariable adjusted mortality risk (p=0.3), while increase in BMI was associated with a trend towards lower mortality (p=0.1, Figure).

Conclusions: Patients with moderately advanced CKD and relatively stable kidney function experienced small changes in BMI and stable protein intake over time. These modest changes in nutritional markers showed no association with all-cause mortality. Larger studies with longer follow-up are needed to better assess the effects of declining kidney function on different PEW components, and the effects of these changes on survival.

	Slope (95%CI)
eGFR (ml/min/1.73m2/year)	-2.09 (-2.84, -1.34), p<0.001
DPI (gm/kgBW/day/year)	-0.0024 (-0.0096, 0.0048), p=0.5
BMI (kg/m2/year)	-0.28 (-0.45, -0.11), p=0.001



SA-PO1051

Efficacy of Segmental Bioelectrical Impedance Analysis in Regular Nutritional Assessment in Autosomal Dominant Polycystic Kidney Disease

Hyunjin Ryu,[1] Hayne C. Park,[2] Hyunsuk Kim,[3] Kook-Hwan Oh,[1] Curie Ahn,[1] Yun Kyu Oh.[4] *[1]Seoul National University Hospital, JongNo-Gu, SEOUL, Republic of Korea; [2]Kangnam Sacred Heart Hospital, Seoul, Republic of Korea; [3]Chuncheon Sacred Heart Hospital, Chuncheon, GANGWON-DO, Republic of Korea; [4]Department of Internal Medicine, Boramae Medical Center, Seoul, Republic of Korea.*

Background: Increased risk of malnutrition in autosomal dominant polycystic kidney disease (ADPKD) are found in patients with declined renal function and/or large abdominal cystic organ volume. Therefore regular nutritional assessment are important in ADPKD patients. Increased ratio of extracellular water to total body water (ECW/TBW) and decreased phase angle (PhA) are known malnutrition marker of bioelectrical impedance analysis (BIA). In this study, we analyzed the efficacy of BIA in the nutritional assessment follow-up compared to modified subjective global assessment (SGA) in ADPKD patients.

Methods: This is a prospective cohort study undertaken at a tertiary university hospital. Nutritional status were assessed with SGA and segmental BIA (Inbody S10) at the two visits of outpatient clinic between Dec. 2013 and Mar 2018. Height adjusted total kidney volume (htTKV) were calculated using ellipsoid method from CT scans of two visits.

Results: Total 135 patients were analyzed and 46.7% were female. At the initial visit, the mean age was 48.1±10.2 years and the mean eGFR was 62.8±21.7 mL/min/1.73m^2. The median values of htTKV were 801 mL/m (IQR 495–1185 mL/m). Interval between two visits were 28.5±4.4 month. Between two visits, eGFR decreased (62.8±21.7→56.4±23.5 mL/min/1.73m^2, p<0.001) and htTKV increased (927.4±627.8→1235.8±868.0 mL/m, p<0.001). However there were no statistical difference in SGA score (6.7±0.6→6.6±0.7), weight, body mass index, serum albumin, and cholesterol level during follow-up. Among the segmental BIA parameters, ECW/TBW of whole body (0.384±0.007→0.386±0.007, p<0.001), trunk (0.383±0.007→0.386±0.008, p<0.001) and lower extremity (0.387±0.008→0.388±0.008 p=0.015) increased significantly. The lean mass of whole body (48.4±10.67→47.8±10.6 p<0.001), upper extremity (2.7±0.8→2.6±0.8 p=0.007) and trunk (22.1±4.8→21.8±4.9 p=0.001) and PhA of upper extremity (5.3±0.6→5.1±0.7 p<0.001), trunk (9.0±1.4→7.8±1.2 p<0.001) and lower extremity (5.3±0.8→5.2±0.8, p<0.001) decreased significantly during the follow up.

Conclusions: Increased ECW/TBW level and decreased lean mass and PhA were found in ADPKD patients during follow up. Using quantitative parameters of segmental BIA, clinician were able to monitor nutritional status of ADPKD patients more sensitively, in addition to laboratory data and SGA.

SA-PO1052

Diet Dependent Systemic Acid Load (AL) Impacts Decline in Kidney Function Through Serum Albumin (SA)

Tanushree Banerjee,[3] Anthony Sebastian,[1] Neil R. Powe,[2] Lynda A. Frassetto.[1] *[1]University of California San Francisco, San Francisco, CA; [2]Priscilla Chan and Mark Zuckerberg San Francisco Gen Hosp & UCSF, San Francisco, CA; [3]San Francisco General Hospital, San Francisco, CA.*

Background: Inflammation may be present with CKD and diet composition may affect inflammation thereby impacting kidney health. Higher intakes of proteins and fats yielding a higher AL have been linked with worsening of kidney function and inflammation may play a role. We investigated whether AL estimated from urine measures is associated with kidney function decline and whether the effect of AL on an inflammatory marker, SA, is a pathway to this association.

Methods: We studied 188 post-menopausal women in a clinical trial of potassium bicarbonate treatment for up to 36 months. 24-hr urine and arterialized blood collections were done at baseline and at subsequent 3 month follow-up visits. AL was estimated from the urine potential renal acid load (UPRAL), calculated using measures of chloride, phosphate, sodium, potassium, calcium, and magnesium. Mixed effects (ME) model with random-intercept and slope was used to estimate subjects' annual decline rate in creatinine clearance (CrCl) and eGFR. We used the ME model to estimate the association between (1) UPRAL and SA, and (2) SA and CrCl, adjusting for age, body mass index, systolic BP, and glucose. A Cox proportional regression model was used to study the relative hazard for decline in CrCl with UPRAL, adjusting for potential covariates and baseline CrCl. Our models were repeated with eGFR decline as the outcome.

Results: A 25 mEq/day increase in UPRAL was inversely associated with SA (95% CI:–0.01[–0.09;-0.0001; p=0.05]). SA was inversely associated with CrCl (p<0.05). During 28 months mean follow-up, 45 women (23.9%) had a rapid decline in kidney function (loss ≥5 ml CrCl/yr). For each 25 mEq/day increase in UPRAL, the risk of a rapid decline in CrCl increased by 17% (95% CI:1.06-1.28). Adjusting for potential confounders, the

risk attenuated to 5% (1.02-1.14). Mediation analysis indicated that of the total effect of the association between UPRAL and CrCl, the proportion mediated by SA was 0.32 (i.e. 32%). Using eGFR, the proportion mediated by SA increased to 0.41.

Conclusions: Higher UPRAL was associated with lower SA as well as reduced kidney function in post-menopausal women. Our findings suggest inflammatory response may exert a modulatory effect on the association of UPRAL and kidney function and might be a potential pathway to explain the effects of systemic AL on kidney function decline.

Dietary Acid Load and the Risk of Metabolic Acidosis in Prevalent Hemodialysis Patients

Mi Jung Lee,[1] Hyung Jong Kim,[1] Jung Tak Park,[2] Jung Pyo Lee,[3] Yon Su Kim,[4] Yong-Lim Kim,[5] Dong-Ryeol Ryu.[6] *[1]Bundang CHA Medical Center, CHA University, Seongnam, GYEONGGI-DO, Republic of Korea; [2]Yonsei University Health System, Seodaemun-Gu, Seoul, Republic of Korea; [3]Seoul National University Boramae Medical Center, Seoul, Republic of Korea; [4]Seoul National University College of Medicine, Seoul, Republic of Korea; [5]Kyungpook National University Hospital, Daegu, Republic of Korea; [6]Ewha Womans University, Seoul, Republic of Korea.*

Background: Metabolic acidosis is associated with protein energy wasting, bone disease, and higher mortality in end-stage renal disease (ESRD). Although higher dietary acid load can exacerbate metabolic acidosis, there is a lack of data evaluating their relationship in ESRD patients. Therefore, we investigated the association between dietary acid load and metabolic acidosis in ESRD patients undergoing hemodialysis (HD).

Methods: One hundred and eleven prevalent HD patients were included from the ESRD-Clinical Research Center (ESRD-CRC) cohort in South Korea. Dietary intake data were obtained from a self-reported food frequency questionnaire and a 7-day food diary. Dietary acid load was estimated using the equation for potential renal acid load (PRAL). Metabolic acidosis was defined as serum bicarbonate <22 mEq/L.

Results: The median value of PRAL was 9.97 (interquartile range, 4.45-14.06) mEq/day. Metabolic acidosis was observed in 47 patients (42.3%). The independent association of PRAL with metabolic acidosis was analyzed by binary logistic regression analysis. Multivariable analysis indicated that higher PRAL was significantly associated with risk of metabolic acidosis after adjusting confounding factors (per 1 standard deviation increase, odds ratio=3.258, 95% confidence interval [CI]=1.106-9.599, P=0.03). Subsequent linear regression analysis was performed to find dietary behavior factors affecting PRAL. Higher intake of processed meat including ham, sausage, or bacon, was significantly associated with increased PRAL (per 1 intake/week increase, β=0.244, 95% CI for B=0.704-9.164, P=0.02).

Conclusions: PRAL was the independent risk factor for metabolic acidosis in prevalent HD patients, suggesting deleterious effect of higher dietary acid load. Therefore, dietary counseling or intervention to reduce processed meat intake may be helpful for management of metabolic acidosis in these patients.

SA-PO1055

Comparison of Three Technology-Supported Behavioral Interventions for Phosphorus Management in Hemodialysis Patients

David E. St-Jules, David S. Goldfarb, Mary Lou Pompeii, Mary A. Sevick. *NYU School of Medicine, New York, NY.*

Background: Behavioral methods enhance the effectiveness of lifestyle interventions, but are often resource intensive. Although mobile health (mHealth) technology can help create lower input interventions, their feasibility, acceptability and efficacy have not been adequately evaluated in hemodialysis (HD) patients.

Methods: Maintenance HD patients with persistent hyperphosphatemia (n=40) were randomized to receive: (1) educational (Edu) videos (EDU), (2) Edu + mobile self-monitoring (SM) with MyNetDiary® (MON), or (3) Edu + SM + social cognitive theory (SCT)-based behavioral counseling videos (SCT) over a 12-week period with videos for each group delivered using iPads. Serum phosphorus concentrations (sPO_4) were measured at baseline, 12 and 24 weeks, and a 5-point Likert scale survey on the mHealth technology was completed at 24-weeks. Two participants in the EDU group with no follow-up sPO_4 measurements were excluded; missing sPO_4 measurements at 12- and 24-weeks were imputed by carrying forward the most recent sPO_4 values.

Results: At the end of the intervention phase (12-weeks), there was a non-significant trend towards greater decreases in sPO_4 in the MON (-0.5±1.6 mg/dL, p=0.32) and SCT (-0.3±2.1 mg/dL, p=0.56) groups compared to the EDU group (+0.2±1.4 mg/dL), but these differences had mostly disappeared by the end of the monitoring phase (24-weeks) (EDU +0.1±1.2 mg/dL, MON -0.1±1.9 mg/dL, SCT -0.1±2.1 mg/dL). Most participants agreed or strongly agreed that the iPads were convenient (64%), and SM helped them stay motivated (68%), take binders (61%), and limit phosphorus intake (68%). Relatively few participants reported that they agreed or strongly agreed that they sometimes "got lost" maneuvering the iPad programs (24%), felt that SM wasn't worthwhile (16%), or would have preferred face-to-face meetings offsite (4%).

Conclusions: Many HD patients are willing, able and report benefits of engaging in technology-supported behavioral interventions involving SM and SCT. Although these programs are easy to disseminate with limited resources once developed, any benefits for phosphorus management in HD patients may last only as long as the intervention is active.

Association Between Healthy Diet Score and Kidney Function: A Population-Based Survey

Suzanne Dominique Genest,[1] Myriam Khalili,[3] Remi Goupil,[2] Amelie Bernier-Jean,[4] Josee Bouchard,[2] Stephan Troyanov,[2] Francois Madore.[2] *[1]Université de Montréal, Montreal, QC, Canada; [2]Hopital du Sacre-Coeur de Montreal, Montreal, AB, Canada; [3]University of Montreal, Montreal, QC, Canada; [4]The University of Sydney, Westmead, NSW, Australia.*

Background: While it is recognised that a healthy diet can reduce the risk of cardiovascular disease, dietary risk factors for chronic kidney disease remain relatively undetermined. This study aimed to assess the association between the American Heart Association's (AHA) healthy diet score and estimated glomerular filtration rate (eGFR).

Methods: The present study is a survey of random adults between 40 and 69 years-old. Diet was assessed using the NIH Diet History Questionnaire II. We determined the association between eGFR (CKD-EPI equation) and the overall AHA diet score (based on five components: fruits and vegetables, fish, fiber, sodium and sugar-sweetened beverages), using linear regression models adjusted for important confounders, including age, sex, income, education, caloric intake, smoking, physical activity, body mass index, hypertension, dyslipidemia, diabetes and cardiovascular disease. We also studied the association between eGFR and protein intake.

Results: The Diet History Questionnaire was completed by 8,128 participants. Mean age was 55.3 ± 7.7 years and mean eGFR was 86.9 ± 14.6mL/min/1.73m². Overall AHA healthy diet score was positively associated with eGFR (p<0.001), after adjusting for potential confounders (listed above). Upon analyzing individual food components, the intake of fruits and vegetables, fish and fiber were associated with improved eGFR, after adjustment for age and sex (cf. table). After further adjustment for confounders, fruits and vegetables consumption and dietary fiber intake remained significantly associated with a higher eGFR, while fish consumption was no longer significant (cf. table). Protein intake was not significantly associated with eGFR.

Conclusions: Among the five dietary components of the AHA healthy diet score, fiber, and to a lesser extent fruits and vegetables, are significantly associated with a higher eGFR in this population-based survey.

Funding: Government Support - Non-U.S.

Nutrition Information: What Resources Are Used by Patients?

Rachel B. Fissell,[1] Zongyang Mou,[2] Laura Binari,[1] Khaled Abdel-Kader.[1] *[1]Vanderbilt University Medical Center, Nashville, TN; [2]University of California San Diego, San Diego, CA.*

Background: It can be challenging for CKD pts to choose safe and healthy foods, partly because of complex dietary recommendations. There are many potential sources of dietary information, including physicians, other pts, dieticians, paper handouts, and the internet. Patients who are empowered and educated about food choices may be more adherent to a prescribed diet. This study surveys patient use of paper and electronic resources to learn about diet, focusing on potassium.

Methods: CKD pts were enrolled during outpatient clinic visits, given a survey assessing knowledge of potassium in foods, and preferences for dietary information sources. Pts were then provided with one handout with written information, and one handout with three investigator curated dietary websites. A second survey was administered several weeks later, reassessing pt knowledge about high potassium foods and pt preference for sources of information.

Results: N=110 responses were analyzed. Mean age was 58.8 yrs, with median 59.5 yrs, and range 28-83 yrs. The sample was 46% female, and 43% diabetic. Distribution of kidney stages were 2: 5%, 3: 50%, 4: 22%, 5: 22%. Pt percentages that were not sure, somewhat sure, and very sure that they could choose low potassium foods were 40%, 40%, and 20%, respectively. 66% of pts knew orange juice has more potassium than apple juice, 5% thought apple juice has more potassium than orange juice, and 29% were unsure. 24% knew whole wheat bread has more potassium than white bread, 38% thought white bread has more potassium than whole wheat bread, and 38% were unsure. 49% preferred paper handouts, 75% preferred internet videos or websites (answers not mutually exclusive). Preference for use of websites decreased with older age. For every 10yr increase in age, the odds of preferring websites decreased by 27% (OR 0.23, 95% CI 0.54, 0.98).

Conclusions: This sample shows variation in knowledge about high potassium foods, and variation in patient-perceived ability to choose low potassium foods. Although it was not surprising that older patients preferred paper handouts over the internet, the percentage of patients who used the internet as an information source for diet was quite high. These initial results suggest areas for improved pt nutrition education, and indicate a need for readily available and accurate paper and internet resources.

SA-PO1058

Salt-Related Knowledge, Attitudes, and Compliance in CKD on Dialysis and Heart Failure

Michael Cinelli,[1] Samer Saouma,[1] Sassine Ghanem,[1] Sami U. Hossri,[1] Nicholas Fuca,[1] Julie Zaidan,[2] Thomas J. Vazzana,[1] James Lafferty,[1] Suzanne E. El Sayegh.[1] *[1]Staten Island University Hospital, Staten Island, NY; [2]Northwell health, Staten island, NY.*

Background: Evidence of the adverse effect of high dietary sodium on the kidney and heart is growing. The WHO, CDC and AHA recommend consumption of <2, <2.3 and <1.5 g/day, respectively. Despite efforts, general and high-risk patient(HF and ESRD) compliance remains low. The primary aim of our study is to evaluate Na intake in HF and ESRD and correlate it with label-reading ability.

Methods: This cross-sectional study recruited patients with ESRD and HF inpatient at Staten Island University Hospital from September 2017-March 2018. A Block Sodium Screener © estimated daily Na intake and a questionnaire asked about shopping habits and label-reading proficiency with Likert scale conversion to a score(6-30). Subjects were grouped based on score, daily Na intake: <1500 mg/day or ≥1500 mg/day. Characteristics were analyzed using Student's t-test, nonparametric Mann-Whitney U test, or $\chi 2$ test then linear regression to evaluate the relationship between Na intake and score.

Results: We recruited 61 patients: 34 ESRD, 14 HF and 13 both. We found a negative correlation between Na intake and score(R= -0.49, p<0.0001, Figure 1). There was no difference in age, BMI and gender among the 2 groups. Compliant patients had less years since diagnosis(2.70 +/-1.16 vs. 5.05 +/-5.75; p=0.0205). Other variables did not show any association with Na intake(Table 1).

Conclusions: This study showed that more knowledge about salt content and better shopping habits are associated with a lower daily Na intake in high risk populations(ESRD and HF). A larger sample is needed to evaluate for patient demographic and medical characteristics associated with non-compliance to low Na diet.

Long Chain Omega-3 Polyunsaturated Fatty Acids and Patient Important Outcomes in CKD: A Systematic Review and Meta-Analysis of Randomized Controlled Trials

Valeria M. Saglimbene,[1,3] Germaine Wong,[1] Anita van Zwieten,[1] Suetonia Palmer,[2] Marinella Ruospo,[3] Patrizia Natale,[3,4] Jonathan C. Craig,[1] Giovanni F. Strippoli.[4,3] *[1]University of Sydney, Sydney, NSW, Australia; [2]University of Otago, Christchurch, New Zealand; [3]Diaverum, Bari, Italy; [4]University of Bari, Bari, Italy.*

Background: Long-chain omega-3 polyunsaturated fatty acid (n-3 PUFA) has recognised vascular benefits in the general population, but knowledge of supplementation among patients with CKD is largely restricted to vascular access outcomes.We aimed to assess the benefits and harms of n-3 PUFA therapy in patients with chronic kidney disease (CKD).

Methods: MEDLINE, Embase, CENTRAL and reference lists were searched up to January date, 2018. We included randomised controlled trials evaluating n-3 PUFA supplementation compared with placebo or standard care on cardiovascular and all-cause mortality, progression to end stage kidney disease (ESKD), acute transplant rejection, and graft loss. Risks of bias and evidence certainty were assessed using Cochrane and Grading of Recommendations Assessment, Development and Evaluation processes, respectively.

Results: Sixty studies (n=4129), median sample size of 41 participants (interquartile range 30 to74) and median follow-up duration of 6 months (3 to 12), were included. N-3 PUFA reduced cardiovascular death (n=1,045; relative risk [95% confidence interval], 0.45 [0.23, 0.89]; moderate evidence certainty) in dialysis patients, and progression to ESKD (n=170; 0.30 [0.09, 0.98]; very low evidence certainty) in patients with moderate to advanced stage CKD. Effects on all-cause mortality (n=1876; 1.05 [0.83, 1.33]; low evidence certainty); acute transplant rejection (n=543; 0.98 [0.80, 1.21]; low evidence certainty) and graft loss (n=434; 0.98 [0.54, 1.81]; very low evidence certainty) were uncertain. Risks of bleeding (n=770; 1.40 [0.78, 2.49]) and gastrointestinal side-effects (n=1455; 1.14 [0.79, 1.67]) were uncertain.

Conclusions: N-3 PUFA supplementation may protect patients on dialysis against cardiovascular mortality. It appeared to prevent ESKD in patients with moderate to advanced stage CKD but the evidence certainty was very limited.

SA-PO1060

Impact of Dialysis Treatment Shift on Malnutrition Indicators

Juan J. Carrero,[4,2] Adam M. Zawada,[1] Katharina Brand,[1] Stefano Stuard,[1] Bernard J. Canaud,[1] Adelheid Gauly,[1] Anke Winter,[1] Denis Fouque.[4,3] *[1]Fresenius Medical Care, Bad Homburg, Germany; [2]Karolinska Institutet, Stockholm, Sweden; [3]University Claude Bernard, Pierre Benite, France; [4]European Renal Nutrition working group, ERA-EDTA, Italy.*

Background: Malnutrition is strongly associated with morbidity and mortality among hemodialysis patients. It has been a long-term clinical concern that patients on afternoon shifts (AS) are more prone to malnutrition than those on morning shifts (MS), as their dialysis scheme and post-dialysis symptoms interfere with their meal intake. Thus, we evaluate the role of dialysis shifts on malnutrition indicators.

Methods: We conducted a retrospective study among 9.963 incident hemodialysis NephroCare patients using 2011-2016 European Clinical Database data. Linear mixed models were used to compare the course of Body Composition Monitor assessed lean and fat tissue index (LTI, FTI) between MS and AS patients over 2 years. These models included fixed effects (age, sex, vascular access, diabetes mellitus) and random effects (country, patient). Secondary malnutrition indicators were body mass index, albumin, creatinine and normalized protein catabolic rate.

Results: Patients had a mean age of 63.6 years, 41.8% were female and 29.9% were diabetic. Mean baseline LTI and FTI levels were comparable between MS (LTI: 12.5±2.9kg/m^2; FTI: 13.7±6.0kg/m^2) and AS (LTI: 12.4±2.9kg/m^2; FTI: 13.2±6.1kg/m^2) patients. During follow-up LTI slightly decreased and FTI constantly increased in both groups with a mean absolute change (baseline-24months) of -0.3 kg/m^2 for LTI and +1.0 kg/m^2 for FTI (**Figure 1**). The course of these malnutrition indicators did not differ between dialysis shift groups (*Treatment x time* interaction p-values ≥0.10). We did not observe substantial differences between groups when descriptively evaluating secondary malnutrition indicators.

Conclusions: Dialysis shift does not seem to impact long-term nutritional status of dialysis patients and may not represent a modifiable risk factor.

Eicosapentaenoic Acid (EPA) Powerfully Prevents the Progression for Both Renal Dysfunction and Atherosclerosis in CKD Patients Due to Benign Nephrosclerosis

Yoshihiko Inoue,[2] Eri Kawashima,[1] Kiyoko Inui,[2] Ashio Yoshimura,[3] Fumihiko Koiwa.[2] *[1]Showa University Fujigaoka Hospital, Yokohama, Japan; [2]Division of Nephrology, Department of Medicine, Showa University Fujigaoka Hospital, Yokohama, Japan; [3]Shinyokohama Daiichi Clinic, Yokohama, Japan.*

Background: Effect of EPA for CKD patients is not fully known. We studied the efficacy of EPA to prevent the progression of both renal impairment and atherosclerosis in CKD stage 3-4 patients due to benign nephrosclerosis (BNS).

Methods: 28 CKD stage 3-4 patients due to BNS with dyslipidemia were followed for 5years after the start of EPA treatment (EPA (+): n=20) or treatment without EPA (EPA (-): n=8). The dosage of 1800 mg/day of EPA was newly prescribed in EPA treatment group. T-cho, LDL-cho, Triglycerides (TG), eGFR, the amount of proteinuria, EPA, arachidonic acid (AA), Dihomo-gamma-linolenic acid (DGLA) and docosa hexaenoic acid (DHA) were examined. Both right and left (RL) brachial-ankle pulse wave velocity (baPWV), RL maximum carotid intima-media thickness (max IMT), RL maximum carotid plaque thickness and RL ankle-brachial index (ABI) were evaluated at before treatment (baseline), after every year and at the end of the study (5-year).

Results: EPA, EPA/AA ratio, TG. RL baPWV, and RL max IMT showed significant improvement and eGFR did not decrease at 5-year in EPA treatment group (table 1). Furthermore, both EPA and DHA levels were significantly low in eGFR exacerbation patients group (n=7) compared with the improvement group (n=13) at both baseline and 5-year in EPA treatment group. EPA treatment patients showing the highest EPA levels at baseline (EPA: 107.5±15.2μg/ml, n=5) showed significant improvement in both eGFR and baPWV compared with those with the lowest EPA levels (31.0±9.2 μg/ml, n=5). There was no difference on both plaque thickness and ABI between baseline and 5-year.

Conclusions: EPA powerfully prevents the progression of both renal dysfunction and the atherosclerotic change in CKD stage 3-4 patients due to BNS.

SA-PO1062

Effect of Intra-Dialysis Nutrients Admixture vs Conventional Intra-Dialysis Parenteral Nutrition on Nutrition Status and Inflammation in Malnourished Hemodialysis Patients

Ouppatham Supasyndh, Wongsakorn Boonkarn, Theerasak Tangwonglert, Pamila Tasanavipas, Amnart Chaiprasert, Naowanit Nata, Bancha Satirapoj. *Phramongkutklao hospital, Bangkok, Thailand.*

Background: Protein/caloric malnutrition and inflammation is a major problem in long-term hemodialysis patients. Total nutrients admixture containing 80% olive oil-base intravenous lipid emulsions and low proportion of polyunsaturated fatty acids may offer several advantages such as a reduction of oxidative and inflammatory effects in end stage renal disease (ESRD).

Methods: The study was a randomized controlled trial; patients with malnourished ESRD on hemodialysis were randomly assigned into an admixture-IDPN group (n=13) and a conventional-IDPN group (n=13). Nutritional assessment, and inflammatory markers including high sensitivity C-reactive protein (hs-CRP) and interleukin-6 (IL-6) were measured at baseline and 4 weeks following intervention.

Results: At the end of 4-week, nutritional parameters including serum albumin (0.41±0.18 vs 0.16±0.22, P=0.004), pre-albumin (7.88±4.6 vs. 2.01±2.63. P=0.001) and urea reduction ratio (2.92±0.76 vs 0.92±2.78, P=0.026) in the admixture-IDPN group have a significantly greater improvement than the conventional-IDPN group. The decline in serum IL-6 levels was -13.9 pg/mL larger among admixture-IDPN vs conventional-IDPN group (95% CI -20.41 to -7.4 pg/mL). The admixture-IDPN group had also higher absolute lymphocyte counts and lower hs-CRP levels after treatment, but there were no significant changes in the conventional-IDPN group. There were no statistically significant differences between the two groups in the risk of electrolytes abnormalities and adverse events.

Conclusions: Malnourished ESRD patients on dialysis receiving olive oil-base lipid emulsions and low polyunsaturated fatty acids IDPN resulted in modest improvements in nutritional status and inflammatory cytokines.

SA-PO1063

1500-Day All-Cause Mortality and Carnitine Profile in Hemodialysis Patients

Daigo Kamei,[1] Yuiko Kamei,[2] Ken Tsuchiya,[1] Kosaku Nitta,[1] Michio Mineshima.[1] *[1]Tokyo Women's Medical University, Tokyo, Japan; [2]Tokyo Metropolitan Health and Medical Treatment Corporation, Tokyo, Japan.*

Background: Patients on dialysis are in a chronic carnitine-deficient state. This condition may be associated with abnormalities of the fatty acid and organic acid metabolisms. Carnitine is required for β-oxidation of the long-chain fatty acids; therefore, carnitine deficiency decreases the efficiency of ATP synthesis and may incur death. However, the details of this association remain unknown. We examined the relationship between β-oxidation efficiency represented by the carnitine profile and 1500-day all-cause mortality in hemodialysis patients.

Methods: The carnitine profiles of 122 hemodialysis patients were determined by liquid chromatography-tandem mass spectrometry (LC-MS/MS). The associations between 1500-day all-cause mortality and carnitine profile as well as the clinical backgrounds of the patients were investigated. A survival analysis was conducted by the Kaplan-Meier survival method and multivariate Cox proportional hazard analysis. The bootstrap method was performed to confirm the stability and robustness of our model.

Results: Of the 122 subjects analyzed, 111 were selected and 24 died during the observation period. Stepwise multivariate Cox regression demonstrated that diabetes state [$p < 0.001$, $\exp(\beta) = 4.981$], age [$p = 0.006$, $\exp(\beta) = 1.052$], and the acetylcarnitine/(palmitoylcarnitine+octadecenoylcarnitine)[C2/(C16+C18:1)]ratio[$p<0.001$,$\exp(\beta)=0.937$] were independent significant factors of 1500-day all-cause mortality. The bootstrap method confirmed the significance of these three factors.

Conclusions: The 1500-day all-cause mortality negatively correlated with the C2/(C16+C18:1) ratio. Improvement of the impaired β-oxidation state after L-carnitine administration may ameliorate prognosis.

SA-PO1064

Ketosteril Prolongs Predialytic Diabetic Nephropathy Patients' Survival: A Nationwide Population-Based Study

Heng-chih Pan,[1] Hsing-Yu Chen,[2] Chiao-Yin Sun.[1] *[1]Chang Gung Memorial Hospital, Taipei, Taiwan; [2]Chang-Gung Memorial Hospital, Taoyuan City, Taiwan.*

Background: Metabolic changes in chronic kidney disease contribute to poor survival. Accumulated evidences indicate that dietary supplementation with branched-chain amino acids exerts a variety of beneficial effects in diabetic animals and humans. The aim of this study was to find out possible impact of Ketosteril supplement on survival of diabetic patients under predialysis status.

Methods: We analyzed a nationwide cohort from Taiwan's National Health Insurance Research Database, to study the long-term impact of Ketosteril supplement in predialytic diabetic nephropathy patients. We enrolled 14257 out of 1,000,000 random subjects with diabetic nephropathy and predialysis status between January 1, 2004, and December 31, 2007. Patients who ever received Ketosteril therapy after confirmation of predialysis status were defined as Ketosteril users. All patients were followed-up for 5 years after entering predialysis status. The study endpoints were all-cause mortality and occurrence of stroke, congestive heart failure, and chronic dialysis.

Results: The prevalence of Keosteril usage in diabetic nephropathy patients with predialysis status was 2.72%. The 5 yrs all-cause mortality of Ketosteril users was significantly lower than that of non-users (33.7% vs 46.5%, $p < 0.001$). After adjustment for known risk factors, the Ketosteril users had significantly lower risk for mortality (hazard ratio:0.61, 95% confidence interval: 0.50-0.75, $p < 0.001$). When further stratified according to age, hazard ratios of mortality were 0.73 and 0.49 among patients who younger and older than 70 years, respectively.

Conclusions: Predialytic diabetic nephropathy patients who received Ketosteril supplement had a significantly prolonged survival. This study suggests Ketosteril might be a therapeutic choice to prolong the survival of predialytic patients.

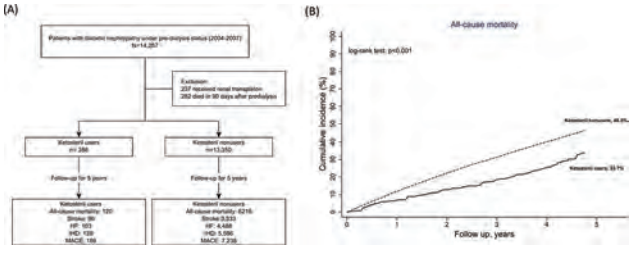

Figure 1. Ketosteril prolongs the survival of predialytic diabetic nephropathy patients. A. Taiwan's National Health Insurance Research Database study flow chart. B. 5 yrs all-cause mortality.

SA-PO1065

Adequate Protein Supplementation for Hospitalized Dialysis Patients

Adhish Agarwal,[1] Jennifer E. Schmidt,[2] Faris A. Ahmed,[1] Carissa Christensen.[3] *[1]University of Utah, Salt Lake City, UT; [2]University of Utah Hospital, Salt Lake City, UT; [3]University of Utah HEALTH, Salt Lake City, UT.*

Background: A high protein diet (1.2 gm/kg/day) is recommended for dialysis patients[1]. It is important for hospitalized dialysis patients to receive a high protein diet since inadequate protein intake worsens outcomes in hospitalized dialysis patients[2,3]. However, chronic kidney disease (CKD) patients who are not on dialysis may benefit from a protein restricted 'renal diet'[4]. Hospitalized dialysis patients could inadvertently receive a protein-restricted diet if placed on a 'renal diet' intended for CKD patients.

Methods: At the University of Utah Hospital, patients with CKD, including dialysis patients, were commonly placed on a 'Renal diet' that consisted of a 60 gm per day protein-restriction. The University of Utah uses EPIC software that has a template for 'Renal diet'. In order to provide dialysis patients with adequate protein, we approached the Nutrition Care Services Department with recommendations to modify this template, to allow for the option of either increasing protein supplementation for dialysis patients, or restricting protein to 60 g/day for patients with CKD but not on dialysis.

Results: In collaboration with the EPIC software team at the University of Utah Hospital, the 'Renal diet' template was modified. When placing this diet order, providers still choose a 'Renal diet' but now are required to select a modifier of either 'Dialysis' or 'Non-Dialysis'. Choosing the 'Dialysis' option provides the patient with a higher protein diet. In the 12 months preceding this template modification, providers ordered a 'Renal diet' 1594 times at our hospital. In the week following the modification, half of the 'Renal diet' orders (13 out of 26) had the 'Dialysis' modifier resulting in an appropriate higher protein diet given to dialysis patients. Modifying the EPIC template for 'Renal diet' has helped the dialysis patients admitted to our facility receive an appropriate higher protein diet.

Conclusions: We recommend that all acute care hospitals around the country examine their 'Renal diet' order templates; and modify renal diet templates, when necessary, to ensure an adequate protein diet for hospitalized dialysis patients.

SA-PO1066

Impact of Patient Awareness and Age on Serum Albumin in Chronic Hemodialysis Patients

Shehabaldeen M. Alanazi,[1] Ezzedine Abderrahim,[1] Wisam H. Al-Badr,[1] Abdulkareem Alsuwaida,[1] Suad Abdulaziz,[1] Amani M. Shams,[1] Riham A. Albalbisi,[1] Saad S. Alobaili,[1] Ibrahim A. Jubran,[1] Abdullah Kashgary.[1,2] *[1]DaVita-Saudi Arabia, Riyadh, Saudi Arabia; [2]King Abdulaziz University, Jeddah, Saudi Arabia.*

Background: Hypoalbuminemia is associated with cardiovascular death in patients on maintenance hemodialysis (HD) and is a marker of malnutrition–inflammation complex syndrome. In addition to dialysis adequacy, serum albumin is influenced by socioeconomic status and level of education and awareness regarding dietary requirements. The aim of our study was to identify potential factors determining hypoalbuminemia in population of prevalent HD patients in Saudi Arabia.

Methods: The study included 372 prevalent patients receiving maintenance HD at DaVita-KSA (215 female, 157 male). Mean age was 54.4 ± 17.2 years. The study population was divided into two groups based on serum albumin recorded in Feb 2018 (G1: ≤3.5 g/dL, G2: >3.5 g/dL) and parameters of socioeconomic status, food preparation/intake, and dialysis adequacy were assessed. We performed multiple logistic regression analysis to identify parameters that were independently associated with serum albumin level.

Results: There were 160 patients in G1 and 212 in G2 with no significant difference between males and females. In univariate analysis, factors found to be associated with hypoalbuminemia were: old age, low level of education, diabetes, short ESRD duration and lack of diet awareness. Patients in G2 had higher levels of serum creatinine, potassium, phosphorus, nPCR, and hemoglobin, and greater gain in dry weight. There were no significant differences between groups with respect to other socioeconomic factors or food intake. Multivariate analysis revealed that old age (RR: 1.032/year; 95% CI [1.017-1.047]) and diet awareness (RR: 1.2; 95% CI [1.0.2-1.36]), were independent predictors of hypoalbuminemia.

Conclusions: In our study, hypoalbuminemia correlated with age and level of diet compliance, which itself is determined by the education level of HD patients. Lower serum albumin is also associated with weight loss without correlation with monthly income or other socioeconomic factors.

SA-PO1067

Clinician Attitudes Toward Lowering Sodium Intake

Manavi Bhagwat,[1] Devasmita Choudhury.[2] *[1]Virginia Tech Carilion School of Medicine, Roanoke, VA; [2]Salem VA Medical Center, University of Virginia, Virginia Tech Carilion School of Medicine, Salem, VA.*

Background: Lowering dietary sodium (Na) intake is of utmost importance for patients with hypertension (HTN), kidney, liver, and heart disease particularly when there is evidence for fluid retention, but patient adherence to low Na diets is suboptimal. Primary care practitioner (PCP) attitudes and prescription of low Na diets can impact adherence. To understand PCP attitudes, prescription and follow up of low Na diets, we administered a brief survey.

Methods: An email 8-question survey was sent to all 234 PCPs at the Salem VA Medical Center (Salem VAMC) and at Carilion Roanoke Memorial Hospital (CRMH) clinics. Questions asked PCP attitudes towards recommending Na restriction for medical conditions including HTN, kidney disease (KD), and lower extremity edema. Survey also queried PCP processes to determine dietary adherence.

Results: We received 57 responses (41 MD/DO, 16 PA/NP) with a 45% response rate at Salem VAMC and 40% at CRMH. PCPs self-reported varied diet instruction practices (Fig 1). 54% of respondents recommend patients with KD follow a low Na diet and 45% personally instruct patients on following a low Na diet. 13% of respondents gave KD patients dietitian referrals for low Na diet instruction. PCPs mostly checked adherence by asking hypertensive patients if they follow a low Na diet (Fig 2).

Conclusions: Of PCP respondents, 46% never discuss or prescribe a low Na diet to patients that can benefit from it. Of those that discuss or prescribe a low Na diet, <20% made a nutrition referral. There is also limited effort with dietary adherence follow up. Given significant variability in PCP practices and attitudes towards low Na diet prescription, suboptimal low Na diet adherence in patients is expected. Improving low Na diet instruction at PCP level can impact key patient risks factors for renal and cardiovascular morbidity.

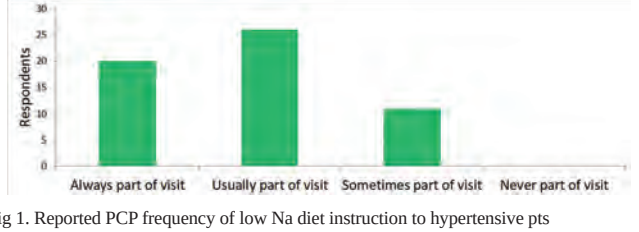

Fig 1. Reported PCP frequency of low Na diet instruction to hypertensive pts

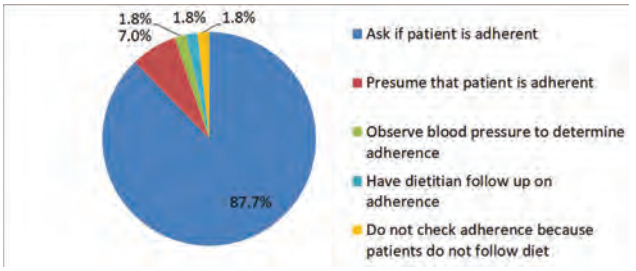

Fig 2. Self-reported methods of determining adherence to low Na diet

SA-PO1068

The Impact of Pre-ESRD Testosterone Level upon Post-ESRD Mortality Among US Male Veterans: A Transition of Care in CKD Study

Jui-Ting Hsiung,[2] Elani Streja,[3] Amy S. You,[2] Praveen Kumar Potukuchi,[4] Melissa Soohoo,[5] Danh V. Nguyen,[2] Alpesh Amin,[6] John J. Sim,[8] Csaba P. Kovesdy,[4] Kamyar Kalantar-Zadeh,[7] Connie Rhee.[1] *[1]University of California Irvine, Huntington Beach, CA; [2]University of California, Irvine, Orange, CA; [3]Harold Simmons Center for Kidney Disease Research and Epidemiology, Orange, CA; [4]University of Tennessee Health Science Center, Memphis, TN; [5]University of California at Irvine, Orange, CA; [6]UC Irvine, Orange, CA; [7]University of California Irvine, School of Medicine, Orange, CA; [8]Kaiser Permanente Southern California, Los Angeles, CA.*

Background: Testosterone deficiency is a common endocrine complication in the elderly male population, with a disproportionately high prevalence observed in those with chronic kidney disease (CKD). While lower circulating levels of testosterone have been linked with higher risk of cardiovascular disease and death in the general population, little is known about the impact of testosterone deficiency upon the health and survival of non-dialysis dependent (NDD) CKD patients transitioning to end-stage renal disease (ESRD).

Methods: Among a national cohort of male US veterans with NDD-CKD transitioning to ESRD over 2007-15, we examined the association of total testosterone levels averaged over the two-year pre-ESRD prelude period with post-ESRD mortality risk using Cox models adjusted for sociodemographics, cause of ESRD, Charlson comorbidity score, and comorbidities.

Results: Among 1219 veterans who underwent one or more total testosterone measurements in the two-year prelude period, those in the lowest testosterone tertile had higher mortality risk in expanded case-mix models (ref: highest tertile): adjusted HR (aHR) (95%CI) 1.31 (1.07-1.62) (Figure). A similar relationship between the lowest total testosterone tertile and higher death risk was observed when measurements were examined over six-month and one-year prelude periods: aHRs (95%CI): 1.70 (1.16-2.49) and 1.46 (1.11-1.93), respectively.

Conclusions: In male US veterans transitioning to dialysis, lower total testosterone levels in the pre-ESRD prelude period were associated with higher post-ESRD mortality risk. Further studies are needed to determine the specific underlying pathways between testosterone deficiency and mortality in this population, and whether administration of testosterone replacement therapy in the pre-ESRD prelude period can improve post-ESRD outcomes.

SA-PO1069

Association Between Pre-ESRD Phosphodiesterase Type 5 Inhibitors Use and Post-ESRD Mortality

Praveen Kumar Potukuchi,[1] Abduzhappar Gaipov,[1] Keiichi Sumida,[2] Miklos Z. Molnar,[1] Fridtjof Thomas,[1] Justin Gatwood,[1] Elani Streja,[3] Connie Rhee,[4] Kamyar Kalantar-Zadeh,[4] Csaba P. Kovesdy.[1] *[1]University of Tennessee Health Science Center, Memphis, TN; [2]Nephrology Center, Toranomon Hospital Kajigaya, Kawasaki, Japan; [3]Harold Simmons Center for Kidney Disease Research and Epidemiology, Orange, CA; [4]University of California Irvine, School of Medicine, Orange, CA.*

Background: Phosphodiesterase 5 inhibitors (PDE5i) are widely used to treat erectile dysfunction. Due to their vasodilatory properties, PDE5i may have systemic benefits, but information about the association between PDE5i and mortality in end-stage renal disease is lacking.

Methods: In a contemporary national cohort of 6,299 male US veterans with incident ESRD, we compared patients who received PDE5i treatment within 1 year prior to dialysis initiation to patients with a diagnosis of erectile dysfunction who did not receive PDE5i therapy. The association between PDE5i use (compared to non-use) and 1-year all-cause mortality after transition to ESRD were assessed using Cox proportional hazards models adjusted for sociodemographics, comorbidities, baseline vital parameters, and medication use.

Results: The mean age of the cohort was 65±10 years, 51% were white, 46% were African Americans, and 78% were diabetic. 2,212 (35%) patients received PDE5i treatment. PDE5i users displayed lower mortality than the non-users [Figure, unadjusted hazard ratio (95%CI): 0.80 (0.71-0.90, p<0.001)], but the survival advantage was attenuated after multivariable adjustments [0.93 (0.76-1.08, p=0.31)].

Conclusions: Pre-ESRD phosphodiesterase type 5 inhibitor use for erectile dysfunction was not associated with post-ESRD mortality. Further clinical studies are needed to study the effects of PDE5i use to determine its potential benefits in patients with ESRD.

SA-PO1070

Clinical Predictors for the Incidence of Severe Acute Pyelonephritis During Antepartum Based on National Health Examination Data

Gang Jee Ko,[1] Shin-Young Ahn,[1] Eunjung Cho,[1] Young-Joo Kwon,[1] Geum joon Cho.[2] *[1]Department of Internal Medicine, Korea University College of Medicine, Guro Hospital, Seoul, Republic of Korea; [2]Department of Obstetric and Gynecology, Korea University College of Medicine, Guro Hospital, Seoul, Republic of Korea.*

Background: Acute pyelonephritis is common during pregnancy, and increases the risk of maternal and fetal outcome. However, it has not been clearly revealed yet which demographic and clinical characteristics are associated with the incidence of acute pyelonephritis during pregnancy

Methods: Study data were collected from the Korea National Health Insurance Claims Database of the Health Insurance Review and Assessment Service. Women who had delivery between 2010 and 2014 in Korea and received health examination prior within one year of pregnancy were enrolled. A model of multivariate logistic regression analysis was performed to evaluate the risk of acute pyelonephritis during pregnancy.

Results: The mean±SD age of the overall cohort of 370,248 women was 31±4 years. The incidence of acute pyelonephritis (APN) treated under hospitalization was 2,526 patients (0.7%). In multivariate logistic regression analysis, younger age (OR 0.93 for every 5 years increase, 95% CI, 0.88-0.98), previous history of APN within one year of pregnancy (OR 9.37, 95% CI, 8.26-10.64), and abnormal results of health examination such as high fasting glucose without history of diabetes (>100mg/dL, OR 2.06, 95% CI, 1.41-2.99) and proteinuria (OR 1.81, 95% CI, 1.16-2.83) were associated with increasing risk of acute pyelonephritis during pregnancy.

Conclusions: Certain maternal demographic and clinical characteristics were associated with the incidence of acute pyelonephritis during pregnancy, and they should be monitored closely during antenatal care.

SA-PO1071

The Effects of Restricted Protein Diet Supplemented with Keto-Analogue on Renal Function, Nutritional Status, and CKD-Mineral and Bone Disorder in CKD Patients: A Meta-Analysis

Paweena Susantitaphong,[1] Api Chewcharat,[1] Kullaya Takkavatakarn,[2] Sasitorn Wongrattanagorn,[1] Krissana Panrong,[3] Piyawan Kittiskulnam,[4] Somchai Eiam-Ong,[1] Kearkiat Praditpornsilpa.[1] *[1]Chulalongkorn University, Bangkok, Thailand; [2]Division of Nephrology, King Chulalongkorn Memorial hospital, Bangkok, Thailand; [3]King Chulalongkorn Memorial Hospital, Bangkok, Thailand; [4]Chulalongkorn university, Bangkok, Thailand.*

Background: The prevalence of CKD and its complications are incessantly increasing. The important strategies are how to delay the progression of CKD and postpone renal replacement therapy. Dietary protein restriction(low or very low protein diet) with or without KA supplement might slow down the rate of renal function declination without increasing the risk of malnutrition. We aimed to evaluate the efficacy and side effects of restricted protein diet supplemented with KA on the treatment of CKD.

Methods: A literature search was performed via PubMed, Scopus, Cochrane Central Register of Controlled Trials and ClinicalTrials.gov from January 1960 to May 2018 to identify randomized controlled trials(RCTs) which explored the effects of restricted protein diet with KA on slowing progression of CKD, nutritional status, and CKD-MBD. Random-effect model was used to compute the weighted mean difference (WMD) for continuous variables.

Results: Seventeen RCTs with 1,475 participants were included in our meta-analysis. Restricted protein diet with KA supplementation significantly improved estimated GFR (WMD = 3.14 mL/min/1.73m^2 (0.68, 5.61), P=0.013), reduced proteinuria (WMD=-0.86g/d(-1.71,-0.02),P=0.046),serumphosphate(WMD=-0.68mg/dl(-1.02,-0.33), P < 0.001), parathyroid hormone level (WMD = -73.70 pg/mL(-132.79, -14.61), P = 0.015), systolic blood pressure (WMD = -4.96 mmHg (-8.03, -1.90), P = 0.002), diastolic blood pressure (WMD = -2.39 mmHg (-3.84, -0.95), P = 0.001), and serum cholesterol (WMD = -17.66 mg/dL (-33.19, -2.14, P = 0.03). Of interest, the treatment could raise serum albumin (WMD = 0.12g/dl (0.01, 0.22), P= 0.04) and serum calcium (WMD =0.50 mg/dL (0.21, 0.80), P=0.001).

Conclusions: Restricted protein diet supplemented with KA could effectively improve kidney endpoints, CKD-MBD parameters and blood pressure parameters without causing malnutrition. However, the significant increased serum calcium should be monitored.

SA-PO1072

Effects of Oral Nutritional Supplements on Clinical Outcomes and Nutritional Markers in Hemodialysis Patients Qualifying with Serum Albumin 3.6 or 3.7 g/dL

Scott Sibbel,[1,2] Becky Brosch,[3] Maria M. Stasios,[3] Abigail Hunt,[1,2] David B. Van Wyck,[2] Allen R. Nissenson,[3] Steven M. Brunelli,[1,2] Deborah A. Benner.[3] *[1]DaVita Clinical Research, Minneapolis, MN; [2]DaVita Institute for Patient Safety, Denver, CO; [3]DaVita Kidney Care, Denver, CO.*

Background: Use of oral nutritional supplements (ONS) has been shown to improve clinical outcomes in dialysis patients with serum albumin ≤ 3.5 g/dL. However, there is evidence indicating patients with albumin < 3.8 g/dL are also at increased risk for death. Here, we evaluated the effects of providing ONS to dialysis patients with serum albumin 3.6 or 3.7 g/dL on clinical outcomes and nutritional markers.

Methods: This was a retrospective evaluation of a pilot program (May-Aug 2017) to provide ONS to in-center hemodialysis patients with a qualifying serum albumin measurement of 3.6 or 3.7 g/dL. ONS was provided to the patient at the time of dialysis treatment. ONS patients were matched to control patients from non-pilot facilities who had the same qualifying albumin (3.6 or 3.7 g/dL) and preceding albumin (n = 2902 per group). Clinical outcomes (death, hospitalization, missed dialysis treatments) and nutritional markers (albumin, normalized protein catabolic rate [nPCR], creatinine) were assessed over 180 days using longitudinal generalized linear models.

Results: There was a significantly lower death rate among ONS patients relative to controls (0.07 vs 0.12 per patient-year [PPY]; adjusted incidence rate ratio [aIRR] = 0.38; 95% confidence interval [CI] = 0.22-0.68). No significant differences were observed in hospitalizations (1.37 vs 1.16 PPY; aIRR = 1.04; 95% CI = 0.88-1.12), missed dialysis treatments (11.2 vs 11.4 PPY; aIRR = 0.98; 95% CI = 0.87-1.10), or nutritional markers.

Conclusions: These finding indicate that provision of ONS to dialysis patients with albumin > 3.5 g/dL could be beneficial in reducing mortality. Dialysis providers should consider expanding ONS programs to include patients with albumin <3.8 g/dL.

New Nutritional Risk Index on the Basis of Protein Energy Wasting for Japanese Hemodialysis Patients

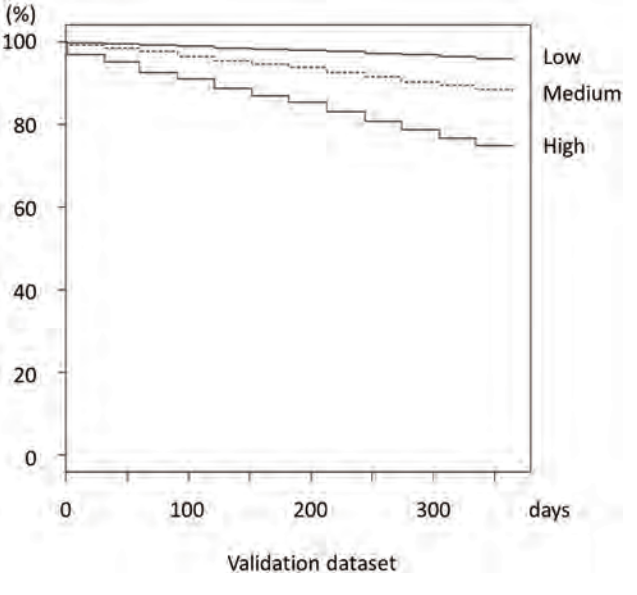
Eiichiro Kanda,[1] Akihiko Kato,[2] Ikuto Masakane,[3] Yoshihiko Kanno.[4] *[1]Kawasaki Medical School, Wakoshi, Japan; [2]Hamamatsu University Hospital, Hamamatsu, Japan; [3]Honcho-Yabuki Clinic, Yamagata, Japan; [4]Tokyo Medical University, Tokyo, Japan.*

Background: Because the criteria for protein energy wasting (PEW), which is a risk factor for death, are not necessarily appropriate for Asian hemodialysis patients, we developed a new nutritional risk index for one-year all-cause death of Japanese maintenance hemodialysis patients on the basis of the concept of PEW, and evaluated their prognosis.

Methods: We analyzed data from a nation-wide prospective cohort study of the Japanese Society for Dialysis Therapy Renal Data Registry to develop and validate a nutritional risk index (n=48349, 48349, respectively). The association of nutritional factors with one-year death was tested using Cox proportional hazards models. Their cutoff levels were determined from the hazard ratios or receiver operating characteristic curves. Then, risk index was developed using scoring models.

Results: Male was 61.5 %; average age, 65.7±12.2 years; and diabetes mellitus, 32.7 %. Four clinical factors were retained in the final model: low BMI (<20kg/m2), yes=3, no=0; low serum albumin level (young <3.5g/dL; old <3.7g/dL), yes=4, no=0; abnormal serum total cholesterol level, low (<130mg/dL)=1, high (220≥mg/dL)=2, no=0; low serum creatinine level (young female, <9.7mg/dL; old female, <8.0mg/dL; young male, <11.6mg/dL; old male, <9.7mg/dL), yes=4, no=0. In the validation dataset (n=48349), medium- and high-risk groups (total score 8 to 10; 11 or more) showed a higher risk of all-cause death than the low-risk group (0 to 7): medium-risk group (10.5%), hazard ratio adjusted for baseline characteristics 1.96 (95% confidence interval 1.77, 2.16); high-risk group (8.2%), 3.91 (3.57, 4.29) (Figure 1). The medium- and high-risk groups also showed a higher risk of cardiovascular disease- and infection-caused deaths than the low-risk group.

Conclusions: We developed a new nutritional risk index for hemodialysis patients, which may be useful for identifying patients with PEW at an increased risk of death for early treatment.



SA-PO1074

Segmentation Outperforms Classification to Enumerate Glomeruli in Whole Slide Renal Biopsy Images Using Deep Learning

Jonathan Street,[1] Rohit R. Chari,[1] Tiffany R. Bellomo,[1] Stephen M. Hewitt,[2] Peter S. Yuen,[1] Robert A. Star.[1] *[1]NIDDK/NIH, Bethesda, MD; [2]NCI/NIH, Bethesda, MD.*

Background: Accurate detection and counting of glomeruli in renal biopsies is used to assess biopsy adequacy, and for diagnosis (for example, the percentage of sclerotic glomeruli). Rosenberg et al. recently showed that standard, manual histopathology methods can under-count glomeruli by ~50% compared to more labor-intensive annotation methods. Deep learning has significantly advanced image analysis with previously impractical technologies, such as facial recognition, now possible. We have applied these advances to classification and segmentation of glomeruli. *Classification* separates small, overlapping *image tiles* into two classes [glomerulus vs. no glomerulus]. *Segmentation* separates *individual pixels* in an image into two classes [inside glomerulus vs outside glomerulus]. Segmentation is similar to masking or finding the border of a glomerulus.

Methods: Fifteen biopsy H&E stained sections were digitized with whole slide scanners (Aperio and Hamamatsu) for training and validation of the model. The outline of each glomerulus was annotated by two people using a custom application we developed. A network with 3 convolutional layers was used for classification and a 7 layer U-Net structure used for the harder problem of segmentation.

Results: The number of glomeruli per biopsy ranged from 1 to 72. Human annotators showed good agreement in the number and area of glomeruli (R^2 = 0.75 and 0.66, respectively). Classification reached an overall machine-human accuracy in cross-validation of 94% on a dataset with an equal number of positive and negative examples. However, classification on full biopsies (with more negative than positive areas) had a low precision (45%) with an overall F1 score (harmonic mean of precision and recall) of 51%. In contrast to classification, segmentation applied to entire biopsies identified glomeruli with zero false positives and an overall F1 score of 99%. Neither model's performance was altered by changes in stain intensity or the scanner used for imaging.

Conclusions: Glomeruli can be detected with high accuracy in renal biopsies using deep learning techniques; image segmentation worked better than image classification. These computational models can be leveraged to improve and automate enumeration of glomeruli, and can be adapted for classification of glomerular morphology.

Artificial Intelligence Can Classify Human Kidney Biopsy Images

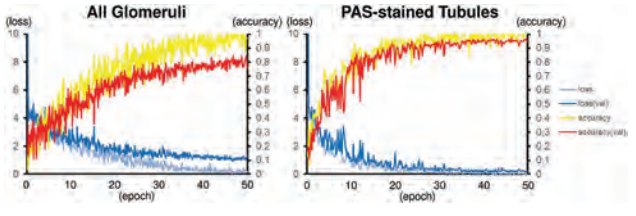
Ayumi Matsumoto, Isao Matsui, Karin Shimada, Nobuhiro Hashimoto, Yohei Doi, Satoshi Yamaguchi, Keiichi Kubota, Tatsufumi Oka, Yusuke Sakaguchi, Takayuki Hamano, Yoshitaka Isaka. *Osaka University Graduate School of Medicine, Suita, Japan.*

Background: Diagnosis based on kidney biopsy is a complicated decision process that includes some elements of uncertainty. Therefore, appropriate diagnoses require trained pathologists. If artificial intelligence could classify kidney biopsy images, it would be beneficial for appropriate and objective diagnosis for kidney diseases.

Methods: We obtained micrographs of PAS, PAM, or Elastica-Masson (EM)-stained human kidney biopsy samples using virtual slide system. Squared 13,017 images were manually cut out from the micrographs and then labelled into 87 (29 disease x 3 staining) categories based on diagnoses made by at least two nephrologists. We also obtained 7,177 squared tubulointerstitial images form PAS stained sections. Validation datasets were generated from the dataset by random selection. GoogLeNet, a convolutional neural network, was used to classify these images.

Results: GoogLeNet was well trained to classify glomerular images. The accuracy and loss of validation dataset were 0.7948 and 1.1301, respectively. To confirm that GoogLeNet really learned glomerular images, we prepared augmented dataset of 52,068 glomeruli which was prepared from original 13,017 squared glomerular images by 90°, 180°, and 270° rotations. We labelled these images according to disease categories and rotations. Learning of this negative control dataset yielded only 0.36866 of accuracy and 1.47506 of loss. We also examined whether GoogLeNet can classify glomerular diseases from tubulointerstitial images. Learning of PAS-stained tubular images yielded 0.9475 of accuracy and 0.2495 of loss.

Conclusions: GoogLeNet can classify glomerular diseases not only by glomerular images but also by tubulointerstitial images.



Light blue, deep blue, yellow, and red lines indicate loss of training data, loss of validation data, accuracy of training data, and accuracy of validation data, respectively.

SA-PO1076

Deep Learning for Segmentation of Glomeruli, Interstitial Fibrosis, and Tubular Atrophy in Renal Biopsies

Kuang-Yu Jen,[1] Brandon G. Ginley,[2] Brendon Lutnick,[2] John E. Tomaszewski,[3] Pinaki Sarder.[2] *[1]University of California, Davis, Sacramento, CA; [2]SUNY Buffalo, Buffalo, NY; [3]University at Buffalo, Buffalo, NY.*

Background: Evaluation of the renal biopsy typically involves assessment of the renal cortical compartments, which consist of glomeruli, tubules, interstitium, and vessels. Of particular importance is the degree of what has been considered "chronic" or irreversible injury in the form of glomerulosclerosis, interstitial fibrosis and tubular atrophy (IFTA). These features are the main indicators for renal prognosis, irrespective of the etiology of renal disease. However, evaluation for such features can be imprecise and variable between experts, especially for IFTA. We have tested a deep convolutional neural network (CNN) segmentation of IFTA and glomeruli from whole slide images (WSIs) in a limited dataset of diabetic nephropathy (DN) biopsies.

Methods: Seven biopsies of patients diagnosed with DN were used. One WSI from each patient was completely annotated for IFTA and glomeruli. A Python interface was designed to accept WSI annotations from Aperio ImageScope, train a deep CNN, and perform subsequent WSI predictions. The network selected was Deeplab V2, implemented in Tensorflow.

Results: In this first study, training and testing was performed on the same 7 biopsies, due to data limitations. The deep CNN achieved significant performance on 3 out of the 7 biopsies tested, for both IFTA and glomeruli. For these cases the network achieved specificity for segmenting both IFTA and glomeruli (see Fig. 1).

Conclusions: For the first time we have shown computational segmentation of IFTA and glomeruli from renal biopsies. The Deeplab V2 system demonstrates the capability for high performance in addition to generalization to other histological compartments with an increase in dataset size. Future work will increase the training cases and implement a validation set.

SA-PO1077

A Proposal of Modified Berden's Classification of ANCA-Associated Glomerulonephritis Focusing on a Proportion of Active Crescents for an Appropriate Treatment

Yayoi Ogawa,[1] Takahisa Kobayashi,[2] Daisuke Nagata,[2] Wako Yumura,[3] Kensuke Joh.[4] *[1]Hokkaido Renal Pathology Center, Sapporo, Japan; [2]Jichi Medical University, Shimotsuke, Japan; [3]Department of nephrology, International University of Health and Welfare Hospital, Nasushiobara, Japan; [4]Tohoku University Graduate School of Medicine, Sendai-city, Japan.*

Background: In 2010, Berden et al. proposed the histological classification of ANCA-associated glomerulonephritis and categorized sclerotic(S), focal(F), crescentic(C), and mixed (M) classes. The validation studies confirmed the best renal prognosis for F and the worst for S. However, the results of C and M were inconsistent. Therefore, we modified the Berden's classification by focusing on a pure proportion of active crescents in each C and M from a view point of a further choice of therapy and analyzed the correlation between these subclasses and renal prognosis.

Methods: The 35 patients with MPO-ANCA-associated glomerulonephritis (male 57%, 68±7.8 yrs), who were followed more than 5 years, were analyzed. E-GFR at entry was 23.7±21.7ml/min per 1.73m^2. In the modified classification, at the first step. S, F and C or M were categorized according to the Berden's original classification. At the second step, in the category of C or M, New Crescent class (NC) was categorized by active crescents with more than 50% after eliminating global sclerosis and the rest were categorized as New Mixed class (NM), because the global sclerosis in the category of C or M did not respond to the immunosuppressive therapy. In each category, cumulative risk of ESRD (0-5 yrs) and ΔeGFR or ΔCr (serum creatinine) (0-5 yrs) were evaluated

Results: F: C: M: S were 13:5:9:8 respectively, whereas F: NC: NM: S were 13:7:7:8 respectively. Cumulative risk of ESRD (0-5 yrs) showed that F and S revealed best and worst prognosis, respectively (log rank $p<0.05$). C and M were in the middle, and the prognoses of C and M were not significantly different. However, NC and NM showed significant difference for ΔeGFR (0-5 yrs) and ΔCr (0-5 yrs). A significant cut off point of

a percent of active crescent for ΔeGFR (0-5 yrs) was 50% but not 25% or 75%. Therefore, NC showed a significant better eGFR-improvement than that of NM ($p<0.05$) indicating a better response to immunosuppressive therapy.

Conclusions: A modified Berden's classification showed clear discrimination between NC and NM and can propose an appropriate rationale for a further choice of immunosuppressive therapy.

SA-PO1078

Utility of the Modified Berden's Histological Classification of ANCA Vasculitis for a Choice of Immunosuppressive Therapy

Takahisa Kobayashi,[1] Yayoi Ogawa,[2] Wako Yumura,[3] Kensuke Joh,[4] Daisuke Nagata.[1] *[1]Jichi Medical University, Shimotsuke, Japan; [2]Hokkaido Renal Pathology Center, Sapporo, Japan; [3]International University of Health and Welfare Hospital, Nasushiobara, Japan; [4]Tohoku University Graduate School of Medicine, Sendai-city, Japan.*

Background: For a rationale of the therapeutic choice for ANCA vasculitis, a quantitative assessment of the active crescents (AC) is indispensable. Since a newly proposed modified Berden's classification (Ogawa Y et al. 2018) focusses a ratio of remaining active crescents, we evaluated a utility of this classification for a choice of therapy by evaluating a correlation between this classification and the clinical profile.

Methods: The 35 patients (pts) with MPO-ANCA-associated glomerulonephritis (male 57%, 68.6 +-7.8 years old), who were followed more than 5 years were analyzed in the present retrospective study. All pts were treated according to the Japanese guideline (JSN 2011). In the modified classification, after classifying Sclerotic (S) Focal (F) and crescent (C) or mixed (M) classes with a cut-off point of 50%, New Crescent class (NC) was categorized by active crescents with more than 50% after eliminating global sclerosis and the rest was categorized as New Mixed class (NM) in the category of C or M. Clinical information including serum creatinine (sCr), eGFR and grade of hematuria (GH) at onset as well as at 5-years (yrs) after renal biopsy, and amelioration of sCr per day (ΔCr/day) were retrieved.

Results: Percent of AC correlated positively with GH ($r=0.337$, $p<0.05$), sCr ($r=0.474$,$p<0.01$), and negatively with eGFR at admission($r=-0.488$, $p<0.01$)and ΔCr/day($r=-0.420$, $p<0.05$). Moreover, 8 mL/min of eGFR was a cut off point for 5 year's renal prognosis, because 50% of the pts with eGFR more than 8 mL/min in the S showed ESRD, whereas no pts with eGFR more than 8mL/min developed ESRD in F, NC, and NM. On the other hand, 100%, 100%, 80%, and 50% of the pts with eGFR less than 8 mL/min developed ESRD in S, NM, NC, and F, respectively. ΔCr/day of the pts with NC(0.41 mg/dL/day) revealed significantly greater than that of pts with NM(0.05mg/dL/day). Cut off of the ΔCr to predict NC was ≧0.16 mg/dL/day.

Conclusions: A newly proposed modified Berden's classification together with 8 mL/min of eGFR and 0.16 mg/dL/day of ΔCr as cut-off points were useful to predict the renal outcome and a response of immunosuppressive therapy.

SA-PO1079

Differences in Renal Histopathology Between PR3-ANCA-Associated Vasculitis and MPO-ANCA-Associated Vasculitis

Maria Wester Trejo,[1] Emma Van Daalen,[11] Ron Wolterbeek,[12] Franco Ferrario,[2] Kensuke Joh,[3] Laure-Helene Noel,[13] Yayoi Ogawa,[4] Suzanne Wilhelmus,[14] Miriam J. Ball,[15] Eva Honsova,[16] Zdenka Hruskova,[5] Renate Kain,[6] Andreas Kronbichler,[17] Kristine Lindhard,[18] Xavier Puéchal,[7] Steven Salvatore,[19] Wladimir M. Szpirt,[8] Vladimir Tesar,[5] Jan A. Bruijn,[9] Ingeborg M. Bajema.[10] *[1]Pathology, Leiden University Medical Center, Leiden, Netherlands; [2]Nephropathology Center, San Gerardo Hospital, Monza, Italy; [3]Pathology, Tohoku University Graduate School of Medicine, Sendai, Japan; [4]Hokkaido Renal Pathology Center, Sapporo, Japan; [5]Nephrology, Charles University and General University Hospital, Prague, Czechia; [6]Clinical Institute of Pathology, Medical University of Vienna, Vienna, Austria; [7]National Referral Centre for Rare Systemic Autoimmune Diseases, Hôpital Cochin, Paris, France; [8]Nephrology, Rigshospitalet, Copenhagen, Denmark; [9]Pathology, Leiden University Medical Center, Leiden, Netherlands; [10]Pathology, Leiden University Medical Center, Leiden, Netherlands; [11]Pathology, Leiden University Medical Center, Leiden, Netherlands; [12]Medical Statistics and Bioinformatics, Leiden University Medical Center, Leiden, Netherlands; [13]Pathology, Necker Hospital, Paris, France; [14]Pathan, Rotterdam, Netherlands; [15]Pathology, Medical University of Vienna, Vienna, Austria; [16]Pathology, Institute for Clinical and Experimental Medicine, Prague, Czechia; [17]Internal Medicine IV, Medical University Innsbruck, Innsbruck, Austria; [18]Nephrology, Rigshospitalet, Copenhagen, Denmark; [19]Pathology, Weill Cornell Medical College, New York, NY.*

Background: Clinical and experimental data suggest a pathogenic role for antineutrophil cytoplasmic antibodies (ANCA) in ANCA-associated glomerulonephritis (AAGN), with possible differences between anti-myeloperoxidase (MPO)- and anti-proteinase 3 (PR3)-ANCA. The aim of this study was to investigate differences in histopathological profile between MPO- AAGN and PR3-AAGN. Additionally, the effect of ANCA serotype on long-term renal outcome was examined.

Methods: 135 patients from 10 centers worldwide (Europe, North-America, Asia) with AAGN who underwent a diagnostic renal biopsy between 1991 and 2011 were included. Biopsies were scored on a secured website. Data on demographics, renal outcome and diagnostic delay were collected retrospectively.

Results: 50 patients were positive for PR3-ANCA and 73 for MPO-ANCA; 12 patients were either double-positive or negative. At diagnosis, patients with MPO-AAGN were significantly older (64.5±12.0 years) than those with PR3-AAGN (57.4±12.8 years). Mean diagnostic delay did not differ between groups. MPO-ANCA-positive patients showed less focal class and more mixed class than PR3-ANCA-positive patients (P=0.04). MPO-AAGN biopsies showed significantly more interstitial fibrosis and tubular atrophy (IFTA) than PR3-AAGN biopsies (P=0.04). On immunofluorescence, MPO-AAGN showed less C3-positive staining than PR3-AAGN (P=0.02). We found no association between ANCA serotype and death, renal relapse or development of end-stage renal disease.

Conclusions: In this large, international, multicenter cohort, we found a different histopathological profile in MPO-AAGN compared to PR3-AAGN, characterized by a lower percentage of focal and higher percentage of mixed histopathological class, more IFTA and less C3 in MPO-AAGN. These findings could not be explained by differences in diagnostic delay between groups and therefore support a difference in pathogenesis between MPO- and PR3-AAGN.

Effect of Autoantibodies to Erythropoietin Receptor in Patients with Anti-Neutrophil Cytoplasmic Antibody-Associated Vasculitis

Akinori Hara,[2] Trang T. Tran,[1] Kiyoki Kitagawa,[3] Shinji Kitajima,[2] Tadashi Toyama,[2] Yasunori Iwata,[2] Norihiko Sakai,[2] Miho Shimizu,[2] Kengo Furuichi,[2] Takashi Wada.[2,1] *[1]Kanazawa University, KANAZAWA, Japan; [2]Division of Nephrology, Kanazawa University Hospital, Kanazawa, Japan; [3]Kanazawa Medical Center, Kanazawa, Japan.*

Background: To examine the effect of autoantibodies to the erythropoietin receptor (EPOR) in patients with anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV).

Methods: Sixty-three Japanese patients with AAV were enrolled in this study and followed for a median of 31 months. Sera from these patients were screened for anti-EPOR antibodies using enzyme-linked immunosorbent assays.

Results: The patients comprised 26 men and 37 women aged 67±14 years. Fifteen patients had developed end-stage renal disease (ESRD) during follow-up period. Anti-EPOR antibodies were detected in 7 patients (11%). Anti-EPOR antibodies were associated with increased Birmingham vasculitis activity score (BVAS), especially systemic and skin scores. In addition, anti-EPOR antibodies were positively correlated with systemic and skin scores of BVAS. Cox regression analysis revealed that male gender, proteinuria and estimated glomerular filtration rate at disease onset were significant risk factors for ESRD. Among 6 patients who were positive for the antibodies at baseline and had follow-up examination of their sera, the antibodies disappeared in 4 patients by 2 months after immunosuppressive treatment, while remained positive in the other 2, and one of these developed ESRD.

Conclusions: Anti-EPOR antibodies were associated with disease activity, especially systemic manifestations and skin lesions in patients with AAV.

SA-PO1081

Impact of Infiltrating Neutrophils' Phenotype on Disease Activity in Various Glomerulonephritis

Hidehito Kimura,[3] Akiko Mii,[1] Yusuke Arakawa,[1] Akira Shimizu,[2] Shuichi Tsuruoka.[1] *[1]Nippon Medical School, Tokyo, Japan; [2]Nippion Medical School, Tokyo, Japan; [3]Nippon medical school, Tokyo, Japan.*

Background: Activated neutrophils release neutrophil extracellular traps (NETs), resulting in cell death called NETosis. NETs formation has been reported to be involved in the onset of systemic lupus erythematosus and ANCA-related vasculitis (AAV). However, the precise mechanism remains unclear. Citrullination of histones is an essential step for NETs formation, and the presence of citrullinated histones in neutrophils may be involved in disease induction and activity. We investigated the association between infiltrating neutrophils with/without citrullinated histone and disease activity in various glomerulonephritis (GN).

Methods: We selected kidney biopsy samples of AAV, lupus nephritis (LN), Henoch schonlein purpura nephritis (HSPN), and acute post-streptococcal GN (APSGN)(n = 5, each), which presented proliferative GN with neutrophil infiltration in glomeruli and interstitium. To identify infiltrating neutrophils and citrullinated histones, we performed immunostaining for myeloperoxidase (MPO) and citrullinated histone H3 (CitH3), and assessed the frequency of citrullinated histone positive neutrophils in glomeruli and interstitium.

Results: Number of MPO+ neutrophils in glomeruli tends to be higher in APSGN, LN and HSPN than in AAV. In APSGN and HSPN, however, CitH3+ neutrophils were very few in their endocapillary proliferative lesions in glomeruli. In addition, a few MPO+ neutrophils and CitH3+ neutrophils infiltrated the interstitium. In LN and AAV, CitH3+ neutrophils were observed in necrotizing lesion and wire-loop lesion along glomerular capillaries. Moreover, in AAV, the frequency of CitH3+ neutrophils in both glomeruli and interstitium was significantly higher than the others and correlated with crescent formation.

Conclusions: CitH3 immunostaining was useful tool for identifying activated neutrophils. In addition, it was suggested that there was correlation disease activity of GN with the frequency of activated neutrophils.

SA-PO1082

Histopathologic Spectrum of Kidney Biopsies in Patients with Eosinophilia

Anam Tariq,[1] Marco Delsante,[2] Mohamed G. Atta,[1] Blaithin A. McMahon.[1] *[1]Johns Hopkins University School of Medicine, Baltimore, MD; [2]Johns Hopkins Pathology, Baltimore, MD.*

Background: Eosinophilia has been linked to diseases including interstitial nephritis (IN) and other autoimmune diseases in many case reports. However, no kidney biopsy series has examined the predictive role of peripheral eosinophilia and tissue eosinophilia within kidney biopsies in patient's with established kidney disease. This study evaluated a large series of kidney biopsies with known eosinophilia to better define the spectrum of kidney disease in this patient population.

Methods: A retrospective review of native and allotransplant kidney biopsies obtained from 1996 to 2018 identified 58 patients with eosinophilia (serum as a percentage of circulating leukocytes >4% on hematology). Patient characteristics, clinical and laboratory data were obtained. Standard processing of all biopsy specimens included light microscopy, immunofluorescence, and electron microscopy, focusing on the number of inflammatory markers including tissue eosinophils, number per high field (hpf), was performed.

Results: While IN was the most common primary diagnosis, other diagnoses include FSGS (17%), ANCA (14%), hypertensive arteriosclerosis (9%) (Table 1). Of the 58 patients, the most common indication for kidney biopsy was acute (51%), acute on chronic kidney failure (41%) and subnephrotic protrinuria (53%). In IN, mean eosinophilia was 13% and mean kidney tissue eosinophil number was 12 per hpf. In FSGS, mean eosinophilia was 14% and mean kidney tissue eosinophil number was higher at 18 per hpf. Outcomes show 17% of IN and 5% of FSGS patients progressed to ESRD.

Conclusions: Eosinophilia is seen in a spectrum of kidney diseases other than IN, such as FSGS and hypertensive arteriosclerosis. The role of eosinophilia in predicting major adverse kidney events requires further investigation.

Primary kidney biopsy findings in patients with peripheral Eosinophilia

Diagnosis	(n/N)
Interstitial nephritis (acute and chronic)	29/58
FSGS	10/58
ANCA	8/58
Hypertensive/arteriosclerosis	5/58
Diabetic nephropathy	4/58
Membranous glomerulopathy	2/58
IgG4 disease	1/58
Minimal change disease	1/58
AA amyloid	1/58
Thrombotic microangiopathy	1/58

SA-PO1083

Glomerular Staining and Serum Antibodies of THSD7A in Malignancy-Associated Membranous Nephropathy

Changming Zhang,[1] Ming-chao Zhang,[1] Da cheng Chen,[2] Qiang Ren,[1] Weiwei Xu,[1] Wei-song Qin,[1] Zhihong Liu.[1] *[1]National Clinical Research Center of Kidney Diseases, Jinling Hospital, Nanjing University School of Medicine, Nanjing, China; [2]National Clinical Research Center of Kidney Diseases, Jinling Hospital, Nanjing University School of Medicine, Nanjing, China, Nanjing, China.*

Background: Thrombospondin type 1 domain-containing 7A (THSD7A) is recently identified as the target antigen in patients with membranous nephropathy (MN). A notable phenomenon is the high rate of cancer (reported to be as high as 20%) in patients with THSD7A-associated MN. The prevalence of THSD7A in patients with malignancy-associated MN deserves further clarification.

Methods: Glomerular expression of THSD7A was examined by immunohistochemistry in 36 patients with malignancy-associated MN. Immunofluorescence assay was performed to investigate anti-THSD7A antibodies. Anti-PLA2R antibodies and glomerular PLA2R expression was also screened. THSD7A expression of cancer tissues was tested in 9 among the 36 patients.

Results: Among the 36 patients with malignancy-associated MN, 3 (8.3%) patients were identified as glomerular THSD7A staining positive: one patient was THSD7A positive alone, which accounted for 6.3% (one of 16) of PLA2R negative patients; two patients were dual-positive for both THSD7A and PLA2R staining. No anti-THSD7A antibody was detected among the 36 patients, whereas 18 of 36 (50%) had anti-PLA2R antibodies. Among the 9 patients who were available for cancer THSD7A staining, five (56%) patients showed enhanced expression of THSD7A localized in cancer tissue: one patient also had enhanced expression of THSD7A in glomeruli.

Conclusions: We found that positive glomerular THSD7A staining was uncommon in patiens with malignancy-associated MN.

SA-PO1084

The Size of Urinary Podocyte in Focal Segmental Glomerulosclerosis

Yoko Shirai,[1] Kenichiro Miura,[1] Takashi Yokoyama,[1] Shigeru Horita,[1] Takaya Iida,[1] Yohei Taniguchi,[1] Takeshi Nagasawa,[1] Hideki Ban,[1] Yoko Takagi,[1] Tomoo Yabuuchi,[1] Naoto Kaneko,[1] Kiyonobu Ishizuka,[1] Masanori Hara,[2] Motoshi Hattori.[1] *[1]Tokyo Women's Medical University, Tokyo, Japan; [2]Niigata Wellness (Iwamuro Health Promotion Center), Niigata, Japan.*

Background: Previous reports indicated that the number of urinary podocytes is higher in FSGS with nephrotic range of proteinuria than those in FSGS in remission and minimal change nephrotic syndrome (MCNS) in relapse. To date, the size of urinary podocyte has not been evaluated. In the present study, we examined the size of urinary podocyte in various glomerular diseases including FSGS in children.

Methods: Eight patients with FSGS (primary, n=6; genetic, n=2), 7 patients with MCNS in relapse and 10 patients with glomerulonephritis (GN) were included in the study. GN included IgAN (n=3), IgA vasculitis (n=4), ANCA-associated GN (n=1), lupus GN (n=1), and infection related GN (n=1). Patients with eGFR <60 ml/min/1.73m^2 were not included. Fresh urine samples of 10ml voided in the morning were obtained and urinary podocyte was detected by immunofluorescence using anti-human podocalyxin monoclonal antibody with a DAPI positive nucleus. The number of urinary podocytes was calculated per 10ml sample. Images of podocalyxin-positive cells were taken under an immunofluorescence microscope with 400-fold magnification and were quantified by image analysis. The size of urinary podocyte was defined as mean area of the podocytes in a field (pixel/cell). Statistical analyses were performed with Wilcoxon tests. Data are expressed as median (IQR). A *P* value of <0.05 was accepted as statistically significant.

Results: Urinary protein/creatinine ratios (UP/UC) were not significantly different among FSGS, MCNS and GN. The number of urinary podocytes (/10ml) in GN (200 (154.5-200)/10ml) was significantly higher than those in FSGS (81.5 (42.8-140.3)/10ml) and MCNS (68 (35-98)/10ml) (*P*=0.0225), while there was not a significant difference between FSGS and MCNS. Of note, the size of podocyte in FSGS (2947.9 (2571.4-3400.0) pixel/cell) was significantly larger than those in MCNS (1242.3 (756.0-2214.5) pixel/cell) and GN (859.4 (753.2-1079.3) pixel/cell) (*P*=0.0034).

Conclusions: This preliminary study suggested that the size of urinary podocyte may be a specific marker of FSGS.

SA-PO1085

Anticoagulants and the Kidney: 10 Years Later After Discovery of Warfarin Related Nephropathy

Sergey V. Brodsky,[1] Anjali A. Satoskar,[1] Brad H. Rovin,[1] Jessica Hemminger,[1,3] Margaret Ryan,[2] Lee A. Hebert,[4] Tibor Nadasdy.[1] *[1]The Ohio State University Wexner Medical Center, Columbus, OH; [2]Pathology, Mayo Clinic, Scottsdale, AZ; [3]Department of Pathology, Mount Carmel Health System, Columbus, OH; [4]Ohio State University Medical Center, Columbus, OH.*

Background: Ten years ago we associated acute kidney injury (AKI) and occlusive red blood cell (RBC) tubular casts with high international normalized ratio (INR) in a patient on warfarin therapy. We named this condition warfarin related nephropathy (WRN). Later, we and others demonstrated that WRN is a part of the broader syndrome, anticoagulant related nephropathy (ARN). Herein we provide our 9-year experience with ARN based on a single-center renal pathology laboratory data.

Methods: The renal pathology database at the Ohio State University Wexner Medical Center (OSUWMC) was searched for native kidney biopsies performed between January 1st 2009 and December 31st 2017 using keywords "kidney biopsy", "warfarin", "anticoagulant", "nephropathy". All identified cases were reviewed and those with kidney biopsy findings suggestive of ARN were included into this study.

Results: Among 8636 native kidney biopsies, there were 47 (0.54 %) patients in whom deterioration in the kidney function could not be explained by kidney biopsy findings alone if anticoagulation was not taken into the equation. There were 32 (68%) males and 15 (32%) females, 90% of the patients were Caucasian. The average age was 61.7 +/- 14 years. Thirty five (74%) were on warfarin therapy, five (11%) were on anti-platelet medications, six (13%) did not have records of anticoagulation therapy, but they had acute coagulopathy at the time of deterioration of kidney function and their biopsy findings suggested of ARN. In addition to acute tubular necrosis and RBC casts, these patients had underlying glomerular changes, but the severity of that glomerular disease was out of proportion to the number of RBC casts and/or hematuria in these patients. The most common was mild glomerular immune complex deposits without significant proliferative lesions (23 cases, 49%), followed by mild focal pauci-immune crescentic glomerulonephritis (7 cases, 15%), diabetic glomerulosclerosis (5 cases, 11%) and focal segmental glomerular sclerosis (FSGS, 5 cases, 11%).

Conclusions: ARN is an uncommon diagnosis in renal pathology practice, but it should be considered when there is a disproportion between the severity of glomerular changes and the number of RBC casts and/or hematuria in a kidney biopsy in patients on anticoagulant therapy or who presented with acute coagulopathy.

SA-PO1086

Congo Red Positive Fibrillary Glomerulonephritis

Maziar Riazy,[1] Nicole K. Andeen,[2] Charles E. Alpers,[3] Kelly D. Smith.[1] UW renal Pathology *[1]University of Washington, Seattle, WA; [2]Oregon Health & Science University, Portland, OR; [3]University of Washington Medical Center, Seattle, WA.*

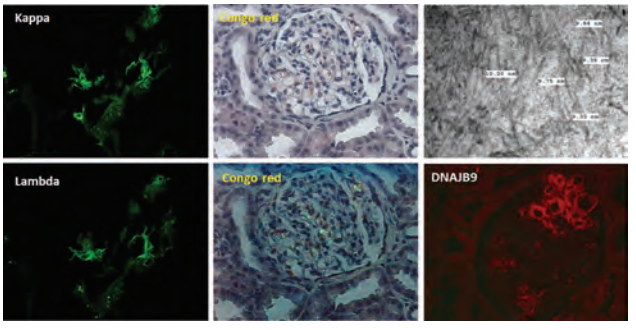
Background: Fibrillary glomerulonephritis (FGN) is characterized by the glomerular deposition of Congo red-negative fibrillary material with fibers that are larger in diameter than amyloid fibrils. With recent identification of DnaJ homolog subfamily B member 9 (DNAJB9) as a sensitive and specific marker for FGN, we sought to examine the specificity of these traditional diagnostic criteria used to distinguish FGN and amyloidosis.

Methods: The study population consisted of renal biopsies accessioned at the University of Washington, Seattle, USA from 01/01/2014 to 05/15/2018. We performed a database search of pathology reports for terms "fibrillary" and "atypical amyloid". Cases were included if all of the following: 1) glomerular and/or extra glomerular fibrillary deposits were present 2) Congo red stain was performed 3) FGN was diagnosed by conventional criteria and/or DNAJB9 was demonstrated in the deposits by liquid chromatography-tandem mass spectrometry (LC-MS/MS) and/or immunofluorescence.

Results: During the study period, 49 patients were diagnosed with FGN, of which 4 patients' biopsies had positive Congo red staining. The most prominent light microscopic findings were necrotizing and crescentic lesions (2 cases) and mesangial expansion with glomerular basement membrane thickening (2 cases). Immunofluorescence showed polytypic IgG staining in all 4 cases. The average fibrillary diameter ranged from 8.8-14.2 nm with two cases below the 12 nm diagnostic cut-off (figure).

Conclusions: Congo red positive staining and fibril diameter less than 12 nm should not be used as exclusion criteria for the diagnosis of FGN. The diagnosis of FGN should be considered in Congo red positive biopsies with findings that are atypical or inconclusive for amyloidosis, and LC-MS/MS and/or DNAJB9 immunostaining should be performed to confirm or exclude the diagnosis of FGN.

Funding: Clinical Revenue Support



The Congo red and immunofluorescence (light chains and DNAJB9) staining and the fibrillary organization of the deposits in one of the cases. LC-MS/MS of the Congo red positive glomerular deposits showed DNAJB9 but no amyloidogenic peptides.

SA-PO1087

Acute Transient Arteriopathy Mimicking Vascular Rejection in Allograft Kidneys

Maziar Riazy,[1] Carrie R. Minnelli,[1] Ryuji Ohashi,[4] Jolanta Kowalewska,[3] Nicolae Leca,[1] Behzad Najafian,[1] Roberto F. Nicosia,[5] Charles E. Alpers,[2] Shreeram Akilesh.[1] UW renal Pathology *[1]University of Washington, Seattle, WA; [2]University of Washington Medical Center, Seattle, WA; [3]Eastern Virginia Medical School, Norfolk, VA; [4]Nipppon Medical School, Tokyo, Japan; [5]VA Puget Sound HCS, Seattle, WA.*

Background: Early dysfunction of renal allografts raises the specter of acute rejection processes that require medical intervention vs. self-limiting peri-operative conditions for which conservative management is indicated. We sought to determine the clinical course in patients who present with delayed graft function and demonstrate a unique pattern of vascular injury that mimics rejection in their biopsy.

Methods: The study population consisted of renal allograft biopsies accessioned at the University of Washington, Seattle, USA from 1/1/2000 to 12/31/2017. We performed a database search of pathology reports for "transplant" and "arteriopathy" within one year following transplantation. Included cases showed a distinct arterial vasculopathy, characterized by endothelial cell swelling, lifting, and intimal edema in the absence of endotheliitis or rejection (Banff IA or higher). We also determined the clinical course of these patients on followup.

Results: We have identified 30 patients with arteriopathy but without rejection in the first year post-transplant. Of these, we have collected follow up on 14 patients to date (*remainder in process*). These patients (10 male, 4 female) were compliant with their immunosuppression and presented with delayed graft function soon after transplantation (median=13 days, range 7-139). Interlobular-sized arteries were most frequently affected. 11/14 patients received no intervention, while 3/14 received anti-thymocyte globulin (ATG), plasmapheresis or intravenous immunoglobulin (IVIg). 30 days post-transplantation, 11 patients were off dialysis and had a median serum creatinine of 1.85 mg/dL. 90 days after transplantation 13 patients were off dialysis with a median creatinine of 1.67 mg/dL (one patient lost the allograft due to suspected early infarction, indeterminate for vascular rejection).

Conclusions: Acute transient transplant arteriopathy is a rare vascular lesion that is associated with early graft dysfunction in the absence of rejection. Recognition of this lesion and distinguishing it from vascular rejection is important to prevent over-treatment since most patients appear to recover function rapidly without specific interventions.

An Epidemic of Serum Amyloid A Protein Amyloidosis Fueled by Injection Heroin Use Associated Infections in the Pacific Northwest

Kelly D. Smith,[1] Shreeram Akilesh,[1] Charles E. Alpers,[1] Behzad Najafian,[1] Roberto F. Nicosia.[2] *[1]University of Washington, Seattle, WA; [2]VA Puget Sound HCS, Seattle, WA.*

Background: Renal amyloidosis is an uncommon but problematic cause of proteinuria and nephrotic syndrome, which has very limited treatment options and usually leads to ESRD requiring renal replacement therapy. In this study, we assessed the incidence of different subtypes of amyloidosis over time in our patient population to better understand the etiology of renal amyloidosis.

Methods: We reviewed our kidney biopsy database from 1984 through 2017 to define the incidence of renal amyloidosis and the subtypes of amyloid contributing to this disease. Amyloidosis subtype was correlated with clinical data.

Results: We observed a dramatic increase in serum amyloid A (AA) protein-type amyloidosis (Fig. 1), beginning in 2000 and becoming in 2015 the most common renal amyloidosis subtype in our patient population. AA-type amyloidosis was associated with heroin injection associated infections (skin and deep muscle abscess, cellulitis and osteomyelitis) in over 90% of the cases. In a subset of patients (n=8) with extensive clinical data, renal biopsy was preceded by Initial documentation of injection drug use associated infections (4.0 -18 years) and proteinuria (1.0 -14 years), and renal failure or death occurred 0.45 – 2.7 years after biopsy.

Conclusions: Since 2000, there has been a dramatic increase in the incidence AA-type amyloidosis, which is attributed to injection drug use and its associated infectious complications. Longitudinal data suggest repeated injection drug use associted infections and asymptomatic proteinuria precede clinical presentation prompting biopsy by several years.

Funding: Clinical Revenue Support

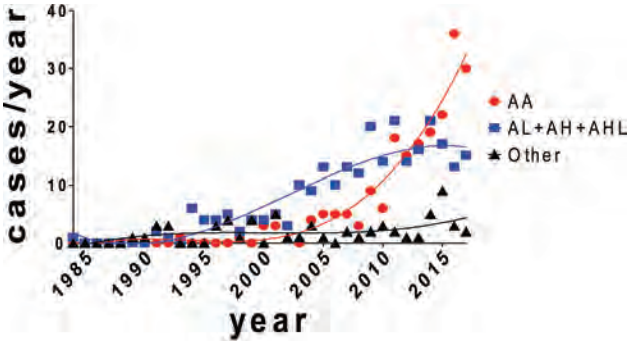

Figure 1. A surge in AA-type amyloidosis diagnosed in renal biopsies after 2000 in our institution. Shown are the number of cases diagnosed per year of AA-type (red), immunoglobulin-type (AL+AH+AHL, blue) and other type (undetermined, ALECT2, APOA4, ALys) amyloidosis. The lines represents represent non-linear third order polynomial fits to the data (r-squared values: AA = 0.94, AL+AH+AHL = 0..88, Other = 0.28).

SA-PO1089

Normal Serum Free Kappa-Lambda Light Chain Ratios in AL Amyloidosis - A Single Center Experience

Ari Seifter,[1] Arouna Senthilkumar,[1] Holly J. Kramer,[1,2] Kavitha Vellanki.[1,2] *[1]Loyola University Medical Center, Maywood, IL; [2]Medicine, Edward Hines VA Hospital, Hines, IL.*

Background: Quantification of serum free light chains (FLC) is reported to be highly sensitive for diagnosis of primary systemic amyloidosis, with reported sensitivities of 90-100%. Although tissue diagnosis remains the gold standard for establishing definitive diagnosis, normal FLC ratios are often interpreted clinically as effectively ruling out amyloidosis. The aim of this study is to examine if our experience is different from the reported literature.

Methods: All patients who had serum FLC quantification and bone marrow biopsy at Loyola University Medical Center between the years 2007-2017 were analyzed in a retrospective chart review. A total of 1,270 patients were identified and 51 had a confirmed diagnosis of AL-amyloidosis. A FLC ratio of 0.26-1.65 was considered normal, consistent with past studies. Reported p-values were determined using a chi-squared test.

Results: Of the 51 patients with tissue diagnosis of AL amyloidosis, 45% had localized disease (confined to one organ) while 55% had systemic disease (more than one organ involvement). Serum FLC ratios were normal in 33% of the cases (17/51). 43% with

localized disease had normal FLC ratios compared to 25% of patients with systemic disease (p=0.14) (Figure 1). 23 patients (45%) had renal involvement and 5 of the 23 had normal FLC ratios at presentation. Overall, 28/51 (55%) patients had a concomitant plasma cell dyscrasia confirmed on bone marrow biopsy. Patients with plasma cell dyscrasia were significantly less likely (14%) than those without a plasma cell dyscrasia (57%) to have a normal free light chain ratios (p=0.001) at presentation. Although patients with systemic disease were more likely to have an underlying plasma cell dyscrasia than those with localized disease, this result did not reach statistical significance (p=0.14).

Conclusions: When amyloidosis is clinically suspected, serum FLC quantification may be insufficient to rule out the diagnosis, leaving biopsy of affected organ(s) as the prevailing gold standard.

SA-PO1090

Importance of Adjusting the Normal Range of the k/L Free Light Chain Ratio According to the CKD Stage in Myeloma Patients

Luis F. Quintana,[1,2] Alícia Molina,[3] Ignacio Gacitua,[5] Elena Guillen,[3] Enrique Montagud,[4] Marc Xipell Font,[3] Esteban Poch.[3,2] *[1]Hospital Clinic de Barcelona. Fundacio Clinic per la Recerca Biomedica, Barcelona, Spain; [2]Medicine, Universidad de Barcelona, Barcelona, Spain; [3]Hospital Clinic, Barcelona, Spain; [4]Hospital Clínic, Barcelona, Spain; [5]University of Chile, Santiago, Chile.*

Background: The development of an effective laboratory test to quantify the concentration of free light chains (FLC) has optimized the diagnosis of multiple myeloma (MM). However, the metabolism of FLC depends to a large extent on renal function, which can lead to a misinterpretation of the results. The objective of this study was to determine the concentration of serum FLC in a group of MM patients and a group of healthy patients, and to establish the variation of the FLC ratio normal range and its diagnostic performance for MM in relation to the CKD stage.

Methods: The FLC ratio κ/λ in serum and GFR was analyzed retrospectively by CKD-EPI in 1469 consecutive patients between December 2014 and December 2017. Two groups were chosen: 1) healthyand complete remission MM patients,(n=174); 2) patients with a diagnosis of active MM (n=416). The reported normal range of the FLC ratio is 0.26-1.65. We excluded patients with a diagnosis of MGUS or other hematological diseases. ROC analysis were made for these groups depending on the GFR and the Sensitivity/Specificity value obtained for each subgroup was compared. The optimal cut-off was established based on the maximum value of Sensitivity/Specificity.

Results: A MM diagnosis based on the initial FLC normal range has a specificity of 96% in the group with GFR>90 (n=244) 79% in GFR 30-60 ml/min (n=87) and 43% in GFR<30 ml/min (N=45). The sensitivity and specificity of the FLC κ/λ ratio is maximum when we divide the patients in two groups (GFR < or > 55 ml/min) and apply an adjusted renal range (0.82 - 2.75):-for MM Kappa patients with GFR<55 ml/min, the initial Specificity/Sensibility of 87.7%/56.5% changed to 80.7%/95.6% while for MM Lambda patients with GFR<55 ml/min, the initialSpecificity/Sensitivity of 73.3%/100% changed to 96.7%/100%.

Conclusions: The FLC k/L ratio is a safe method for the study of selective proteinuria in MM in patients with normal renal function but, if we do not correct the FLC ratio as the GFR decreases, its specificity is reduced. The need for this correction is most likely due to the different clearance rates of the kappa and lambda FLC and how they change with GFR levels. Thus, it is necessary to take into account the GFR for its interpretation and validate this new renal range for CKD stage 4 and 5, in future studies.

SA-PO1091

Clinical and Pathological Analysis of Renal Light Chain Deposition Disease With or Without Cast Nephropathy

Dan Y. Li,[1] Gao X. Ying,[3] Su X. Wang.[2] *[1]Peking university first hospital, Beijing, China; [2]Laboratory of Electron Microscopy, Peking University First Hospital, Bejing, China; [3]Xining First People's Hospital, Xining, China.*

Background: To investigate the clinicopathological features of renal light chain deposition disease (LCDD) with or without cast nephropathy (LCDD & LCN).

Methods: The clinical features of the 55 cases of LCDD diagnosed by renal biopsy from January 2000 to March 2018 were retrospectively analyzed. The pathological sections were re-read and divided into two groups: isolated LCDD group (I-LCDD, 36 cases) and LCDD coexisted with cast nephropathy group (LCDD & LCN, 19 cases). The semi-quantitative evaluation of the main features of renal pathology include the degree of glomerular mesangial expansion, acute tubular injury, tubulointerstitial inflammatory cell infiltration, tubular atrophy with interstitial fibrosis, and renal arteriosclerosis.

Results: all LCDD patients (55 cases) had a mean age of 53.6 years with a male to female ratio of 2.7:1, and the average duration of the disease was 10.3 months. The multiple myeloma (MM) accounted for 31.58% in LCDD patients. The type of light chain is predominantly κ (κ: λ, 2.6:1). The incidence of hypertension, anemia, renal dysfunction, urine protein (≥3.5 g/24h) and microscopic hematuria in patients with LCDD were 43.6%, 80.4%, 82.1%, 54.5%, and 76.4%, respectively. The percentage of LCDD & LCN was 34.6% (19/55 cases). Compared with the I-LCDD group, the LCDD&LCN group had an acute onset (P=0.04), higher serum creatinine (P=0.000), lower hemoglobulin level (p=0.027). The composition of urine protein was mainly small-molecule protein in LCDD&LCN and albumin dominant urinary protien in I-LCDD respectively (P = 0.007, P = 0.021). The type of light chain was λ dominant (λ:κ=7:3) in LCDD&LCN (vs I-LCDD, λ:κ=3:11, p=0.035). The glomerulopathy varied from mild mesangial expansion to typical mesangial nodular sclerosis, and crescents were existed in 27.3% of LCDD patients. The frequency of typical mesangial nodular sclerosis was significant lower in LCDD&LCN patients (15.8% vs 58.2% in I-LCDD, p=0.01). There was no significant difference in tubulointerstitial lesions between the two groups.

Conclusions: One third of LCDD coexisted with cast nephropathy. The dominant λ light chain and less mesangial nodular sclerosis was the prominent features of LCDD&LCN compared with isolated LCDD, which suggested LCDD&LCN has a distinct pathogenesis from that of I-LCDD.

SA-PO1092

Paraneoplastic Cast Nephropathy Associated with Secretary Pancreatic Carcinoma

Edgard I. Wehbe,[1,2] Samar M. Said,[3] Samih H. Nasr.[3] *[1]Wichita Nephrology Group, Wichita, KS; [2]Internal Medicine, University of Kansas, Wichita, KS; [3]Mayo Clinic, Rochester, MN.*

Introduction: We report the case of a patient with pancreatic mixed acinar-neuroendocrine carcinoma who presented with irreversible acute kidney injury (AKI) due to myeloma-like cast nephropathy. We performed proteomic and immunohistochemical studies which revealed that the AKI was triggered by tubular obstruction by acinar cell carcinoma-secreted proteins. A novel pathomechanism for carcinoma-associated nephropathy is being described.

Case Description: A 64-year old male was found with a large abdominal mass after workup for unintentional 35 pound weight loss over 6 month period. Biopsy of the mass showed pancreatic mixed acinar-neuroendocrine carcinoma. He developped AKI after the diagnosis. Urinalysis showed 1 + protein but no hematuria. Serologies were negative. Serum protein electrophoresis with immunofixation did not show monoclonal protein and serum free kappa/lambda ratio was normal. Kidney biopsy showed myeloma-like cast nephropathy. He was initiated on hemodialysis and received rescue plasmapheresis without success in renal recovery. He received gemcitabine and Abraxane with no improvement in his condition. He remained on dialysis, had a decline in his clinical condition, developed severe refractory septic shock and died 4 months after cancer diagnosis.

Discussion: Kidney biopsy showed acute cast nephropathy with many distal tubular PAS-negative and trichrome-polychromatic casts, associated with mononuclear and giant cell reaction, acute tubular injury, and mild interstitial inflammation and fibrosis. Ultrastructurally, the casts were electron dense and some were admixed with fibrillar uromodulin casts. The casts did not stain for kappa or lambda on immunofluorescence. Analysis by laser microdissection/mass spectrometry and by immunohistochemistry detected large amounts of two acinar-cell specific proteins, REG 1α and CPA1, in the renal casts and the patient's pancreatic carcinoma cells. Thus, the acute kidney injury in this patient is likely due to distal tubular obstruction by aggregates of filtered carcinoma-secreted proteins and uromodulin, with subsequent tubular injury, interstitial inflammation and fibrosis, as has been proposed in myeloma cast nephropathy. This case describe a new mechanism for paraneoplastic cast nephropathy in the absence of multiple myeloma.

SA-PO1093

Beyond Morse: How Do Kidney Biopsy Registries Code Renal Disease? On Behalf of the Kidney Biopsy Codes (KBC) for Pathologists Project

Amélie Dendooven,[1,2] Mark J. Helbert,[5,1] Han Peetermans,[5] Tri Q. Nguyen,[4] Sabine Leh.[3] Kidney Biopsy Codes for Pathologists project *[1]University Hospital of Antwerp (UZA), Edegem, Belgium; [2]University of Antwerp, Antwerp, Belgium; [3]Haukeland University Hospital, Bergen, Norway; [4]UMC Utrecht, Utrecht, Netherlands; [5]Ziekenhuis Netwerk Antwerpen, Antwerpen, Belgium.*

Background: Data collected from kidney biopsy registries are used for quality control, research, teaching and health policy decisions. For analysis and comparison, unified pathology codes are a prerequisite. The KBC for pathologists project aims to provide a complete, structured set of terms and codes applicable to non-neoplastic kidney biopsies for use by nephropathologists or kidney biopsy registries. The first step is an inventory of existing coding practice.

Methods: A structured 10-question questionnaire was sent out to 12 national and regional kidney biopsy registries. Additional information was collected by a pubmed search, through web pages of registries and personal communication.

Results: The questionaire was returned by 11/12 registries; 7/10 use self-made codes, 2/10 ERA-EDTA codes and 1/10 an updated SNOMED version based on SNOMED II. One registry does not code, only lists diagnosis. Codes are compatible with SNOMED-CT

in 3/11 registries. Mean user satisfaction was 3.4 on a scale from 0 to 5. Self-made coding systems represented classifications with hierarchical structures and meaningful, easy to understand code numbers. Problems were: coding difficulties with clinically-based coding systems, problematic mapping of systems to one another, updates and maintenance lacking, difficulties in coding multiple diagnoses and missing codes, e.g. documentation of applied technology or diagnostic certainty.

Conclusions: The inventory phase of the KBC project has identified multiple challenges in coding kidney disease. Considering the current coding practice and future needs, a common system should be easy to understand, apply, maintain and update. It should contain specific pathology codes. Mapping to a reference terminology would be necessary for interoperability.

SA-PO1094

Accuracy of Nephrologist in Identifying Kidney Disorders Prior to Kidney Biopsy

Manasi Bapat,[1] Timothy C. Martin,[7] Siddhartha Kattamanchi,[2] Joji E. Tokita,[3] Shuchita Sharma,[1] Girish N. Nadkarni,[4] Steven G. Coca,[5] Swati Mehta,[6] Lili Chan.[1] *[1]Icahn School of Medicine, Mount Sinai Hospital, NY, New York, NY; [2]Mount Sinai Medical Center, New Rochelle, NY; [3]Mount Sinai School of Medicine, New York, NY; [4]Ichan School of Medicine, New York, NY; [5]Icahn School of Medicine at Mount Sinai, New York, NY; [6]Icahn school of medicine at Mount Sinai, Rensselaer, NY; [7]Albany Medical Center, Albany, NY.*

Background: New biomarkers have been developed for identification of kidney diseases; however the kidney biopsies remain the gold standard in diagnosis and management. Our aim was to determine the ability of nephrologist to accurately identify etiology of kidney dysfunction prior to a biopsy.

Methods: This is a retrospective cohort study of 251 patients who underwent a native kidney biopsy at Mount Sinai Hospital (MSH) and Albany Medical Center (AMC) from 2013 - 2017. Clinical indication and nephrologist diagnosis was determined by review of pre-biopsy provider notes while final diagnoses were determined by review of biopsy pathology reports.

Results: There were 251 patients who underwent kidney biopsy; mean age was 51 ± 16 years, 52% were male, 50% were inpatient, and 60% were done under ultrasound guidance. The most frequent indication for biopsy was non-nephrotic range proteinuria, 83 (33.2%) and acute kidney injury, 79 (32%). We were able to identify the nephrologist pre-biopsy diagnosis in only 93 patients. The most frequent diagnoses were diabetic nephropathy (20%), ANCA vasculitis (12%), and membranous nephropathy (8%). The post-biopsy diagnosis matched 45% of the time; the highest concordance was seen in diabetic nephropathy (32/39) and IgA nephropathy (10/11) while the lowest concordance seen in ANCA (6/21), FSGS (2/12), and minimal change (2/7). There was no consistent alternative diagnosis in the lowest concordance groups; patients who were biopsied with a presumptive diagnosis of ANCA were found to have diabetic nephropathy, HSP, and MPGN among others on pathology.

Conclusions: Nephrologists were able to accurately identify underlying etiologies nearly half the time in patients who were referred for biopsy. Given the relative safety of kidney biopsies, we should have a low threshold to refer patients for kidney biopsies.

SA-PO1095

Pre-Biopsy Lab Work and Decision Making

Orly F. Kohn, Rita L. McGill. *University of Chicago, Chicago, IL.*

Background: Labwork is often ordered prior to obtaining a kidney biopsy, to assess risk of bleeding and less often ordered afterwards. We sought to determine which factors influenced the decision to monitor hemoglobin (Hb) levels after biopsy.

Methods: All kidney biopsies performed on adult patients by the Nephrology service at the University of Chicago between September 2009-October 2015 were retrospectively assessed. Pre-biopsy Hb, INR, platelet count, and platelet function assays (PFA) were collected, and the nadir Hb level over the next 14 days was assessed, when available. Median values compared with Wilcoxon test, with P<0.01 due to multiple comparisons. A multinomial regression model was used to calculate odds ratios (OR) for post-biopsy outcomes of: a) Significant drop in Hb (defined as >1.5 grams), b) Lack of post-biopsy labwork, compared to a reference outcome of available post-biopsy Hb with no significant drop. Models adjusted for age, sex, and allograft vs. native organ, with single imputation of median values for missing pre-biopsy data.

Results: Among 905 kidney biopsies, 43.8% were native and 56.2% were allografts, 49.2% were women and the mean age was 47.5±15.2 years. Hb drop > 1.5 gm occurred in 11.7%, and post-Hb data was missing for 44.6%. Labwork by outcome and OR for each post-Hb outcome are shown in the tables. Female sex, higher pre-biopsy Hb and INR were positively associated with significant Hb drop, as were lower eGFR and platelet count. Omission of the post biopsy Hb was associated with increased age, female sex, higher pre-biopsy Hb, and negatively associated with higher INR. PFA did not contribute significantly for either outcome.

Conclusions: Post biopsy Hb was more likely to be checked for allograft biopsies and patients with elevated INR, but not for several other factors that had significant associations to the risk of bleeding. Platelet function assays did not appear to contribute to decision making or blood loss. Utilization of labwork before and after kidney biopsies deserves further study.

Kidney Injury Molecule-1 (KIM-1) Identifies Antemortem Injury in Fetal Postmortem Kidney

Wenqing Yin,[1] Ping L. Zhang,[2] Jacqueline K. Macknis,[3] Joseph V. Bonventre.[1] *[1]Brigham and Women's Hospital, Boston, MA; [2]William Beaumont Hospital, Royal Oak, Royal Oak, MI; [3]Beaumont Health, Royal Oak, MI.*

Background: KIM-1, a type I transmembranous protein, is a specific and stable protein marker for identifying injury in proximal tubules during acute kidney injury. There is currently no technique to unambiguously diagnose antemortem kidney injury on postmortem examination since postmortem tissue damage and autolysis are common. We hypothesized that KIM-1 could be very useful for detecting antemortem proximal tubular injury in autolyzed kidneys upon postmortem examination.

Methods: A total of 52 fetal/neonatal autopsy kidneys, from 30 stillborns and 22 liveborns, were assessed for KIM-1 staining. Kidney autolysis was evaluated by light microscopy and disappearance of CD133 expression. The autolysis was graded from 0 (no autolysis) to 3+ (entire loss of chromatin staining). Correlation between KIM-1 and autolysis scores was evaluated by linear regression analysis. Given that serum creatinine is unreliable in neonates, we assessed pre-terminal hypoxia in fetuses by the presence of squames in pulmonary alveoli and/or the need for intubation.

Results: The expression of KIM-1 was seen in a majority of the fetal and neonatal autopsy kidneys (77%, 40/52) as early as 16 weeks of gestation, even in the presence of autolysis. There was no significant correlation between KIM-1 scores and autolysis scores ($r = 0.201$ and $p = 0.1521$). There was a high correlation between KIM-1 expression and these clinical indices of hypoxia, either presence of aspirated amniotic fluid contents in stillborn or need for intubation in liveborn.

Conclusions: Our data suggest that KIM-1 is a specific and stable marker of antemortem tubular injury in fetuses, despite postmortem autolysis. A high correlation between KIM-1 expression and these clinical indices of hypoxia implies that KIM-1 may be a reliable marker to indicate the hypoxic state in pediatric autopsies.

SA-PO1097

Extensive Tubular Ectasia Indicating Occult Urological Obstruction in Renal Allografts

Marija Bojic,[1] Heinz Regele,[3] Christian Seitz,[3] Zeljko Kikic.[2] *[1]Medicine III/ Nephrology and Dialysis, Medical University of Vienna, Vienna, Austria; [2]Medical University Vienna, Vienna, Austria; [3]Medical University of Vienna, Vienna, Austria.*

Background: Urological obstructive complications (UOC) affect up to 10 % of kidney transplantation (KTX) cases. The majority of the cases may be excluded by routine ultrasound (US), however its accuracy may be limited in the early transplant setting. Renal allograft biopsy (BX) may be valuable, but histological features indicating UOC are ill defined. Experimental data suggest that extensive tubular ectasia (TE) may be indicative

of OUC. In our center, occult UOC is suspected when tubular ectasia (TE) occurs together with one or more of the following distinct features: acute tubular injury, tubular protein casts and tubular vacuolization. In this study we aimed to assess their accuracy for UOC.

Methods: We included 976 of 1537 consecutive KTX with an early indication BX. Relevant hydronephrosis (HN) was excluded by routine US. The bioptical finding of TE suspicious of UOC by the renal pathologist was compared to clinical endpoints as delayed graft function (DGF) and occurrence of UOC. Thereafter, all biopsies initially classified as suspicious for UOC were reevaluated by a single pathologist (H.R.) in order to increase accuracy of histomorphology suggestive of UOC.

Results: Fifty eight (5.9%) presented with TE indicative of UOC which was associated with a higher rate of DGF (40% vs. 29%; p=0.08) and was not related to long-term graft loss. Out of these, 23 (39.7%) had UOC, (most frequently ureteral stenosis) close to BX. To assess the relevance of TE as a marker of UOC without relevant HN, cases with TE were then subsequently compared to matched controls. Solely TE was significantly associated with an increased risk for UOC [OR 2.69 (IQR: 1.19 – 6.09); p = 0.018]. For histopathological reevaluation of the 58 cases, we defined extensive TE (>20% of the renal cortex). Subsequently, a score including additional histological criteria (tubular injury, tubular protein casts and tubular vacuolization) was developed: AUC 0.705, p=0.012. Using a threshold of 1.5, we observed 91% sensitivity, 37% specificity and a 84% negative predictive value.

Conclusions: Occult UOC may be identified in up to 40% of the cases by subtle histopathology including extensive TE together with additional signs of tubular injury. This phenotype should trigger more detailed evaluation for UOC when there is no evidence of relevant HN in the ultrasound.

SA-PO1098

Non-Lupus Immune-Complex Glomerulonephropathy (ICGN) After Kidney Transplantation: A Report of 9 Cases

Kuo-Kai Chin, Michelle M. O'Shaughnessy, Paul C. Grimm, Megan L. Troxell, Xingxing S. Cheng. *Stanford University School of Medicine, Stanford, CA.*

Background: ICGN with positive immunofluorescence (IF) for IgG, IgA, IgG, C3, and C1q has been termed "non-lupus full-house nephropathy (FHN)" in the absence of clinical or serologic features of systemic lupus erythematosus (SLE). We describe characteristics and outcomes of ICGN with IgG, C3, and C1q +/- IgM/IgA deposits in the kidney allograft.

Methods: We retrospectively reviewed a single-institution pathology database from 2007-2017 to identify cases of allograft ICGN with IgG, C3 and C1q in the absence of SLE. Clinicopathologic and outcome data were derived from patient records.

Results: Of 9 patients, most were non-white (89%), male (89%), and pediatric-adolescent (66%). None had ICGN as cause of ESRD. Median time from transplant to ICGN was 1.6 (range 0.5-5.2) years and 5/9 (56%) were identified on surveillance biopsy. Two of 7 patients had a positive donor-specific antibodies. By light microscopy, 7 cases had mesangial hypercellularity, and two had FSGS. At last follow-up (median 3.9 years, range 0.5-13.8), 7 of 9 patients (78%) had a stable serum creatinine with minimal proteinuria in 6. The remaining 2 patients had persistent allograft dysfunction. Four patients had subsequent biopsies with immunofluorescence: 3 (75%) showed persistent ICGN while 1 (25%) had resolution of immune complexes.

Conclusions: Post-transplant ICGN with IgG, C3 and C1q may be clinically silent and/or resolve spontaneously and in most cases appears to follow an indolent clinical course. Whether immune complex formation results from an auto- or allo-immune response remains to be elucidated.

SA-PO1099

Human Chorionic Gonadotropin (hCG) in Dialysis Patients

Natalja Haninger-Vacariu,[1] Harald Herkner,[2] Matthias Lorenz,[5] Marcus D. Saemann,[4] Andreas Vychytil,[1] Martin Jansen,[6] Rodrig Marculescu,[1] Reinhard Kramar,[3] Gere Sunder-Plassmann,[2] Alice Schmidt.[1] *[1]Medical University of Vienna, Vienna, Austria; [2]Medical University Vienna, Vienna, Austria; [3]Austrian Dialysis and Transplant Registry, Kematen, Austria; [4]Wilhelminen Hospital, Vienna, Austria; [5]Dialysis Centre Vienna, Vienna, Austria; [6]Hospital St. John of God, Vienna, Austria.*

Background: The FDA mandates pregnancy testing before and 8 days after initiation of therapy with MMF/MPA because its use in pregnancy is associated with an increased risk of miscarriage and congenital defects. However, a few case reports showed hCG to be elevated in transplant candidates resulting in refusal of transplantation.

Methods: We examined hCG serum concentrations in female dialysis patients, 18-50 years of age, and defined fertility status according to STRAW criteria. We classified hCG positive above a cut-off at 5 mIU/l. For an enhanced index test we classified hCG positive above a cut-off at 5 mIU/l for fertile patients and 14 mIU/l for non-fertile patients to calculate diagnostic test accuracy. We estimated the ideal cut-off for hCG using Liu's method with bootstrapped 95% CIs. We report estimates for hCG as a diagnostic test and predictors for elevated hCG using multivariable linear regression.

Results: Among 71 women two (2.8 %) were pregnant presenting with elevated hCG serum concentrations. We observed hCG concentrations greater than 5 mIU/ml, potentially indicating pregnancy, in 10 further patients. A hCG serum concentration > 5 mIU/ml had a sensitivity of 100% (95% CI: 100 to 100), a specificity of 86% (95% CI: 77 to 94), a positive predictive value (PPV) of 17% (95% CI: 8 to 25) and a negative predictive value (NPV) of 100% (95% CI: 100 to 100) for the diagnosis of pregnancy. Using a hCG cut-off of > 14 mIU/ml for non-fertile patients sensitivity and NPV did not change, the specificity increased to 93% (95% CI: 87 to 99) and the PPV was 29% (95% CI: 18 to 39). Excluding 23 non-fertile patients resulted in a specificity of 98% (95% CI: 94 to 100) and a PPV of 67% (95% CI: 53 to 80) whereas sensitivity and NPV did not change. The ideal hCG cut-off was 25.0 mIU/ml (95% CI: 17 to 33). Pregnancy (coefficient: 8.7; 95% CI: 6.6 to 10.7; p<0.001) and fertility (coefficient: -2.7; 95% CI: -3.5 to -1.8; p<0.001), but not age (coefficient -0.03; 95% CI: -0.08 to 0.01; p=0.13) were independent predictors of log transformed hCG.

Conclusions: hCG is elevated > 5 mIU/ml in 14,5% of non-pregnant dialysis patients of child-bearing age. In fertile women this cut-off can be used to exclude pregnancy. For our population the ideal hCG cut-off was 25 mIU/ml.

SA-PO1100

Post-Translational Modifications of Albumin Causes a Decreased Binding Capacity of Hydrophobic Metabolites

Vera Jankowski,[3] Heidi Noels,[2] Joachim Jankowski.[1] *[1]RWTH Aachen, Aachen, Germany; [2]RWTH University Aachen, Aachen, Germany; [3]University hospital RWTH Aachen, Aachen, Germany.*

Background: Since post-translational modifications of proteins may have an impact on the pathogenesis of diseases like atherosclerosis or chronic kidney disease (CKD), post-translational modifications are currently gaining increasing interest. In this study, a comprehensive method for analysis ofpost-translational modifications is established for the clinical diagnostic routine.

Methods: Here, we analysed albumin isolated from CKD patients and healthy controls by chromatographic steps and identified by mass-spectrometry. Post-translational modifications of albumin were identified after digestion by analysing mass-signal shifts of albumin peptides using pertinent mass-databases.

Results: Albumin isolated from plasma of CKD patients but not from healthy control subjects was specifically post-translationally modified by guanidylation of lysines at positions 249, 468, 548, 565 and 588. After identification of guanidylations as post-translational modifications of albumin isolated from CKD patients, these modifications were quantified by mass-spectrometry demonstrating a significant increase in the corresponding mass-signal intensities in CKD patients compared to healthy controls. The relative amount of guanidylation of lysine at position 468 in CKD patients was determined as 63 ± 32 % (N=3). *In-vitro* guanidylation of albumin from healthy control subjects caused a decreased binding capacity of albumin in a time-dependent manner. Binding of indoxyl sulfate (protein bound fraction) decreased from 82 ± 1 % of non post-translationally modified albumin to 56 ± 1 % after *in-vitro* guanidylation ($p < 0.01$) whereas the binding of tryptophan decreased from 20 to 4%. These results are in accordance with the binding of indoxyl sulfate to albumin from healthy control subjects and CKD patients (88 ± 3 vs. 74 ± 10, $p < 0.01$). Thus, *in-vitro* post-translational guanidylation of albumin had a direct effect on the binding capacity of hydrophobic metabolites like indoxyl sulfate and tryptophan.

Conclusions: We used a mass spectrometry-based method for the characterisation of post-translational modification and demonstrated the pathophysiological impact of a representative post-translational modification of plasma albumin. The data described in this study may help to elucidate the pathophysiological role of protein modifications.

SA-PO1101

Validation of a Modified Serum Ammonia Assay to Quantify Urine Ammonium in CKD

Valentinas Gruzdys,[2] Kenneth Cahoon,[4] Lauren N. Pearson,[3] Christopher Lehman,[2] Kalani L. Raphael.[1,2] *[1]VA Salt Lake City Health Care System, Salt Lake City, UT; [2]University of Utah, Salt Lake City, UT; [3]University of Utah & ARUP Laboratories, Salt Lake City, UT; [4]ARUP Laboratories, Salt Lake City, UT.*

Background: Low urine (u) NH_4^+ excretion is associated with higher risk of GFR decline in CKD. Few clinical laboratories measure uNH_4^+ limiting clinical application, and urine anion and osmolar gaps poorly estimate uNH_4^+ in CKD. We determined whether a clinically-approved serum NH_3 assay reliably quantifies uNH_4^+ in CKD.

Methods: uNH_4^+ was measured using the Randox (Ireland; glutamate dehydrogenase method) serum NH_3 assay on the Architect *ci*8200 chemistry analyzer. Preliminary studies found that 1:40 dilution of urine with Architect on-board diluent quantified uNH_4^+ within limits of the assay (20–1180 µmol/L). Precision studies were performed using synthetic urines with known [NH_4^+] (2.5, 15.6, and 29.5 mmol/L) over 20 days (n=80 measurements per synthetic urine). We then compared [uNH_4^+] obtained by the Randox assay and by formalin-titration in 22 CKD patients (n=58 samples) using Deming regression.

Results: Randox serum NH_3 assay total imprecision (%CV) with 1:40 dilution was 17.7%, 5.1%, and 2.2% in the 2.5, 15.6 and 29.5 mmol/L uNH_4^+ synthetic urines, respectively. In all 58 patient samples, 1:40 dilution quantified uNH_4^+ within the range of the Randox NH_3 assay. After accounting for the pH of formalin, the correlation between uNH_4^+ by formalin-titration and the modified Randox assay was 0.9778 with a regression slope of 1.01 and intercept of 0.70 mmol/L (Figure).

Conclusions: After 1:40 urine dilution, precision of the Randox serum NH_3 assay to quantify uNH_4^+ was better with higher uNH_4^+. Nevertheless, agreement between uNH_4^+ by this approach and by formalin-titration was excellent across a wide range of values in CKD. uNH_4^+ can be reliably quantified in CKD after 1:40 dilution using a standard plasma NH_3 assay and an automated chemistry analyzer.

Comparison of uNH_4^+ by the modified Randox serum NH_3 assay and formalin-titration

SA-PO1102

Validation of the Novel SOMAscan-Based Proteomic Platform in ESRD

Zhongji Han,[1] Zhousheng Xiao,[2] Leigh D. Quarles,[1] Csaba P. Kovesdy.[1] *[1]University of Tennessee Health Science Center, Memphis, TN; [2]The University of Tennessee Health Science Center, Memphis, TN.*

Background: End stage renal disease (ESRD) is characterized by complex metabolic abnormalities. The clinical relevance of many abnormalities in ESRD remains unclear due to the lack of clinically applicable and reproducible diagnostic tests to measure the full spectrum of abnormal proteins and metabolites seen in these patients. The development of multiplex diagnostic platforms is creating opportunities to develop novel diagnostic and therapeutic approaches in patients with ESRD. SOMAscan is a novel multiplex proteomic platform which can measure >1,300 circulating proteins, which, however, has not yet been validated in patients with ESRD. In the present study, we aimed to explore the reliability of SOMAscan for ESRD biomarker measurement.

Methods: We obtained plasma samples from 21 maintenance hemodialysis patients and applied the commercially available SOMAScan proteomic assay to simultaneously measure the concentrations of 1,372 proteins. We employed quality control assessments to remove the SOMAscan assay and sample bias and used Student's t tests to identify differentially expressed SOMAmer reagents. We compared concentrations of SOMAScan-measured prostate specific antigen (PSA) between males and females to test for the presence of biologically expected differences. We validated the SOMAScan concentrations of fibroblast growth factor 23 (FGF23), FGF receptor 1 (FGFR1), and FGFR4 using ELISA. We used Pearson correlation coefficients for correlation analysis and we performed principal component analysis.

Results: Patients were 57±14 years old, 52% were males and 48% were African American. All 21 samples passed the quality control assessments of SOMAscan assay. The mean (± standard deviation) SOMAScan PSA concentration was 4205.6 ± 2799.3 relative fluorescence units (RFU) in males vs. 1060.8 ± 1102.5 RFU in females ($p<0.01$), suggesting biological plausibility. Concentrations measured by SOMAscan correlated well with the ELISA results for FGF23 (R=0.970) and FGFR4 (R=0.507). No significant correlation was found between the FGFR1 SOMAscan and ELISA measurements (R=0.055).

Conclusions: There is a good albeit not perfect correlation between the SOMAscan assay and standard immunoassays. The SOMAscan technology may be useful for the measurement of circulating plasma proteins in ESRD.

A Vicious Cycle of Steroid Therapy, Hyperlipidemia, and Macrophage Activation in the Progression of Chronic Renal Lesions

Yohei Ikezumi,[1] Yuji Matsumoto,[1] Tomomi Kondo,[1] Hiroya Hasegawa,[2] Takeshi Yamada,[2] David J. Nikolic-Paterson.[3] *[1]Fujita Health University School of Medicine, Toyoake, Japan; [2]Niigata University Medical and Dental Hospital, Niigata-City, Japan; [3]Monash Medical Centre, Clayton, VIC, Australia.*

Background: We have previously reported that increasing numbers of LDL-scavenger receptor $(SR)^+$ macrophages (MQ) is a feature of refractory nephrotic syndrome (RNS) in hyperlipidemic patients treated with high-dose glucocorticoids. To investigate potential pathogenic mechanisms, we examined how glucocorticoids and hyperlipidemia alter the function of human MQ.

Methods: Normal human monocyte-derived MQ (huMQ) were incubated with dexamethasone (Dex), or oxidized LDL (oxLDL) or both, for 48 hours and then analysed by DNA microarray.

Results: Dex and/or ox-LDL stimulation induced up-regulation of scavenger receptors characteristic of M2-type MQ (CD163, CD204 and CD36). Dex and/or ox-LDL also induced up-regulation of cytokines and growth factors associated with inflammation and fibrosis (CCL2, CXCL13, NOS2, TGF-β1, FGF-1, FGF-2 and VEGF-D). In addition, a change in MQ metabolism is suggested altered expression of glucokinase regulator, aldose reductase and acetyl-CoA carboxylase. Immunohistochemistry revealed significant expression of FGF1 in biopsies from RNS patients with RNS which co-localized with $CD204^+$ MQ in areas of fibrosis.

Conclusions: Our data suggest that a vicious cycle of steroid therapy, hyperlipidemia, and M2-type MQ activation promote the progression of renal chronic lesions and treatment resistance.

Effects of Kidney Diseases on Platelet Activation

Naoki Ikegaya,[1] Takuya Yoshida,[3] Hiromichi Kumagai,[3] Tatsuo Yamamoto,[4] George Seki,[2] Akira Hishida.[2] *[1]Department of Medicine, Yaizu City Hospital, Yaizu, Japan; [2]Department of Nephrology, Yaizu City Hospital, Yaizu, Japan; [3]University of Shizuoka, Shizuoka, Japan; [4]Department of Nephrology, Fujieda City Hospital, Fujieda, Japan.*

Background: Platelet activation can lead to intravascular thrombosis formation. Immature platelets comprise the youngest component of circulating platelet pool and actively participate in thrombosis formation. Although patients with kidney diseases are at increased risk of altered coagulation of both thrombotic and bleeding, little data on the presence of immature platelets in kidney diseases are available. We investigated the relationship between renal function and immature platelets count (IPC) and evaluated effects of endothelial dysfunction, inflammation and thrombopoietin on IPC in patients with kidney diseases.

Methods: First, we measured IPC in patients with 235 chronic kidney diseases, 32 patients with acute kidney injury (AKI), and 75 patients with hemodialysis (HD). Immature platelets were measured with an automated hematoanalyzer that uses fluorescent dyes containing polymethine and oxazine. Second, we analyzed serum interleukin-6, thrombopoietin, and thrombomodulin in HD patients and evaluated the correlation between IPC and them.

Results: In patients with CKD, IPC had a tendency to decrease with the deterioration of renal function, but was not significantly correlated with eGFR (G1+2: n=69, 0.71±0.33, G3: n=83, 0.66±0.35, G4+5: n=83, 0.62±0.38×10^4 /µL). Patients with HD showed significantly lower IPC than patients with CKD (0.47±0.33×10^4 /µL, $p < 0.05$). On the other hand, patients with AKI showed significantly higher IPC than other groups at the peak of serum creatinine (0.99±0.76×10^4 /µL, $p < 0.05$). Among HD patients, patients with catheters showed significantly increased IPC compared to patients with fistulas (0.69 vs. 0.38×10^4 /µL, $p < 0.05$). Second, IPC was not correlated with thrombopoietin (r=-0.159) and IL-6 (r=0.223), but significantly related with thrombomodulin (r=0.359, P< 0.01) in HD patients.

Conclusions: HD patients showed decreased platelet activation compared to non-HD patients, suggesting that uremia might decrease the activation of platelets. In AKI patients, there was a transient platelet activation in the course of AKI. Microvascular endothelial dysfunction might cause platelet activation and intravascular thrombus formation.

SA-PO1105

Removal of sFLT-1 and PlGF with Plasmapheresis in Pregnancy

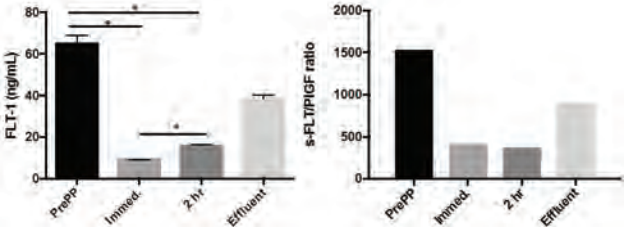
Milani Sivagnanam, Huiting Wei, Samia Q. Khan, Vineet Gupta, Mamoor S. Latef, Casey N. Gashti, William L. Whittier. *Rush University Medical Center, Chicago, IL.*

Background: Preeclampsia is characterized by HTN and proteinuria >20 weeks of gestation with glomerular endotheliosis thought to be due to an imbalance of angiogenesis (placental growth factor (PlGF) and soluble fms-like tyrosine kinase 1 (sFLT-1)). sFLT-1 levels are higher near the end of normal pregnancies; however, sFLT-1 levels increase earlier and to higher concentrations and inhibit PlGF in preeclampsia. Removal of sFLT-1 using selective apheresis in early preeclampsia prolongs time to delivery. The effect of membrane-based plasma exchange (mTPE) on sFLT-1 and PlGF levels are not known.

Methods: A 33 y/o 35 week pregnant patient presented with a concern for HELLP vs. TTP. Empiric daily mTPE sessions with FFP replacement were initiated until her ADAMTS13 returned at 42%. Her clinical status gradually improved after delivery of the placenta and a viable baby. Serum samples were obtained before, immediately following, and two hours after one mTPE session. We examined sFLT-1 and PlGF concentration of these samples as well as in the effluent in duplicate.

Results: sFLT-1 was immediately reduced by 86% with mTPE (64.94 ng/ml to 9.17 ng/mL, p=0.03) and rebounded to 15.88 ng/mL two hours after (p=0.02), 4 times less than pre-mTPE values. Effluent sFLT-1 was 38.46 ng/mL. PlGF was immediately reduced by 48% (42.40 pg/ml to 21.89 pg/ml, p=0.13) and rebounded to pre-mTPE values two hours after (42.7 pg/mL, p=0.07). Effluent PlGF level was 42.4 pg/ml. The reduction in the sFLT-1/PLGF ratio was 1.53 to 0.42 (73% reduction) (p<0.01) (Fig 1).

Conclusions: mTPE removed sFLT-1 from the serum at nearly a 4:1 ratio compared to PlGF in pregnancy, and PlGF rebounded to pre-mTPE values within two hours. This ratio reduction is theoretically favorable to improve the angiogenic imbalance in preeclampsia and suggests that mTPE may have a role as therapy for preeclampsia in the future.



Removal of sFLT-1 and sFLT-1/PlGF ratio in pregnancy with mTPE. *p<0.05

SA-PO1106

Sterile Pyuria Is Common in CKD and Differential Counting of Urinary Leukocytes Could Be Helpful for Predicting Urinary Tract Infection

Hye Min Choi,[1] Young Eun Kwon,[2] Dong-jin Oh.[3] *[1]Internal medicine, Myongji Hospital, Goyang-si, Republic of Korea; [2]Myoungji hospital, Goyang-si, Gyeonggi-do, seoul, Republic of Korea; [3]Myongji Hospital, Koyang, Republic of Korea.*

Background: Pyuria is a helpful marker for urinary tract infection (UTI) in general population. Meanwhile, pyuria is not infrequent in advanced chronic kidney disease (CKD) patients. There has been assumption that sterile pyuria can be seen in CKD due to chronic renal parenchymal inflammation. However, there are limited data on whether CKD increases the rate of pyuria or how we should interpret pyuria of CKD. Here, we aimed to investigate the prevalence and characteristics of pyruia of CKD.

Methods: This was a cross-sectional study of a single center. Urine analysis (UA) was performed in all the stable hemodialysis (HD) and non-dialysis CKD (eGFR < 60ml/min/1.73m^2) patients of the outpatient clinic during 3 month. Patients with urinary symptom or recent history of antibiotics were excluded. Pyuria was defined as white blood cell (WBC) ≥ 5/high power filed by microscopy. WBC differential counting was done in case UA showed pyuria. Culture-positive pyuria was defined as UTI.

Results: UA was examined in 70 HD patients who voids at least once every day and 228 non-dialysis CKD patients. The prevalence of pyuria was 51.4% (male (M) 36.1%, female (F) 67.6%) in HD and 22.4% (M 12.5%, F 39.3%) in CKD population, and were much higher compared to that of the age-matched general population (overall 7.3%, M 1.6%, F 19.1%) which was obtained from health examination in the same hospital (n=4897). Of the 86 patients with pyuria, only 22.1% were proven to be UTI (11.1% of HD and 30.0% of CKD). Female gender, lower stages of CKD, more leukocytes in urine, and positive nitrite-response were associated with true UTI in pyuric patients. As for differential counting, the majority of urinary leukocytes were still neutrophils even in sterile pyuria. However, the percentage of neutrophil was significantly lower (69.1% vs 92.5%), and the percentages of lymphocyte and monocyte were higher (18.5% vs 4.9% and 9.9% vs 2.1%, respectively) in sterile pyuria compared with UTI. In multivariate logistic regression analysis, the degree of pyuria, nitrite response, and the percentage of neutrophil remained independently associated with UTI in pyuric patients.

Conclusions: Pyuria is more common in CKD than in the general population. Differential cell counting of urinary leukocytes could be helpful for predicting UTI in asymptomatic CKD patients with pyuria.

SA-PO1107

New Urine Biomarkers for Site-Unique Injuries in the Kidney

Keiko Yamamoto,[1] Shigeru Miyazaki,[3] Tadashi Yamamoto.[1,2] Biofluid Biomarker Center *[1]Niigata University, Niigata, Japan; [2]Shinrakuen Hospital, Niigata, Japan; [3]Shinraku-en Hospital, Niigata, Japan.*

Background: In kidney diseases, various sites, such as glomerulus and other sites are injured to appear functional impairments and symptoms varied according to the injured sites and its degree. We aimed to develop urine examination to obtain the kidney site-unique injuries by proteomic biomarker discovery. To select kidney site-unique proteins as candidates of urine biomarkers for these site injuries, various parts of the kidney sections were analyzed by proteomics. To validate usefulness of the biomarker candidates, we established antibody-based assays for measurement of these biomarker candidates in urine and examined relationship between the urine excretion and the degree of kidney injuries. Finally we could select several urine biomarkers for injuries at various parts such as the glomerulus, proximal tubule and interstitium.

Methods: Sections of human kidney parts (glomerulus, proximal tubule, distal tubule, collecting duct etc) were laser micro-dissected from formalin-fixed paraffin-embedded kidney sections and peptides were collected from these sections of kidney parts by the on-site direct digestion method for mass spectrometry (Orbitrap Fusion, Thermo Scientific). The proteomes of these kidney parts were compared each other and also with those of plasma and urine proteomes to select proteins, which were uniquely excreted from each site or part of the kidney. We established immunoassay system by using a surface plasmon resonance (SPR) device (ProteOn, Bio-Rad). Several site-unique urine proteins selected by proteomics: PRA2R1 and GPRC5C for glomerulus-, NPR1 for proximal tubule- and GGT5 for interstitium-injury) were quantitatively measured in urine samples from CKD patients (IgA nephropathy and diabetic nephropathy) by SPR for validation.

Results: Concentrations of the proteins increased significantly in urine with the stage of CKD: PRA2R1 and GPRC5C excretion in urine presumed to reflect the degree of glomerular injury, NPR1 to predict the proximal tubule reactions and GGT5 the interstitial expansion, indicating that these new urine biomarkers are useful for evaluation of kidney injuries more precisely as or more than the kidney biopsies or evaluation of kidney injuries more precisely.

Conclusions: Non-invasive urine tests for the new biomarkers may be beneficial for clinical quantitative evaluation of kidney site-unique injuries for precision medicine in the near future.

Comparison of Urine and Plasma Biomarker Levels Measured by Aptamer-Based versus Immunoassay Methods in Cardiac Surgery Patients

Lidiya Kukova,[2] Sherry Mansour,[2] Steven G. Coca,[1] Heather Thiessen Philbrook,[2] Michael Shlipak,[3] Chirag R. Parikh.[4] *[1]Icahn School of Medicine at Mount Sinai, New York, NY; [2]Yale University, New Haven, CT; [3]San Francisco VA Medical Center, San Francisco, CA; [4]Yale University and VAMC, New Haven, CT.*

Background: Protein-detection assays are invaluable tools in biomarker discovery. However, only immunoassays are widely used, measuring 10-20 analytes per biosample. The novel aptamer-based assay uses nucleotide aptamer technology to measure over 1,300 analytes per biosample. We sought to compare the aptamer-based platform versus traditional immunoassay approaches to quantify analytes in paired samples before and after cardiac surgery.

Methods: In a sub-study of the TRIBE-AKI cohort, 54 individuals with acute kidney injury (AKI) after cardiac surgery were identified. The group included AKI progressors and AKI non-progressors. The levels of preoperative and postoperative plasma and urine biomarkers which had been previously evaluated via immunoassays were compared to the levels detected by an aptamer-based assay using Spearman correlations.

Results: Spearman correlations were estimated when at least 50% of biomarker values were within detectable ranges (plasma: preoperative 26/33, postoperative 31/33; urine: preoperative 13/16, postoperative 16/16). Twenty seven percent of reportable plasma preoperative biomarkers displayed correlations ≥0.75 between immunoassay and aptamer measurements, 23% displayed correlations of 0.50-0.75, and 50% displayed correlations <0.50. In urine these values were 15%, 39%, and 46%, respectively. Forty two percent of reportable plasma postoperative biomarkers displayed correlations ≥0.75, 16% displayed correlations 0.50-0.75, and 42% displayed correlations <0.50. In urine these values were 19%, 25%, and 56%, respectively.

Conclusions: The aptamer-based assay detects proteins with moderate to strong correlation to current immunoassay methods. The correlations in urine are weaker compared to plasma. Aptamer-based assay technology should be further validated in multiple settings as a high-throughput screening tool for biomarker discovery.

GFR Adjusted Uric Acid Levels Are a Superior Cardiovascular Outcome and Mortality Predictor Than Uric Acid Levels Alone

Eva Koenigshausen,[1] Johanna Rubel,[1] Winfried März,[3] Lars C. Rump,[1] Lorenz Sellin.[2] *[1]Medical Faculty Heinrich-Heine-University Düsseldorf, Düsseldorf, Germany; [2]Heinrich-Heine University Duesseldorf, Duesseldorf, Germany; [3]V. Medical Clinic, University Hospital, Mannheim, Germany.*

Background: Hyperuricemia is associated with increased cardiovascular risk and mortality. Chronic renal failure increases uric acid (UA) levels due to decreased filtration. A formula calculating GFR adjusted UA levels (estimated UA, eUA) has been developed by our group. The aim of this study was to evaluate the potential of eUA levels in predicting cardiovascular outcome and mortality in a cardiovascular risk cohort of patients.

Methods: The relation of GFR and UA levels was investigated with the eUA-formula in the LURIC cohort. LURIC was a prospective cohort study to identify genetic and metabolic risk factors in coronary heart disease. Patients were excluded with GFR levels <10ml/min and >100ml/min because of eUA-formula reasons. Subgroup analysis was performed (eUA < UA as risk group and eUA > UA as control group). Mortality, chronic heart failure (CHF) and cardiac events (CE) were documented outcome parameters. Binary univariate and multivariate logistic regression analysis were performed to study prediction of outcome variables by eUA or UA.

Results: 3316 patients were included in the LURIC cohort. Due to GFR, 652 patients were excluded. Of 2654 patients (1774 male) at an age of 64.71 ± 9.21 the GFR was 75.78 ± 16.98 ml/min. UA levels were measured with 5.24 ± 1.75 mg/dl. 686 patients (25.8%) died of all-cause mortality during the follow up period of the study. Mean UA levels in the subgroups did not differ. GFR was significantly lower in the risk group vs. the control group. Mortality and CHF NYHA > 1 were significantly higher in the risk group than in the control group (OR 1.35 and 1.65), while no differences were noted for CE. Univariate analysis revealed a significant benefit of using the eUA model compared to the classic UA model in predicting mortality (OR 1.8 vs. 1.23; -2LL 2874.32 vs. 2962.33) and CE (OR 1.54 vs. 1.16; -2LL 3231.37 vs. 3301.27). Multivariate regression analysis showed a significant better prediction of the outcome variables mortality (OR 6.06 vs. 1.25; -2LL 2187.17 vs. 2264.13), CHF (OR 2.96 vs. 1.65; -2LL 3160.43 vs. 3170.40) and CE (OR 2.35 vs. 1.48; -2LL 2445.85 vs. 2474.54) in the adjusted eUA-model compared to the UA-model group.

Conclusions: GFR adjusted uric acid (eUA) levels predict cardiovascular outcome significantly better in a cardiovascular risk cohort than uric acid levels alone.

The Automated Urinalysis in Proliferative Glomerulonephritis

Ragnar Palsson,[2] Anand Srivastava,[1] Sushrut S. Waikar.[2] *[1]Northwestern University Feinberg School of Medicine, Chicago, IL; [2]Harvard Medical School, Boston, MA.*

Background: Since the introduction of automated urine analyzers, manual examination of the urine sediment has rapidly fallen out of favor. Limited data are available on the test performance characteristics of the modern automated urinalysis (UA).

Methods: We studied whether features on an automated UA distinguish proliferative glomerulonephritis (PGN) from other forms of kidney disease using a prospective observational cohort of adult patients undergoing native kidney biopsies at 3 tertiary care hospitals in Boston, MA. We included individuals who had an automated UA within 30 days of kidney biopsy along with an adjudicated clinicopathologic diagnosis. We excluded individuals who were on immunosuppression at the time of the biopsy.

Results: 134 of 512 patients had PGN. The mean age was 53.9±15.9 years, 46.3% were female, and 68.6% were white. The mean estimated glomerular filtration rate was 53±34 mL/min/1.73m^2 and median proteinuria was 2.0 (interquartile range 0.63-4.97) g/g creatinine. **Table 1** shows the sensitivity and specificity of automated urine RBC counts for diagnosis of PGN at different levels of dipstick proteinuria. The automated urine RBC count identified PGN with an area under the receiver operating characteristic curve of 0.75. At a threshold of >2 RBCs per high-power field (HPF), the positive predictive value was 38% and the negative predictive value was 91% for PGN. Among those with ≤1+ proteinuria, the negative predictive value rose to 97%. RBC casts and dysmorphic RBCs were rarely reported (1 and 3 cases of PGN, respectively).

Conclusions: Hematuria and proteinuria from the automated UA had modest ability to differentiate PGN from other kidney diseases. The diagnostic performance characteristics of the manual sediment exam should be investigated and compared directly to those of the automated UA.

Funding: NIDDK Support

Table 1. Sensitivity and specificity of automated UA RBC counts and dipstick protein for diagnosis of PGN.

	RBCs ≥0/HPF (sensitivity/specificity)	RBCs >2/HPF (sensitivity/specificity)	RBCs >5/HPF (sensitivity/specificity)	RBCs >10/HPF (sensitivity/specificity)	RBCs >15/HPF (sensitivity/specificity)
Dipstick protein ≥ 0	100% / 0.0%	86.2% / 51.0%	77.1% / 61.9%	61.5% / 75.0%	51.4% / 80.8%
Dipstick protein ≥ Trace	94.7% / 14.7%	82.6% / 57.3%	73.4% / 68.0%	58.7% / 78.0%	48.6% / 82.9%
Dipstick protein ≥ 1+	85.7% / 24.3%	74.3% / 59.2%	67.0% / 69.3% %	52.3% / 78.6%	43.1% / 83.5%
Dipstick protein ≥ 2+	73.7% / 36.0%	64.2% / 65.1%	57.8% / 73.8%	45.0% / 82.2%	36.7% / 86.7%
Dipstick protein ≥ 3+	39.1% / 61.3%	35.8% / 77.4%	33.0% / 83.2%	25.7% / 89.0%	18.4% / 91.9%

Comparison of Different Methods of Urinary Protein Excretion Measurement–Is the King Really Dead?

Alicja Rydzewska-Rosolowska,[1] Katarzyna Kakareko,[1] Tomasz Hryszko,[2] Szymon Brzosko,[3] Beata Naumnik.[1] *[1]Medical University of Bialystok, BIALYSTOK, Poland; [2]II Department of Nephrology and Hypertension, Medical University of Bialystok, Bialystok, Poland; [3]DaVita Poland, Bialystok, Poland.*

Background: Assessing proteinuria is one of the most important diagnostic tests for a clinical nephrologist. When treating patients, it is often indispensable to accurately quantify the amount of protein lost, hence cumbersome timed urine collections (the gold standard or "king" of methods– 24h protein excretion rate- PER) are often replaced by spot urinary protein to creatinine ratio (PCR). The aim of the study was to determine whether the latter can reliably compare to the gold standard and whether "timing" of a spot urine sample is essential (as there is a diurnal and postural effect on protein excretion).

Methods: 143 adult patients hospitalized in the I Department of Nephrology with proteinuria (both primary and secondary glomerular diseases) were examined (a total of 187 cases). Subjects with an active infection or tumors of the urinary tract were excluded. Each patient was instructed how to perform a 24-hour urine collection and on the same day three consecutive urine samples were also collected (starting with the first morning void). Concentration of protein and creatinine in spot urine samples and the timed urine collection were measured.

Results: PCR from all three spot samples moderately correlated with 24h PER (0.76, 0.79 and 0.82 respectively). Log transformation of examined variables slightly improved observed association (0.80, 0.84 and 0.86). The sensitivity and specificity for proteinuria above 1.0 g/day were 0.79 and 0.73 for sample 1, 0.82 and 0.68 for sample 2 and 0.82 and 0.67 for sample 3. For nephrotic proteinuria it was respectively 0.62 and 0.94, 0.62 and 0.93, 0.66 and 0.92. Sex, age, weight and serum albumin concentration were significantly associated with 24h PER and were used for development of prediction equation yielding adjusted $R^2$of 0.78, 0.83 and 0.86. Bland-Altman analysis revealed an increasing difference between 24h PER and PCR with increasing proteinuria irrespectively of sampling time.

Conclusions: In patients with primary and secondary glomerular diseases spot urine protein to creatinine ratio only modestly correlates with daily proteinuria whether it's morning or random urine sample. It seems, while searching for new markers, nephrologists can just say: "long live the king".

SA-PO1112

Quantitation of Urinary Sediment Podocalyxin (u-sed-PCX) Predicts Urinary Podocyte Numbers

Masanori Hara,[1] Hiroyuki Kurosawa.[2] *[1]Niigata Wellness (Iwamuro Health Promotion Center), Niigata, Japan; [2]Denka Seiken Co., Ltd, Gosen, Japan.*

Background: Immunostaining of urine sediments shows a small number of podocytes and numerous cell debris resulting from the destruction of podocytes due to cell death, therefore, to know the exact number of urinary podocytes it needs to add a portion of cell debris to the number of podocytes evaluated as whole cells. In the present study we developed a procedure to count the exact podocyte numbers (podocytes + cell debris) in the sediments.

Methods: 1) Urinary sediment PCX was quantified by ELISA (Diabetologia 55:2913, 2012) in normal control and various glomerular diseases. 2) The idea to obtain the exact number of urine podocytes is based on the calculation of urine sediment PCX (reflecting whole podocytes + cell debris from destructed podocytes) divided by PCX content belonging to single podocyte. We named this number as estimated urine podocyte number (eUPN). 3) To obtain the PCX content belonging to single podocyte we caluculated from 3 models;

model 1 (assuming that it takes 150 years until complete podocyte loss from glomeruli in normal control), model 2 (evaluating podocyte loss during the interval in serial performed renal biopsies from our own patient with IgA nephropathy) and model 3 (evaluating podocyte loss from the published data in diabetic kidney disease (Diabetes 51;3083-3089, 2002). The mean value from 3 models was used in this study. 4) Several assumptive figures for normal control were used such as; urine volume:1000ml/day, Creatinine excretion:1 g/day, nephron number:$1.5x10^6$, podocyte number/glomerulus:500 cells.

Results: 1) Single podocyte PCX content was calculated as 141.6, 153.2 and 100.0 pg/podocyte by model 1, 2 and 3, respectively. The mean value (131.6 pg/podocyte) was taken for determining eUPN in this study. 2) U-sed-PCX and (eUPN) in normal control, DKD, IgAGN, Nephrotic syndrome, Lupus nephritis, membranous nephropathy, ANCA related GN, and others were1.9 ng/mg creatinine (14.7 podocytes/mg creatinine), 3.6 (27.3), 2.0 (15.0), 11.5 (87.0), 7.1 (54.3), 5.2 (39.1), 1.7 (13.1), and 1.8 (13.3), respectively. 3) U-sed-PCX and (eUPN) in diabetic kidney diseases (normoalbuminuric, microalbuminuric and macroalbuminuric) was 1.6 (11.8), 3.7 (27.9) and 8.8 (66.7), respectively.

Conclusions: Quantitation of u-sed-PCX predicts more exact urinary podocyte number (eUPN), indicating this might be a better podometric biomarker in clinical nephrology.

SA-PO1113

Genotyping Apolipoprotein L1 (ApoL1) from Dry Plasma with Proteomics

Christopher M. Shuford, Meghan N. Bradley, Patricia L. Holland, Michael Levandoski, Jennifer L. Ennis, John R. Asplin, Russell P. Grant. *Laboratory Corporation of America, Burlington, NC.*

Background: ApoL1 has two genetic risk variants (G1 & G2) associated with increased risk of nondiabetic CKD and kidney transplant failure. As these risk variants occur almost exclusively in African Americans, genetic testing may improve both monitoring and outcomes of CKD as well as allocation of donor organs in this population. To this end, we developed a bottom-up proteomic assay to identify genetic variants of ApoL1 from both liquid plasma samples collected by venipuncture as well as from dry plasma samples produced on a blood plasma separation device that can be collected in-home via a finger prick.

Methods: Both 20 μL of plasma or ~95 mm^2 punch of dried plasma were processed using a common workflow. Samples were denatured in DTT and deoxycholate for 30min at 56°C, then digested with 800μg of trypsin for 30min at 37°C (pH 8) after addition of labeled internal standards. Digestion was quenched and the deoxycholate precipitated by the addition of formic acid and the clarified supernatant analyzed by liquid chromatography coupled with tandem mass spectrometry. The three ApoL1 protein variants (WT, G1, G2) were uniquely detected by monitoring for the specific surrogate peptides containing the point mutations, which were produced by the trypsin digestion. Two surrogate peptides common among all protein variants were also monitored for quality control of sample processing.

Results: Reproducibility of the proteomic assay was demonstrated over 20 assay runs by analysis of dry and liquid specimens from 3 heterozygous individuals (WT/G1, WT/G2, and G1/G2). Dry plasma from the same heterozygous genotypes were observed to be stable for up to 4 weeks stored at ambient (22°C) and elevated temperature (37°C). Finally, perfect agreement with a Sanger Sequencing assay was observed in matched liquid and dry plasma specimens in a cohort of 209 African American donors, which consisted of 82 WT/WT, 64 WT/G1, 38 WT/G2, 10 G1/G1, 10 G1/G2, and 5 G2/G2 individuals.

Conclusions: This proteomic assay provides the feasibility for ApoL1 genotyping using dry plasma which can be collected in-home via finger prick using blood plasma separation devices. Such testing should allow for more widespread and cost-effective genotyping of this high risk population.

Macrophages as a Marker for Endocapillary Hypercellularity in Lupus Nephritis

Elisabeth M. Bos,[1] Suzanne Wilhelmus,[1] Ron Wolterbeek,[5] Natasha Jordan,[2] David D'Cruz,[7] David Isenberg,[3] H. Terence Cook,[6] Jan A. Bruijn,[4] Ingeborg M. Bajema.[5] *[1]Pathan, Rotterdam, Netherlands; [2]Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; [3]University College London, London, United Kingdom; [4]Leiden University Medical Center, Dept.Pathology, Leiden, Netherlands; [5]Leiden University Medical Centre, Leiden, Netherlands; [6]Imperial College of London, London, United Kingdom; [7]Guy's and St. Thomas' Hospitals NHS Foundation Trust, London, United Kingdom.*

Background: Lupus Nephritis (LN) is a manifestation of Systemic Lupus Erythematosus (SLE) which occurs in up to 60% of patients suffering from SLE. LN is strongly related to mortality and morbidity in SLE, especially class III and IV LN. The interobserver agreement of endocapillary hypercellularity which determines whether a biopsy is classified as class III or IV in LN, has been found to be moderate. In IgAN, the presence of glomerular macrophages was put forward as a surrogate marker for endocapillary hypercellularity. We investigated whether in LN, the presence of glomerular macrophages could serve as a surrogate marker for endocapillary hypercellularity as well.

Methods: 99 lupus nephritis biopsies were scored for the number of endo- and extracapillary macrophages per glomerulus using CD68 staining, as well as the overall presence of endocapillary hypercellularity (categorical variable *E0/E1*) and percentage of glomeruli with endocapillary hypercellularity (continuous variable *E-continuous*) per biopsy using a silver staining. Overall presence of endocapillary hypercellularity and percentage of glomeruli with endocapillary hypercellularity were both correlated with endo- and extracapillary macrophage count using a Mann-Whitney U test and a Spearman correlation test.

Results: A strong correlation was found between the quantity of glomerular macrophages and the presence of hypercelullarity, as well as between the percentage of glomeruli with endocapillary hypercellularity and number of glomerular macrophages. The correlation was stronger using only endocapillary macrophages in our analysis compared to extracapillary macrophages.

Conclusions: In lupus nephritis, the presence of glomerular macrophages is an excellent surrogate marker for endocapillary hypercellularity. This marker could be a useful tool towards a more effective and reproducible usage of the LN classification.

	E1/E0	E continuous	
	p	p	rho
Total glomerular Macrophages	<,001	<,001	0,780
Endocapillary Macrophages	<,001	<,001	0,764
Extracapillary Macrophages	<,001	<,001	0,566

SA-PO1115

The Japanese Histological Grade Classification and the Oxford Classification of IgA Nephropathy Show the Same Prediction Performance on Renal Functional Decline in 905 Japanese Patients

Kensuke Joh,[1] Akinori Hashiguchi,[2] Akira Shimizu,[3] Satoshi Hisano,[4] Ritsuko Katafuchi,[5] Tetsuya Kawamura.[6] *[1]Tohoku University Graduate School of Medicine, Sendai-city, Japan; [2]Keio University School of Medicine, Tokyo, Japan; [3]Nippon Medical School, Tokyo, Japan; [4]University of Occupational and Environment Health, Kitakyushu, Japan; [5]National Fukuoka-Higashi Medical Center, Koga, Fukuoka, Japan; [6]Jikei University School of Medicine, Division of Kidney and Hypertension, Tokyo, Japan.*

Background: The Japanese Histological Grade Classification (JHGC) (Gr1-Gr4) was established as a lumped system corresponding to <25%, 25-49%, 50-74% and ≥75% of total glomeruli exhibiting active crescents (C), global sclerosis (G), segmental sclerosis (S), or fibrous crescents. In contrast, the Oxford classification is a split system constituting of dichotomized M, E, S, T1, T2, C1, and C2. The purpose was to compare the 2 classifications systems focusing on their ability to predict renal functional decline.

Methods: The 905 Japanese patients (pts) with IgA nephropathy (male : 49%, median age: 38 yrs) were prospectively followed for a median of 48 months. The average amount of proteinuria (PU) was 1.07 g/day. Mean eGFR and median rate of decline in eGFR were 77.0 ml/min/1.73m^2 and -0.95 ml/min/1.73m^2/y, respectively. The prediction performance was compared using the Harrell's C statistic (HCS). The clinical and therapeutic variables were additionally collected including initial PU, initial square root eGFR (SReGFR), initial mean arterial pressure, steroid therapy (ST), RAS blockade (RASB) and tonsillectomy (TON).

Results: 66 %, 54% and 42% of the patients were treated by ST, RASB, and TON, respectively. In stepwise Cox regression analysis for the full model, Gr4, Gr3, Gr2, PU, SReGFR, TON and ST for 1.5 time's increase of serum creatinine (sCr) were selected as independent predictors, whose HR were 28, 7, 4, 2, 1, 1 and 0, respectively. HCS was 0.87. In Oxford, T2, T1, M, RASB, C1, PU, TON, SReGFR, ST and E were selected, whose HR were 4, 3, 2, 2, 2, 2, 1, 1, and 0, respectively, HCS was 0.86, which was statistically not different from that of JHGC. For the limited model without clinical and therapeutic parameters, Gr4, Gr3, and Gr2 were selected, whose HR was 79, 14, and 5, respectively. HCS was 0.82. In Oxford, T2, T1, M, and E but not S, C1, and C2 were selected, whose HR were 20, 5, 3, and 1, respectively. HCS was 0.81.

Conclusions: Both the lumped system of JHGC and the split system of Oxford showed the same high prediction performance on renal functional decline in full and limited model. However, a flexibility in a lumped approach of JHGC as opposed to a split system of Oxford may be more robust when being applied to diverse cohorts.

PUB001

Renal Transplant Function After Coronary Angiography with Iodinated Contrast

Jennifer S. Lees,[1,2] Mark D. Findlay,[2] Patrick B. Mark,[3] Colin C. Geddes.[2] *[1]Institute of Cardiovascular and Medical Sciences, University of Glasgow, Glasgow, United Kingdom; [2]Glasgow Renal and Transplant Unit, NHS Greater Glasgow and Clyde, Glasgow, United Kingdom; [3]University of Glasgow, Glasgow, United Kingdom.*

Background: There is perceived risk to renal transplant function in administering iodinated contrast agents. There may be reluctance to perform coronary angiography in kidney transplant patients, despite an increased risk of cardiovascular disease compared with the general population. We sought to determine if renal transplant function was adversely affected within 30 days of coronary angiography.

Methods: Prevalent renal transplant patients undergoing coronary angiography in a single centre (01/2006 – 02/2018) were identified. Biochemical and demographic data were extracted from the electronic patient record. The most recent serum creatinine (SCr) prior to angiography (or average value over 3 months) was considered the baseline. Highest SCr within 7 days and within 30 days (or next available) of coronary angiography were extracted. Rise in creatinine >26 micromol /l was considered significant (equivalent to Acute Kidney Injury (AKI) Network criteria stage 1 AKI).

Results: There were 127 coronary angiographies conducted in 89 patients: 67.4% were male and mean age was 58.0 ± 10.1 years. Median time since transplant was 6.2 years (IQR 2.5 – 16.1); median time since start of first renal replacement therapy was 13.4 years (IQR 6.8 – 25.0). Median baseline SCr was 155 micromol/l (IQR 110-220, range 56-738). The most common indications for coronary angiography were angina (27.6%) and non-ST

elevation myocardial infarction (23.6%). Diagnostic angiography was conducted in 59.1%; balloon angioplasty or stenting in 40.9%. There was a significant rise in SCr within 7 days in 24.5% cases (n=24/98; median rise 52, range 28-163 micromol /l). SCr returned to baseline within 7 days or there was an alternative explanation for rise in SCr in 20/24 cases. In 4 cases with a clinically significant rise in SCr, there was known severe and progressive renal transplant dysfunction. Of those with no available SCr within 7 days (n=29/127), none had a persistent rise in SCr (7-30 days/next available). In the absence of critical illness at time of coronary angiography, no patient required dialysis or extended hospital stay for contrast-associated AKI.

Conclusions: In this cohort of renal transplant recipients undergoing coronary angiography, there was a clinically significant rise in SCr in a minority of cases. Renal transplant should not be regarded as a contra-indication to coronary angiography.

Community Acquired AKI in Mansoura Nephrology Dialysis Unit, One Year Prospective Observational Study

Mostafa A. Abdelkhalek,[1] Sherouk S. Elnagar,[2] Ashraf Hassan,[2] Mona M. Tawfik,[3] Nagy A. Sayed-Ahmed.[4] *[1]Internal medicine, Hemodialysis and nephrology unit, Mansoura University, Faculty of Medicine, Mansoura, Egypt; [2]Internal medicine, Mansoura University, Faculty of Medicine, Mansoura, Egypt; [3]Internal medicine, Hemodialysis and nephrology unit, Mansoura University, Faculty of Medicine, Mansoura, Egypt; [4]Internal medicine, Hemodialysis and nephrology unit, Mansoura University, Faculty of Medicine, Mansoura, Egypt*.

Background: Acute kidney injury (AKI) is a major health problem with poor patient prognosis. We evaluated the clinical characteristics, risk factors, associated comorbidities and outcomes of AKI patients

Methods: A single center prospective observational study. The patients were admitted in Nephrology and Dialysis Unit in Mansoura University Hospitals over one year from January, 2016 to December, 2016. These patients were diagnosed to have AKI or AKI on top of CKD according to the KDIGO 2013 criteria. All patients were subjected to complete history taking, physical examination and full laboratory investigations

Results: We evaluated 199 (96 males plus 103 females) aged between 18 to 88 years old. Dehydration was the commonest precipitating factor for AKI in our patients (68.8%) and Oliguria was the commonest symptom present in 47.7 % of patients. 65.8 % of patients received intravenous fluids, 22.6 % of patients received diuretics and 33.7 % received renal replacement therapy in the form of intermittent haemodialysis while twenty five patients (13.16%) died and 44 patients showed no recovery

Conclusions: community acquired AKI (secondary mainly to dehydration and infections) is a major health problem with high morbidity and mortality

Urinary Urea Excretion as an Early Biomarker of AKI

David G. Morais, Gabriel A. Maranhão, Mirela Santinho, Victor F. Seabra, Leandro U. Taniguchi, Lucia Andrade, Camila E. Rodrigues. *University of Sao Paulo School of Medicine, Sao Paulo, Brazil*.

Background: Acute kidney injury (AKI) increases intensive care unit (ICU) morbidity and mortality, the diagnosis being based on urine output (UO) and serum creatinine (sCr), neither of which provides reliable, timely information. Most of the known AKI biomarkers are costly to determine and not widely used. Urinary concentration is impaired early in chronic kidney disease, and higher excretion of urea may be a marker of renal recovery for hemodialysis weaning. We hypothesized that low fractional excretion of urea (FeU) would be a timely biomarker of AKI.

Methods: We evaluated adult ICU patients at high risk for AKI according to a clinical score. We excluded patients with a basal estimated glomerular filtration rate (eGFR) <45ml/min/1.73m^2, history of AKI or kidney transplantation, or body mass index <19kg/m^2. On a daily basis, we evaluated urinary urea (UU), 6h-excreted urinary urea volume (UUv), FeU, and the UU/urinary creatinine (UU/Ucr) ratio. AKI was diagnosed on the basis of the KDIGO criteria (i.e., sCr or UO). Results are mean±SD.

Results: At baseline, the 17 patients included were 54±15 years of age, with a SAPS3 of 50.6±11.9, sCr of 0.72±0.30mg/dl, and eGFR of 106±30ml/min/1.73m^2. One day before AKI diagnosis (D–1), FeU was lower in the patients with AKI (n=5) than in those without (Table 1), with an area under the receiver operating characteristic curve of 0.88 (Figure 1). An FeU cut-off ≤22.75 had 80% sensitivity and 81.8% specificity for next-day AKI development.

Conclusions: FeU may be a feasible, accessible early biomarker of AKI. Supported by FAPESP.

Risk Factors of Postoperative AKI in Patients with CKD

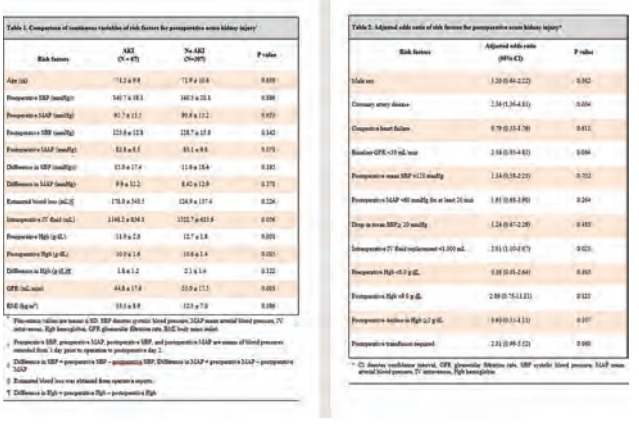
Seolhyun Lee,[1] Bhuwan Kayastha,[1] Si-Nae Kim,[2] Kaylee A. Carr,[2] Rachel Y. Kim,[2] Genevieve Birang,[2] Ella F. Kuchmiy,[2] Yuriy Golub,[2] Woo hyun Lee.[3] *[1]MultiCare Good Samaritan Hospital, Puyallup, WA; [2]Pacific Northwest University of Health Sciences, Seattle, WA; [3]Kangwon National University School of Medicine, Chuncheon, Republic of Korea.*

Background: Postoperative acute kidney injury is associated with increased mortality and cost in major inpatient surgeries. Patients with chronic kidney disease are at high risk of postoperative acute kidney injury and associated complications.

Methods: We retrospectively collected perioperative data of 399 patients with chronic kidney disease who underwent common inpatient orthopedic or general surgeries (appendectomy, colectomy, cholecystectomy, total hip replacement, total knee replacement) at 5 hospitals in Washington State between January of 2015 and October of 2017. Total of 374 patients were included for data analysis. Multivariate logistic regression analysis was used to identify statistical significance of each risk factor.

Results: 67 out of 374 patients (17.9%) developed acute kidney injury. Between the acute kidney injury group and the no acute kidney injury group, there were significant differences in preoperative hemoglobin (mean±SD 11.9±2.0 vs. 12.7±1.8 g/dL, P=0.001), postoperative hemoglobin (10.0±1.6 vs. 10.6±1.4 g/dL, P=0.005), and baseline glomerular filtration rate (44.8±17.6 vs. 53.0±17.5 mL/min, P=0.001). Coronary artery disease (29.8% vs. 12.6%, P <0.001), postoperative mean arterial blood pressure less than 60 mmHg for at least 20 minutes (29.8% vs. 16.2%, P=0.023), and postoperative transfusion (38.1% vs. 15.3%, P<0.001) were more common in the acute kidney injury group. In the multivariate logistic regression analysis, history of coronary artery disease (adjusted odd ratio [OR] = 2.56, Confidence Interval [CI] = 1.36 - 4.81) and intraoperative intravenous fluid replacement less than 1,000 mL (OR = 2.01, CI = 1.10 – 3.67) were associated with increased risk of postoperative acute kidney injury.

Conclusions: History of coronary artery disease and intraoperative intravenous fluid replacement less than 1,000 mL were associated with postoperative acute kidney injury in patients with chronic kidney disease.



PUB005

Arterial Stiffness in CABG - A Pilot Study

Ahmad Salha,[1] Bayiha daho Klaud francheska,[1] Racquel M. Lowe-Jones,[1] Joe Wang,[2] Robin Kanagasabay,[1] Debasish Banerjee.[1] *[1]St George's University Hospitals NHS Foundation Trust, London, United Kingdom; [2]Epsom & St Helier Hospital NHS Trust, London, United Kingdom.*

Background: AKI following coronary artery bypass graft (CABG) affects 20% of patients and is potentially preventable but there is currently no widely accepted risk stratification method to identify those at risk. This was a pilot study to assess the hypothesis that vascular stiffness may be a predictor of AKI post CABG surgery.

Methods: 43 patients (18-80 years) undergoing isolated elective CABG were recruited. Anthropometric variables, renal function and pulse wave velocity (PWV) were measured pre-operatively and renal function post-operatively for 5 days. Aortic tissue samples obtained intra-operatively were histologically analysed. AKI staging was based on the KDIGO definition. Statistical analysis was obtained using SPSS 25.

Results: Baseline characteristics are as shown in table 1. There was no statistically significant differences between AKI and non-AKI patients. Three patients (7%) developed AKI stage 1 following surgery. PWV in patients who developed AKI tended to be higher but not statistically significant (11.7 ± 3.1 vs 10.1 ± 2.5 m/s; p=0.306). PWV increased with age (Pearson correlation 0.568; p=0.000), diabetes (12.4 ± 2.0 vs 9.5 ± 2.3 m/s; p=0.001). PWV was also high with high systolic BP, <140mmHg vs >140mmHg, (9.3 ± 2.4 vs 11.7 ±2.2 m/s; p=0.002). Histological comparison of aortic samples of an AKI patient with high PWV compared to a non- AKI patient with low PWV (Figure 1) shows differences in calcification and elastin.

Conclusions: The PWV was higher in CABG patients with diabetes, older age and sBP. Patients with AKI following CABG trend towards high PWV but further study will be needed with more patients to establish a link.

Variable	Study population (n=43)	Patients who did not develop AKI (n=40)	Patients who developed AKI (n=3)

Two Cases of AKI Caused by Asymptomatic Unilateral Ureteral Tract Obstruction in Patients with Underlying Kidney Disease

Takeshi Nakata,[1] Norihiro Furutera,[1] Suzuki Tomoko,[1] Okita Jun,[1] Yuko Suenaga,[1] Kohei Aoki,[1] Akihiro Fukuda,[1] Tadasuke Ando,[2] Naoya Fukunaga,[1] Hirotaka Shibata.[1] *[1]Oita University Faculty of Medicine, Yufu city, Japan; [2]Oita university, Yufu, Japan.*

Introduction: Postrenal kidney injury is one of the causes of acute and chronic kidney injury. Nephrologists and urologists should not miss or delay the diagnosis of postrenal kidney injury as renal function can be easily recovered with appropriate treatment.

Case Description: Case-1 A 79-year-old man was admitted to our hospital due to the acute exacerbation of kidney function (serum creatinine 1.30 mg/dl to 2.89 mg/dl). The patient was diagnosed with IgA nephropathy by renal biopsy when he was 58 years old. After being diagnosed with IgA nephropathy he had a tonsillectomy and steroid therapy followed by oral prednisolone for one year and achieved complete remission of IgA nephropathy (defined as proteinuria less than 0.30 mg/gCr and macrohematuria less than 5/High Power Field). For six months prior to admission, the patient had been aware of general fatigue and pretibial edema. However, he felt no symptoms related to renal stones

such as back pain or pyuria. On admission, his urinary protein was 3+ (2.07 g/gCr), and occult urinary blood was ±. First, we considered the worsening of his renal function as a relapse of his IgA nephropathy because he had no newly prescribed medication, symptoms such as back pain, or fever. In addition, he had a history of worsening proteinuria up to nephrotic range, which recovered upon conservative therapy. However, routine abdominal ultrasound examination revealed right kidney hydronephrosis caused by a ureter stone. After inserting a W-J stent, serum creatinine improved to 1.41 mg/dl, and his urinary protein decreased. Case-2 Similarly, a 54-year-old woman with CKD due to nephrosclerosis was admitted to our hospital due to worsening renal function, with her eGFR decreasing from 13.5 ml/min to 5.9 ml/min during the previous three months without symptoms. Although we decided to start her on dialysis, routine abdominal ultrasonography revealed right ureter dilation and hydronephrosis caused by an abdominal aortic aneurysm operation scar from two years previously. After appropriate procedures, she avoided starting hemodialysis.

Discussion: Routine abdominal ultrasonography is an essential examination when we meet worsening of renal function even if patients have no back pain, fever, and pyuria.

PUB007

The Need for Dialysis Treatment Among Hospitalized Patients with AKI: A Single Centre Experience

Eleni Chelioti,[4] Eleni Theodoropoulou,[1] Kyriaki Stamatelou,[2] Evdokia Efthimiou,[3] Maria Tsilivigou.[4] *[1]Dept. of Nephrology, General Hospital of Athens "Alexandra", Athens, Greece; [2]Athens Medical, Dafni Clinic, Vrilisssia, Greece; [3]Renal Unit "Frontis", Piraeus, Greece; [4]Dept. of Nephrology, "Tzaneio" General Hospital of Piraeus, Athens, Greece*.

Background: Acute Kidney Injury (AKI) is a serious complication in hospitalized patients, with single-center studies reporting a rising incidence over the past two decades and case fatality rates exceeding 50% among those who require dialysis treatment. Our aim was to assess the risk for dialysis among hospitalized patients with AKI and previously normal renal function. Secondarily we assessed the effect of comorbidities such as arterial hypertension (HTN), diabetes mellitus (DM) and coronary artery disease (CAD) on dialysis risk.

Methods: The study was conducted prospectively for 24 months recording all consenting hospitalized patients in a single general hospital in Piraeus, Greece. Patients were included if they had previously normal renal function and AKI at the time of their admission at the hospital. Parameters recorded and analyzed were: demographics, full blood and biochemistry tests, history for HTN, DM and CAD and the need for dialysis treatment. The statistical analysis was carried out by single-factorial and multivariate regression analyses.

Results: 212 patients were studied, (115 men and 97 women), average age of 75 ± 12 years. 10.8% (23/212) of the patients with AKI (95% CI 7.1; 16.0) underwent dialysis. The effect of comorbidities was not statistically significant. Statistically important factors associated with the need for dialysis in single-factorial analysis were admission values of serum creatinine (SCr) > 3.3 mg / dL (p = 0.03), age >80 years (p = 0.001) and male gender (p = 0.045). In the multifactorial analysis the only independent dialysis factor was SCr> 3.3 mg / dL (p = 0.045).

Conclusions: The percent of hospitalized patients with AKI needing dialysis in our hospital was relatively low. Comorbidities did not aggravate the need for dialysis.The only parameter significantly affecting the risk for dialysis was the SCr value at the time of admission.

qSOFA as a Predictor of AKI in Patients with Sepsis: A Single-Center, Retrospective, Chart Review

Shimshon Wiesel,[2] Anna S. Gutman,[2] Youssef Shammaa,[4] Marco Campitelli,[3] Nicholas Fuca,[2] Naureen Narula,[2] Suzanne E. El Sayegh.[1] *[1]Staten Island University Hospital, Staten island, NY; [2]Northwell Health, Brooklyn, NY; [3]staten island university hospital, Staten Island, NY; [4]Staten island university hospital, Staten Island, NY*.

Background: According to the new surviving sepsis campaign (sepsis-3), the application of a new scoring system to gauge severity of infection is needed as the initial theorized continuum of the Systemic Inflammatory Response Syndrome (SIRS) criteria was too broad and did not effectively risk stratify patients. A proposed algorithm called the Sequential Organ Failure Assessment (SOFA) was introduced. However, the feasibility of incorporating all the required data in a timely fashion led to the development of an initial "quick" screening tool entitled the qSOFA. We propose that qSOFA is a more specific predictor of development of AKI.

Methods: The study was designed by the first two and last author as a single-center retrospective chart review. Data were abstracted from the electronic medical records at Staten Island University Hospital using the search terms "sepsis", "septic shock", and "severe sepsis". Charts were analyzed for number of SIRS criteria obtained as well as the number of qSOFA criteria obtained. Serum creatinine on admission as well as within 48 hours after admission were documented to assess for acute kidney injury both at admission and at 48 hours.

Results: The preliminary data analysis of 219 patients show that the odds ratio (OR) for qSOFA to predict AKI was 2.79 (CI 1.11 – 6.96, p =0.04), whereas the OR for SIRS to predict AKI was 0.57 (CI 0.33 - 0.98, p = 0.052). The AUROC for qSOFA to predict AKI was 0.547 (CI 0.503 – 0.590) compared to SIRS, which was 0.569 (CI 0.503 – 0.636). The results also showed that the OR of qSOFA to predict ICU admission was 7.26 (CI 2.78 - 18.9, p = <0.0001) compared to SIRS, which was 0.825 (CI 0.45 – 1.51, p = 0.54). The AUROC for predicting ICU admission for qSOFA was 0.605 (CI 0.546 – 0.663) compared to SIRS, which was 0.524 (CI 0.449 – 0.599). Both mortality at 48 hours and total mortality did not show statistically significant results for both SIRS and qSOFA.

Conclusions: In this preliminary analysis the authors found that when compared to SIRS, qSOFA was a marginally stronger predictor of AKI. However, when predicting ICU admission qSOFA was a stronger prognostic indicator than SIRS.

PUB009

Relation of Kidney Function Decline and NT-ProBNP with Outcomes in ADHF

Wendy I. McCallum, Hocine Tighiouart, Gordon S. Huggins, Michael S. Kiernan, Mark J. Sarnak. *Tufts Medical Center, Boston, MA*.

Background: Approximately 30% of patients admitted for acute decompensated heart failure (ADHF) experience an in-hospital decline in estimated glomerular filtration rate (eGFR). The association between this decline and clinical outcomes has been inconsistent. Understanding the circumstances in which a decline in kidney function is associated with either improved or adverse outcomes may influence clinical care. We hypothesized that adequate decongestion, as measured by a decrease in levels of N-terminal pro-brain natriuretic peptide (NT-proBNP), may modify the relationship between decline in eGFR and clinical outcomes.

Methods: We performed a retrospective analysis of a limited dataset from the NHLBI of the Ultrafiltration in Decompensated Heart Failure with Cardiorenal Syndrome Study (CARRESS) and Diuretic Optimization Strategies Evaluation (DOSE) trials, in which patients with ADHF were randomized to various modalities of decongestion with serial measures of kidney function and NT-proBNP. Multivariable Cox proportional hazards regression models were used to evaluate the association of decline in eGFR with a composite outcome of mortality and re-hospitalization. We evaluated for an interaction between decline in eGFR and change in NT-proBNP with this same outcome.

Results: A total of 496 patients were included in this analysis, with median follow-up of 59 days. Median (IQR) baseline eGFR was 40.5 ml/min/1.73m^2 (IQR 29.4, 60.1). In-hospital eGFR decline was not associated with risk for composite outcome of death or re-hospitalization (HR of 0.85 per every 2-fold decline in eGFR, 95% CI 0.60, 1.21). However, there was a significant interaction (p-value=0.007) between decline in eGFR and change in NT-proBNP such that decline in eGFR is associated with better outcomes with a decline in NT-proBNP but worse outcomes with an increase in NT-proBNP (Figure).

Conclusions: Incorporation of changes in markers of congestion may provide additional data to help decision making in cases of eGFR declines in ADHF.

Comparison of Renal Prognosis Between Renal AKI and Prerenal AKI: A Single Center Study

Taro Horino, Keitaro Nagata, Tatsuki Matsumoto, Yutaka Hatakeyama, Yoshiyasu Okuhara, Yoshio Terada. *Kochi Medical School, Kochi University, Kochi, Japan*.

Background: Acute kidney injury (AKI) is a relatively new disease concept that represents a sharp decline in kidney function in several days. AKI is divided into renal, prerenal and postrenal. There is much debate about the difference in prognosis between renal AKI and prerenal AKI. Here, we estimated the difference of renal prognosis between renal AKI and prerenal AKI in the Japanese population.

Methods: Inpatients and outpatients aged 18-80 years were retrospectively enrolled. AKI was diagnosed according to the Kidney Disease Improving Global Outcomes (KDIGO) criteria, using SCr levels. Patients who received infusion and who recovered within 7 days after the onset of AKI were defined as prerenal AKI and patients requiring more than 8 days as renal AKI. Survival time analysis was performed by defining the recovery date as zero hour, the 30% decrease in eGFR as an event, and the time to event occurrence as survival time, and the Kaplan - Meier (KM) curve and the Cox proportional hazard ratio were obtained.

Results: We analyzed data from 76,160 Japanese patients. The number of renal AKI patients and prerenal AKI patients were 563 and 760, respectively. In the KM curve, results showing that the prerenal AKI is significantly longer than the renal AKI has been obtained. Compared with non-AKI control, the hazard ratio of the 30% decrease in eGFR in renal

AKI and prerenal AKI were 5.10 and 3.42, respectively. the hazard ratio in renal AKI was significantly higher than that in prerenal AKI.

Conclusions: For long-term prognosis after recovery from AKI, prerenal AKI has better renal prognosis than renal AKI but worse than non-AKI. We suggest that prerenal AKI is not a favorable prognosis condition.

PUB011

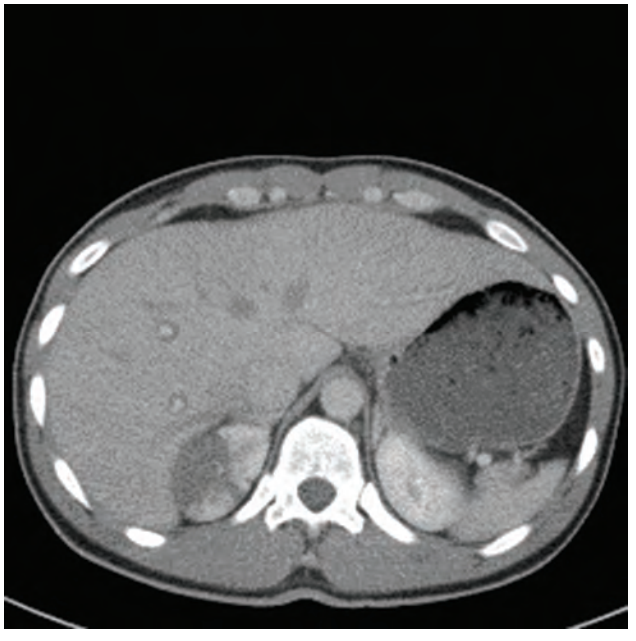
Renal Injury Caused by Cocaine and Polysubstance Abuse: A Case Report

Mohammed Nazmul. *Creighton University, Omaha, NE.*

Introduction: Drug abuse involves life time exposure of 46% of US population. Recreational substances like alcohol, opioids, cocaine, cannabis, nicotine etc. can cause both acute and chronic renal injury.

Case Description: A 46 years old male with no significant past medical history, came to ER for sudden onset right flank pain. His vitals were stable except blood pressure was elevated to 150/90 mmHg. He had right costovertebral angle tenderness. Basic metabolic panel, LDH, complete blood count and urine dipstick were unremarkable except creatinine of 1.3mg/dl. Computed tomography showed diffusely reduced blood flow on right renal parenchyma involving 80 % of cortex suggestive of renal infarction. Renal doppler ultrasound showed vasospasm of right single renal artery. Urine was positive for cocaine, amphetamine and marijuana. Patient was treated with heparin infusion and intravenous normal saline. His hypercoagulability work up and vasculitis panel were negative. Patient's renal function improved to 0,6mg/dl after 24 hours of conservative care. He was discharged home with lisinopril and aspirin.

Discussion: Here renal injury is caused by ischemia due to a renal artery vasospasm. Pathophysiology of cocaine nephrotoxicity is multifactorial including changes in renal hemodynamics, glomerular matrix synthesis, toxic metabolites degradation, oxidative stress, and induction of renal atherogenesis. We need more epidemiological studies and translational researches on the mechanism of multiorgan damages or failures due to chronic polysubstance abuse which can causes acute organ injuries like renal infarction as well as promotes sub clinical renal hypoperfusion. Early diagnosis, prompt withdrawal of recreational drugs, aggressive supportive measures, as well as prophylactic treatments with aspirin, RAAS blockade, anti-cholesterol medications etc. may improve long term renal outcome.



PUB012

Kidney and Blood Pressure Outcomes from 6 to 11 Years After Pediatric Intensive Care Admission

Mariya Yordanova,[1] Catherine Morgan,[2] Kelly Benisty,[1] Teodora Riglea,[1] Louis Huynh,[1] Frédérik Crépeau-Hubert,[1] Erin Hessey,[1] Kelly McMahon,[1] Michael Zappitelli.[3] *[1]McGill University Health Centre, Montreal, QC, Canada; [2]University of Alberta, Edmonton, AB, Canada; [3]Toronto Hospital for Sick Children, University of Toronto, Toronto, ON, Canada.*

Background: Acute kidney injury (AKI) during pediatric intensive care unit (PICU) admission may be a risk factor for chronic kidney disease (CKD) and hypertension development. We determined 1)CKD and elevated BP (eBP) prevalence 11years(y) after PICU admission; 2)If PICU-AKI is associated with worsening CKD and BP from 6-11y post-PICU.

Methods: Follow-up study (≥9.5y post-PICU) of children previously studied at 6y post-PICU. Protocol: Children were contacted for a study visit 11±1.5y post-PICU admission; blood (serum creatinine) and urine (albumin/creatinine[ACR]) were collected and height/weight/BP measured. Exposure: AKI during PICU (KDIGO definition). Outcomes: CKD [estimated glomerular filtration rate (eGFR) <90ml/min/1.73m^2 or ACR ≥3mg/mmol]; eBP: BP ≥90th percentile or ≥120/80mmHg in adults. 6 *vs.* 11y outcome prevalences and AKI *vs.* non-AKI change in eGFR, ACR and BP percentile were compared (univariate tests).

Results: Data were available for n=71(4.5±5.3y old at PICU; 55% male). Prevalences of low eGFR, high ACR, CKD and eBP remained high at 11y post-PICU, similar to 6y post-PICU (Table). There was a statistically significant decrease in eGFR and diastolic BP from 6y to 11y follow-up ($p<0.05$), but no significant change in ACR or systolic BP (Table). AKI during PICU was not significantly associated with change in eGFR, ACR or BP percentile from 6y to 11y follow-up (Table, all $p>0.05$).

Conclusions: High prevalence of CKD and eBP persists at 11y after PICU admission. We did not find that PICU-AKI impacts on CKD or eBP progression over time. Interventions are needed to reduce long-term cardiovascular risk in PICU patients. Risk factors for persistent or progressive CKD and eBP must be elucidated.

Funding: Government Support - Non-U.S.

Prevalence of AKI in an ICU Department in Chihuahua, Mexico

Victor A. Salgado yañez,[1,2] Javier Soto-Vargas,[3] Julio A. Gutierrez-Prieto.[3] *[1]Nefrología, Hospital Central Universitario, Chihuahua, Mexico; [2]Medicina Interna, Hospital Christus Muguerza del Parque, Chihuahua, Mexico; [3]Universidad de Guadalajara, Centro Universitario de Ciencias de la Salud, Especialidad en Nefrologia, Hospital General Regional No 46 del IMSS, Guadalajara, Mexico.*

Background: The impact and prognosis of acute kidney injury (AKI) vary considerably depending on the severity, clinical setting, comorbid factors, and also geographical location. AKI is associated with higher mortality, hospital length of stay, re-admission, costs and CKD development. The aim of our study was to report the prevalence of AKI in an intensive care unit (ICU) from northern Mexico in a private hospital.

Methods: A retrospective observational study was carried out from May 2014 – May 2017. Data from 1436 patients that were admitted to the intensive care unit in this period were analyzed, only 1158 patients had enough data to screen for AKI, AKI was diagnosed by serum creatinine criteria from KDIGO guidelines.

Results: Baseline characteristics of the patients, ICU department of admission and AKI severity are summarized in Table 1.

Conclusions: The prevalence of AKI in our ICU was similar to previous reports. This is the first epidemiological study for AKI of northern Mexico in an ICU and in our hospital, currently there is not a single nephrologist in our hospital in charge of AKI consultations, this study highlights the importance of this entity. The lack of recognition of AKI in our hospital should encourage the creation of an AKI clinic / Nephrology rapid response team.

vomiting associated with sharp left flank pain. Examination revealed tenderness on right upper quadrant palpitation. Laboratory findings were notable for creatinine of 80umol/L, bland urine analysis, negative urine culture and Lactate dehydrogenase of 1,282U/L. She received oral analgesia along with IV fluids. CT imaging with IV contrast showed a wedged shape reduced enhancement on right kidney. On second day with migrating pain to left, a second CT scan revealed evolving wedged shape defect on left kidney [Figure1]. Patient was started on anticoagulation with heparin and warfarin. Furthermore, patient underwent a transesophageal echocardiogram for embolic disease, holter monitor, antibody screen for vasculitis and antiphospholipid syndrome, flowcytometry for PNH, and hemophilia screen that were all normal. Patient was started on Topiremate, and has been off zolmitriptan with no recurrence of disease on 3 months follow up.

Discussion: Renal infarction should be considered in severe flank pain with negative work up for kidney stone and pyelonephritis. Although zolmitriptan is an effective drug to treat maigraine headaches, it can potentially cause renal artery vasospasm leading to acute renal infarction.

Early Persistent AKI Is Associated with Death and Renal Recovery in Cardiac Surgery

Ryo Matsuura,[1,2] Masao Iwagami,[3] Hidekazu Moriya,[2] Takayasu Ohtake,[2] Kent Doi,[1] Masaomi Nangaku,[1] Shuzo Kobayashi,[2] Eisei Noiri.[1] *[1]The University of Tokyo Hospital, Tokyo, Japan; [2]Shonan Kamakura General Hospital, Kamakura, Japan; [3]University of Tsukuba, Tsukuba, Japan.*

Background: Early recovery of acute kidney injury (AKI) is associated with better prognosis in critically ill patients. It remains to be known which type of cardiac surgery-associated AKI (CSA-AKI) impacts prognosis. This study investigated the association between type of CSA-AKI and prognosis.

Methods: We analyzed the data on 2,060 non-CKD, post-cardiac surgery patients admitted to ICUs in 18 hospitals in the Tokushukai Medical Database between 2012 and 2014 who had No-AKI (n = 1,530), transient AKI (<3 days of ICU admission; n = 300), persistent AKI (≥3 days of ICU admission; n = 91), and late-onset AKI (occurred after ICU discharge; n = 139). The primary outcome was in-hospital death or renal recovery at hospital discharge, and the secondary outcome, eGFR decline > 50% during 3-year follow-up.

Results: There were more, older male patients in AKI groups. There were no differences in the type of surgery or use of cardiopulmonary bypass. Transient and persistent AKI were prognostic factors for in-hospital mortality (odds ratio [OR], 24.2 [8.7-85.9] and 195.6 [65.0-743.6], respectively). Persistent AKI was associated with a significantly lower OR for renal recovery (0.13 [0.07-0.26]). Most of patients with persistent AKI met the secondary outcome within 1 year of discharge (hazard ratio [HR], 8.13 [4.75-13.9]; *P*<0.001). It took two years or more for half of patients with transient and late-onset AKI to achieve the outcome (HR, 3.04 [2.08-4.43] and 2.58 [1.60-4.16]; *P*<0.001).

Conclusions: Persistent AKI was a notable prognostic factor for mortality and non-recovery and associated with fast eGFR decline, while transient and late-onset AKI were associated with moderate eGFR decline.

PUB015

Bilateral Renal Infarction During the Use of Zolmitriptan

Essa Abuhelaiqa, Awais Nauman. *Nephrology, Hamad Medical Corporation, Doha, Qatar.*

Introduction: Zolmitriptan is a 5-HT_{1B} agonist that leads to vasocontriction of blood vessels and used for the treatment of migraine headaches. Triptans have been associated with myocardial infarction and bowel ischemia, but there are only 5 reports associating them with renal infarction. Here we report a case of bilateral renal infarction following treatment with Zolmitriptan.

Case Description: This is a 58 year old lady history of chronic migraine presented to emergency department with flank pain and vomiting. Patient has been on zolmitriptan 2.5mg as needed for migraine headache which she reports taking frequently in past month, with last dose 3 days prior to presentation. Patient experienced sudden onset nausea and

PUB016

Prediction Scale for the Development of AKI in a Hispanic Population

José Franco,[1] Emma Puron Gonzalez,[2] Jesus Cruz Valdez,[3] Lilia M. Rizo Topete.[4] *[1]Hospital Universitario UANL, Monterrey, Mexico; [2]Christus Muguerza Hospital Alta Especialidad, Universidad de Monterrey, Monterrey, Mexico; [3]Hospital Universitario, Monterrey, Mexico; [4]Hospital Universitario, UANL, Monterrey, Mexico.*

Background: Acute kidney injury (AKI) affects 10 million people annually in the world. Is an independent risk factor for mortality. The impact of this entity is more significant in developing countries where there are limited resources, and patients struggle to obtain renal replacement therapy. There is a worldwide need to recognize, detect and early approach of AKI and provide a better prognosis of renal recovery. The objective of the study is to evaluate the capacity of a practical risk scale for the detection of patients at risk of developing AKI

Methods: Prospective analytical cross-sectional study. 83 patients were registered from May to October in the 2018. Patients were evaluated from admission to hospitals in northeastern Mexico recording the most prevalent risk factors in our population and were followed until discharge, recording those who developed AKI based on the current KDIGO classification and degree severity. The primary analysis was performed with multiple logistic regression, the calculation of sensitivity, specificity was performed through ROC curve

Results: Mean age was 61 years, 52 patients (62%) developed AKI, 55% KDIGO stage I, 25% stage II, 19% stage III. Identifying statistical significance in the proposed model (p =< 0.001), each variable was converted into a score coded by its OR (anemia 3 points, IV contrast and cirrhosis 1 pt, CKD 9 pts, sepsis 2 pt, nephrotoxic drugs 1 pt each). With these values the calculation of the total score of each patient with AKI was made (OR= 2.6, p =<0.001). The best performance of the diagnostic test through a ROC curve was a score of 4 points with a sensitivity of 84% and a specificity of 73%

Conclusions: In AKI, early recognition and protective measures are essential to obtain a higher rate of renal recovery and positively impacting the survival and quality of life of patients. Access to new biomarkers of early kidney injury is limited in our setting and the proposed screening scale prompts detection of kidney damage. We obtained a quick and practical prediction scale with a sensitivity level of 84%, being an adequate screening tool to detect patients at risk of developing AKI allowing the establishment of appropriate nephroprotective measures to reduce the incidence and/or severity of AKI. Nevertheless, in future this predictive model together with AKI biomarkers could be an interesting tool to predict AKI

PUB017

An Interesting Case of Renal Infarction and Spontaneous Adrenal Haemorrhage in a Patient on Thrombopoietin (TPO) Receptor Agonist Therapy and Vitamin K Antagonist

Arvind K. Singh. Renal team gloucetsershire Royal Hospital *Gloucestershire Royal Hospital, Gloucester, United Kingdom*.

Introduction: Eltrombopag is the first TPO-receptor agonist and is widely used for the treatment of Idiopathic thrombotic purpura (ITP). Though the British National Formulary (BNF) cautions against use of Eltrombopag in patients with risk factors for venous thromboembolisms (VTEs), there is a paucity of guidance of its concomittant use with anticoagulant therapy.

Case Description: A 61 year old lady presented with two day history of abdominal pain and vomiting 10 days after starting Eltrombopag for ITP. She has a background of discoid lupus, antiphospholipid syndrome, hypothyroidsim and haemolytic anaemia. She had previosly been treated for deep venous thrombosis, pulmonary embolism and ischaemic stroke with haemorrhagic transformation. She was on warfarin for prevention of VTEs secondary to her antiphospholipid syndrome. She had a tender right upper quadrant of her abdomen, with normal bowel sound and no organomegaly. Her chest was clear and with normal heart sounds. She was afebrile, haemodynamically stable and a urine dipstick was negative for any sediments. Admission bloods revealed an increase in her platelet count from 32,000/mL to 1,84,000/mL within days of starting Eltrombopag. She also had acute kidney injury stage 2 (eGFR 31 from 87 ml/min/1.732 m2) and International normalised ratio of 2.5 on admission. Her eGFR dropped to 9 ml/min/1.732 m2 and she required haemodialysis secondary to deteriorating renal function and fluid overload. A computeriseed tomography of her abdomen showed evidence of organised left adrenal haematoma. She was seen by the haematology and rheumatology teams who agreed that in all likelihood the patient had an intrarenal thrombus with sencondary haemorrhagic tranformation. Her Eltrombopag was stopped and she was managed with unfractioned heparin and bridged to warfarin with an INR target of 3.5. for Her kidney function improved few weeks after the treament and she is now dialysis independent with gradual improvement in her kidney function.

Discussion: After this expeience we advice cautionary use of Eltromobag in patients with previous episodes or high risk for VTE on or off anticoagulation. There should also be guidelines to dictate the rate of increase in platelt count to avoid thrombotic complications related to a sudden increase in platelet count.

PUB018

Urinary Cystatin C (UCysC) as an Early Biomarker of AKI in Critically Ill Patients

Jeyaraj Balasubramaniam.[1,2] Kidney Care Centre [1]*Kidney Care Centre, Tirunelveli, India;* [2]*Sri Ramachandra Medical College & Research Institute, Chennai, India*.

Background: AKI is common in critically ill patients. Despite all advancements prognosis of AKI continues to be bad. Early diagnosis results in better outcome. Serum creatinine is an insensitive marker in early stages of AKI. A marker which can predict AKI or identify AKI early is a great need. Cystatin C is a cysteine protease inhibitor, synthesized by all nucleated cells in the body, freely filtered by the glomerulus, fully reabsorbed and not secreted by the tubule, making serum cystatin a better marker for estimation of GFR than creatinine. The urinary excretion of Cystatin C indicates acute tubular injury. Urinary Cystatin C is a marker of renal tubular injury which precedes the elevation of serum creatinine or serum cystatin C. **Aim:** To evaluate UCysC as early biomarker of AKI.

Methods: A prospective observational study. Consecutive critically ill subjects admitted to ICU during Jan 2017 to Oct 2017 were taken for the study. **Exclusion:** Age <18 years & over 80 years; Hematuria, and polycythemia; Preexisting renal failure; Not expected to survive 72 hrs; **Methods:** Serum creatinine (daily), UCysC, sodium, electrolytes and haemoglobin levels were measured using standard protocols. Glomerular filtration rate was calculated using the standard MDRD formula. RIFLE classification system was used to define AKI. The patients were divided in to two groups based on development of AKI. Finally, the statistical analyses were performed between the groups to see if urinary cystatin C levels could be a reliable diagnostic marker for AKI.

Results: Total 83. Male 57; Female 26. 36 (43%) developed AKI. Sepsis was the common cause. Out of day 1 investigations UCysC was the one which was significantly indicative of development of AKI.

Conclusions: 1. UCysC was significantly elevated in critically ill patients who developed AKI than in those who did not. 2. UCysC on the first day was significantly elevated than serum creatinine in those who developed AKI. 2. UCysC is an ideal early biomarker for AKI.

AKI of Nephrotic Syndrome in Children

Mi young Kim,[1] Ji hyun Kim,[1] Myung hyun Cho,[2] Yo Han Ahn,[4] IL-Soo Ha,[3] Hae Il Cheong,[3] Hee Gyung Kang.[3] [1]*Seoul National University Children's Hospital, Seoul, Republic of Korea;* [2]*Seoul National university Children's hospital, Seoul, Republic of Korea;* [3]*Seoul National University Children's Hospital, Seoul, Republic of Korea;* [4]*Seoul National University Bundang Hospital, Seongnam, KYUNGGI-DO, Republic of Korea*.

Background: Nephrotic syndrome is the most common kidney disease in children. Acute kidney injury (AKI) is one of the common complications of nephrotic syndrome, and its incidence is reported from 1% to 50.9% in various studies worldwide. Well known risk factors of acute kidney injury are intravascular volume depletion, infection, edema and steroid resistance. Detailed report about incidence and risk factors of pediatric nephrotic syndrome in Korea is lacking, therefore we studied incidence, causes, risk factors of acute kidney injury of nephrotic syndrome in children in this study.

Methods: We conducted a retrospective review of the electronic medical records of pediatric patients who were admitted to Seoul National University Children's Hospital for occurrence or recurrence of idiopathic nephrotic syndrome, from January 1st, 2015 to July 31th, 2017. Patients with chronic kidney disease or congenital nephrotic syndrome were excluded.

Results: During the study period, 90 cases (Male:Female 44(67.7%):21(32.3%)) were admitted for management of nephrotic syndrome. Among them, total 47 cases met the KDIGO criteria of AKI (52.2%, Male:Female 2(66.7%):1(33.3%), median age 7). AKI developed in association with infection (24), aggravation of nephrotic syndrome (17), methyl prednisolone pulse therapy (4), and dehydration (2). Those with AKI were not statistically different from those without AKI in regard of sex, age, pathological diagnosis, age of nephrotic syndrome onset, number of relapse during the previous year, or trough level of calcineurin inhibitors (CNI) if they were taking CNIs. On the other hand, AKI occurred more commonly when the patients were taking cyclosporine (67.5% with cyclosporine, p=0.011, odds ratio=3.115). The median recovery time of serum creatinine level was 7 days and most patients had AKI at the time of admission. While most of the AKI episodes had resolved without long-term complication, duration of hospitalization was longer in the AKI group than the non-AKI group.

Conclusions: Complication of AKI occurred in more than half of the hospitalization of pediatric nephrotic syndrome. Cyclosporine increased the risk of AKI. Therefore in managing children with nephrotic syndrome, we need to consider AKI especially for those taking cyclosporine.

PUB020

Biomarkers N-Gal and Kim-1 for AKI Post Major Elective Non-Vascular Abdominal Surgeries

Graziela R. de Souza,[1] Lia J. Marçal,[2] Luis Yu,[3] Leila Antonangelo,[2] Dirce M. Zanetta,[4] Emmanuel A. Burdmann.[5] [1]*São Paulo University, São Paulo, Brazil;* [2]*Universidade De Sao Paulo, Sao Paulo - SP, Brazil;* [3]*University of Sao Paulo School of Medicine, Sao Paulo, Brazil;* [4]*University of São Paulo, S Paulo, Brazil;* [5]*University of Sao Paulo Medical School, Sao Paulo, Brazil*.

Background: The role of renal injury urinary biomarkers (uBMs)for predicting AKI in surgical patients (pts) remains undetermined. The aim of this study was to compare the efficacy of urinary biomarkers, NGAL and KIM-1, in patients submitted to major elective non-vascular abdominal surgeries (MENVAS) admitted to ICU.

Methods: Two hundred and twenty five pts were prospectively evaluated, peri-operatively, from the ICU admission until day 7. Serum creatinine (SCr mg/dl) was measured before surgery and once a day until day 7 or ICU discharge. AKI was diagnosed using either SCr or urinary output (UO) according to KDIGO definition. Two uBMs were assessed: NGAL and KIM-1 by Luminex x-MAP method. Urine sample was collected 1 day before surgery (baseline); upon arrival in ICU and 12 h after ICU admission. The value of the fifth quintile was considered positive for uBMs. Data are presented as mean S SD, median (first and fourth quartiles) or frequencies. Statistical significance was $p<0.05$.

Results: A total of 225 pts were analysed, 126 (56%) developed AKI. Most frequent types of surgery were: hepatectomy, sleeve gastroplasty, gastrectomy, hepatectomy + cholecystectomy, gastroduodenopancreatectomy and adrenalectomy. AKI pts were older 57.6 ± 1,2 vs. 50.8 ± 1,6 (p = 0.0007). Mortality in the AKI group was 10.2% vs. 2.0 % in Non-AKI (p=0.0149). The following table (image) shows the efficacy of the biomarkers NGAL and KIM-1 in the outcomes hospital length of stay (LoS) and ICU LoS. Among the non-survivor (15 pts), 4 had higher biomarkers (uBM +) without functional alteration (SCr-) and 4 had functional deterioration (SCr+) with no uBM increase (uBM -). After 12h from ICU admission, 4 pts had higher biomarkers (uBM +) without functional alteration (SCr -) and 4 had functional deterioration (SCr+) with no uBM increase (uBM -). On the other hand, six pts with both functional alteration (SCr +) and uBM increase (uBM+) all died.

Conclusions: Surgical patients with higher urinary biomarkers N-GAL and KIM-1 even without functional deterioration (SCr increase) presented longer hospital and ICU LoS and higher mortality.

High Serum Sodium Levels at the Time of Nephrology Consultation and Adverse Outcomes in Burn Patients with AKI

Igor Smolentzov,[2] Luanne F. Soares,[2] Valkercyo A. Feitosa,[4] Marcia Fernanda Arantes de Oliveira,[2] Marcelo D. Silveira,[2] Lucia Andrade,[1,2] Victor F. Seabra.[2,3] *[1]University of Sao Paulo School of Medicine, Sao Paulo, Brazil; [2]Hospital clinicas SP HCFMUSP, Sao Paulo, Brazil; [3]Albert Einstein Hospital, Sao Paulo, Brazil; [4]USP, SAO PAULO, Brazil.*

Background: Acute kidney injury (AKI) is a common complication after severe burn injuries and is associated with high mortality. Dysnatremias have been found to be associated with mortality in many populations, but its role in burn patients with AKI is not fully understood.

Methods: We retrospectively evaluated data on burn patients with acute kidney injury in the ICU of a tertiary hospital using logistic regression to evaluate the association of serum sodium levels with adverse outcomes.

Results: 109 patients were included in the analysis. At the time of the nephrology consultation, the median age was 42.5 years, 70% were males, the baseline GFR was 101 mL/min/1.73m^2, the median total body surface area (%TBSA) burned was 34.5%, and the median serum creatinine was 2.31 mg/dL. Median serum sodium was 143 mEq/L (IQR 139-149 mEq/L), 44 subjects had serum sodium above the upper limit of the normal range (> 145 mEq/L). On univariate analysis, serum sodium levels above 145 mEq/L were associated with higher odds of the composite outcome of RRT requirement or in-hospital death (OR=3.27, 95% CI: 1.10–12.10, p=0.048) but this association did not persist in multivariate analysis (OR=1.79, 95% CI: 0.63–5.38, p=0.282). In this population, sepsis, baseline GFR, fluid balance, and the requirement of mechanical ventilation were also associated with the composite outcome in univariate analysis. Sepsis and baseline GFR remained associated with an increased risk of the composite outcome (OR=28.18, 95% CI 3.47-371.40, p=0.004 and OR=0.96, 95% CI 0.94-0.99, p=0.003, respectively) on the final multivariate model that also included sodium level, %TBSA burned, mechanical ventilation, and SOFA score.

Conclusions: Hypernatremia at the time of nephrology consultation might predict the composite outcome of RRT and death. Larger studies are warranted to confirm or dispute these findings.

PUB022

Gender and Age Differences in AKI During Hospitalization for Left Ventricular Assist Device Implantation: National Estimates

Michael Holliday, Carl P. Walther, Jenny S. Pan. *Baylor College of Medicine, Houston, TX.*

Background: Left ventricular assist device (LVAD) placement is associated with high incidence of AKI, and AKI post-LVAD is associated with increased mortality. Outcomes are gender-dependent, with females having higher risk for thrombosis, right heart failure and mortality. Gender differences in renal disease have been described in trauma, cardiopulmonary bypass, chemotherapy toxicity and rates of delayed graft function after kidney transplant. Rodent models of ischemia/reperfusion and other AKI have demonstrated protective effects of the female hormonal milieu and deleterious effects of male hormones. We therefore investigated relationships of sex and age with AKI diagnosis during hospitalizations for implantable LVAD placement.

Methods: We performed a retrospective, observational cohort study using the National Inpatient Sample (2006-2015) to estimate diagnoses of AKI in females versus males among patients ≥ 18 years of age who received LVAD. ICD-9 codes were used for identification of LVAD placement, presence of AKI without and with RRT (AKI-D), and comorbidities. We used appropriate survey methods to obtain national estimates. We used logistic regression models (adjusted for demographics, comorbidities, year of implantation) and predictive margins to assess relationships of age, sex, and AKI.

Results: An estimated 5,681 female (mean age 53) and 18,702 male (mean age 57) patients received LVADs, with men having higher prevalence of hypertension (43% versus 36%) but not diabetes. 50% of females carried AKI diagnosis, versus 57% of males. The adjusted risk of AKI in females age less than 60 was 47% (CI 0.44-0.51) versus 56% (CI 0.53-0.59) for males. No difference was found in AKI of males versus females greater than age 60, or in AKI-D between males and females, regardless of age. Mortality was higher in females with AKI (OR 1.53, CI 1.13-1.92).

Conclusions: Women had lower risk of AKI in this population of LVAD patients; this protective effect was lost in postmenopausal women. However, women with AKI had higher mortality. Given that female gender has demonstrated reno-protective effects in animal and human models, it would be judicious to consider the effects of gender, hormone status and supplementation, and sex-directed therapeutics in the design of future studies of ischemia/reperfusion injury, transplant and AKI.

PUB023

Prevalence of AKI in PD-1 Inhibitors: A Single Center Experience

Sandhya Manohar,[1] Busra N. Bacik Goksu,[1] Heidi D. Finnes,[2] Joerg Herrmann,[1] Sandra Herrmann.[1] *[1]Mayo Clinic, Rochester, MN; [2]Mayo Clinic, Rochester, MN.*

Background: Programmed cell death protein 1 (PD-1) inhibitors, i.e. nivolumab and pembrolizumab, are being increasingly used and the incidence of acute kidney injury (AKI) has been reported to be 2.2% by a recent meta-analysis of clinical trials.

Methods: The major objective of this study is to determine the AKI rates of all patients that have received a PD-1 inhibitor at Mayo Clinic Rochester over a span of 3 years. We performed a retrospective chart review of all patients that had a PD-1 inhibitor until April 1, 2017. We included patients that had a baseline creatinine value within 30 days of drug initiation. We searched for AKI episodes as defined by AKIN criteria as increase in creatinine of ≥0.3 mg/dl form baseline at 3 different time points – Day 1-14, day 80-100 and day 300-400 from the time of initiation of the drug.

Results: Out of the 495 unique patients that received either nivolumab or pembrolizumab, only 134 patients fit our inclusion criteria. We found 53% (33/62) in nivolumab and 43% (31/72) in pembrolizumab group had AKI episodes. Out of those that clinically significant AKI (AKIN stage 2 and greater), in nivolumab 2 of 3 patients and in pembrolizumab 5 of 8 patients had likely drug related AKI. Only 2 of these patients had a kidney biopsy showing nephritis. A large proportion of these patients were closer to the 1 year time point 38% (24/62) in nivolumab and 22.2% (16/72) in pembrolizumab group.

Conclusions: Our study reinforces the ongoing concern among nephrologists that AKI episodes are being missed. We also found that consistent with the current literature the AKI appears to be of a delayed onset. Only a handful of these patients were seen by nephrology and fewer had kidney biopsies. With the increasing use of these drugs in cancer therapy there is a need for more definitive guideline for nephrologists in the management of these AKI patients.

Obesity Linked to AKI and Mortality in Acute Distress Respiratory Syndrome

Luis I. Bonilla,[1,3] Raymundo Vera,[2] Sara Samoni,[3,4] Claudio Ronco,[4,3] Lilia M. Rizo Topete.[5,3] *[1]Nephrology, Hospital Universitario Dr. José Eleuterio Gonzalez, Monterrey, Mexico; [2]Hospital Universitario, Monterrey, Mexico; [3]International Renal Research Institute of Vicenza, Vicenza, Italy; [4]Ospedale "S. Bortolo" AZ. ULSS 6, Vicenza, Italy; [5]Hospital Universitario, UANL, Monterrey, Mexico.*

Background: One of the most important organ to organ cross-talk in critically ill patients is the one taking place between the lung and kidney, especially in patients under mechanical ventilation. Barotrauma, volutrauma, atelectrauma and biotrauma have been the mechanisms described as responsible for damage in both organs. Acute distress respiratory syndrome (ADRS)is characterized by a global reaction of the lung parenchyma which leads to fluid extravasation and edema. One of the most common comorbidities found in ARDS patients is obesity. It has been linked to increase in both, mortality and incidence of acute kidney injury (AKI)

Methods: This is a retrospective analysis of 30 records of patients admitted to the intensive care unit (ICU) with ARDS during the Influenza season 2016-2017. Demographic, laboratory, and clinical data were obtained. We measured weight and height of each patient at admission and used the body mass index (BMI) formula (weight in kg/(height in m)^2 to obtain each patient's BMI. We classified patients into two groups, obese (BMI ≥30 kg/m^2) (group A) and not obese (BMI <30 kg/m^2) (group B). We compared both groups.

Results: Mean age in our cohort was 46.4yrs, 66.6% were male and 46.6% were obese. Global mortality among obese patients was 57.9%, compared with a 42% in non-obese patients (p=0.11). AKI was diagnosed in 20 patients (66.6%) with 16.6%, 10% and 36.6% of KDIGO stages 1-3 respectively. RRT was initiated in 10 (50%) of AKI patients. Among groups A and B AKI was diagnosed in 55% and 45% of patients respectively (p=0.2). ICU mortality was 60% among the whole cohort, 61.1% of obese patients died during the ICU stay compared with 38.9% of non-obese patients (p: 0.72)

Conclusions: In our cohort of ARDS patients, obesity with BMI ≥30kg/m^2 was linked to an increase in the incidence of AKI and increase global mortality as well as ICU mortality. With these findings, we can strongly recommend special attention in obese patients with ARDS because of the greater susceptibility to complications and mortality. More studies with bigger cohorts are needed to obtain statistical significance and clearly demonstrate these associations.

PUB025

Acute Interstitial Nephritis in Patients with Hepatitis C Virus Infection and CKD Treated with Direct Acting Antiviral Agents: A Case Series

Juan C. Duque Ballesteros,[2] Adriana Dejman,[2] Karla G. Carias martinez,[2] Vasuki N. Venkat,[1] Maria D. Hernandez,[1] David Roth,[2] Marco A. LadinoAvellaneda.[1] *[1]Miami VA Medical Center, Miami, FL; [2]University of Miami, Miami, FL.*

Background: Hepatitis C virus (HCV) infection has been shown to have an adverse impact on clinical outcomes in patients with chronic kidney disease (CKD) and end stage renal disease (ESRD), including an accelerated rate of loss of kidney function and an increased mortality. Patients achieving a sustained viral response at 12 weeks post treatment completion (SVR12) are considered to be cured. Clinical trials using the direct-acting antiviral agents (DAAs) uniformly achieve SVR12 rates of >90% in the general population as well as in patients with CKD/ESRD. Both sofosbuvir and its metabolite are renally excreted and its use has been associated with worsening kidney function. In the HCV-TARGET study, patients with eGFR <30 ml/min/1.73m2 at start of sofosbuvir-based therapy had higher rates of deterioration of kidney function compared to patients with higher eGFR. Current recommendations are to avoid sofosbuvir in patients with eGFR <30 ml/min

Methods: The current report describes 8 HCV-infected patients who developed acute kidney injury with biopsy-proven acute interstitial nephritis (AIN) associated with the use of DAAs.

Results: Mean age of the group was 61.3 (±6 years) with 100% men and 5 (62.5%) African Americans. The most common genotype (GT) was 1a (n=7) with 1 GT 4. The DAA formulations were sofosbuvir/ledipasvir (n=5), elbasvir/grazoprevir (n=2) and sofosbuvir/simeprevir (n=1). All patients achieved SVR12. The mean creatinine at start of DAA treatment was 1.6 mg/dl (±0.6) and increased to 2.0 mg/dl (±0.8) at the conclusion of therapy (p=0.03). All patients received a course of high dose steroids after the diagnosis of AIN was confirmed. Serum creatinine at 3 and 6 months post steroids was 3.0 (±1.2) and 3.2 mg/dl (±1.4), respectively. Three patients had progression of the CKD and developed ESRD

Conclusions: These results are consistent with earlier studies demonstrating the efficacy of DAAs in HCV-infected CKD patients. Biopsy-proven AIN may explain the AKI events reported with the use of DAAs in CKD patients. Our results show that AIN can occur with use of different DAAs, although particular caution must be used prescribing sofosbuvir to patients with eGFR <30 ml/min1.73m2 as it is the only DAA renally cleared.

PUB026

Postoperative AKI: A Prospective Randomized Controlled Trial of the Impact of Two Different Intraoperative Systolic Blood Pressure Levels on Renal Outcomes

Macaulay A. Onuigbo. Postoperative Acute Kidney Injury Research Group *Medicine, University of Vermont, BURLINGTON, VT.*

Background: Postoperative acute kidney injury (PO-AKI) is a significant contributor to hospital acquired AKI. It is unclear what the optimal intraoperative blood pressure is for preserved renal health. Evidence that controlled hypotension has advantages like shortened surgery time, reduced blood loss and less blood transfusions but without renal consequences were based on studies of younger patients with preserved kidney function. There is accruing evidence that more severe and longer periods of IOH in older patients with later stage CKD could indeed result in catastrophic renal failure. We had raised concerns about IOH as a neglected risk factor for PO-AKI in the Mayo Clinic Health System. The most common definition of IOH are SBP <80 mm Hg, MAP <55-60 mm Hg, and/or decreased SBP or MAP of 25% from baseline. For intraoperative MAP <60 mm Hg, the adjusted odds ratio for AKI was 1.84 (1.11–3.06) for 11–20-min exposure (Sun; 2015). From our experience and from the published literature, we hypothesize that the comparison of renal outcomes while keeping SBP >105 mm Hg versus SBP >85 mm Hg in the operating room would enable a scientifically robust study of this question. We therefore plan to carry out a pilot study of this RCT in orthopedic surgery (joint replacement) and in CV (non-bypass) surgery, respectively.

Methods: A prospective randomized controlled trial (pilot study) of PO-AKI in two subsets of patients undergoing noncardiac (orthopaedic) surgery and cardaic (non-bypass) surgery, with target intraoperative SBP >105 mm Hg vs >85 mm Hg in each category and we aim to have at least 20-30 patients randomized to each of the two arms of each substudy.

Results: The primary outcome is PO-AKI as defined by the AKIN criteria as a 50% relative or 0.3 mg/dL absolute increase in serum creatinine over the preoperative value during the first two post-operative days.

Conclusions: We hope to confirm our hypothesis that during anesthesia/controlled hypotension, the maintenance of SBP >105 mm Hg vs SBP >85 mm Hg reduced PO-AKI, patient morbidity and mortality, length of stay, the need for RRT and resulted in significant reductions in cost of care. Subsequently, we intend to use this pilot study preliminary data to apply for an NIH-funded study that would enable a larger national multi-center randomized controlled study.

PUB027

Enteric Fever Causing Hemolytic Uremic Syndrome

Hussein M. Bagha,[1] Shamsa H. Ahmed,[2] Ahmed Twahir.[3] *[1]Nephrology, M P Shah Hospital, Nairobi, Kenya; [2]M. P Shah Hospital, Nairobi, Kenya; [3]Parkland Kidney Centre, Nairobi, Kenya.*

Introduction: Hemolytic uremic syndrome presents with a classic triad of microangiopathic hemolytic anemia, thrombocytopenia and acute kidney injury. It is usually caused by toxigenic strains of Escherichia coli and Shigella dysenteriae. It can also be caused by Streptococcus pneumoniae and complement disorders. Typhoid fever causing hemolytic uremic syndrome is quite rare.

Case Description: A fifty four year ol male with no known comorbids presented with a seven day history of diarrhea. He had been started on ciprofloxacin after a stool for salmonella antigen was found to be positive. He presented after seven days with worsening of diarrhea and one day history of vomiting. Examination revealed mild dehydration with normal vital signs and tenderness in the right and left iliac fossa regions. His laboratory investigations showed an elevated urea and creatinine with a low potassium. Blood cultures done on the day of admission grew Salmonella typhi which was sensitive to ciprofloxacin. The platelets and hemoglobin dropped on the second and third day after admission. The lactate dehydrogenase was markedly elevated and a peripheral blood film showed schistocytes. He was started on hemodialysis, intravenous antibiotics and potassium supplementation. After three sessions of dialysis his kidney function started improving and had complete recovery of his renal function.

Discussion: Typical hemolytic uremic syndrome occurs secondary to infection by shiga-toxin producing E.coli and less frequently due to S.dysenteriae. It can also be caused by Streptococcus pneumoniae. Salmonella typhi is not a common cause of hemolytic uremic syndrome and there a few case reports in the literature of salmonella induced HUS. The inciting toxin in HUS due to Salmonella has not been identified. The treatment is mainly supportive comprising appropriate antibiotics, correcting fluid and electrolyte imbalances and timely dialysis. Most cases of acute kidney secondary to typical HUS are self limiting like in our case.

PUB028

Effect of Renin-Angiotensin-Aldosterone System Blockade on Long-Term Outcomes in Post AKI Patients with Hypertension

David Chih-Yu Yang,[1,2] Der-Cherng Tarng.[2] *[1]National Chiao Tung University, Taipei, Taiwan; [2]Taipei Veterans General Hospital, Taipei, Taiwan.*

Background: Post-acute kidney injury (AKI) patients are at risks for various complications. However, evidence regarding effective therapies to improve patient outcomes is lacking. We hypothesized that RAAS blockade is effective in improving renal outcomes in post-AKI patients who have hypertension.

Methods: From 2000 to 2013, we identified 12,084 AKI patients with hypertension in the nationwide database. All these patients experienced an AKI episode which required temporary hemodialysis therapy.

Results: In a median follow-up of 3.6 years, 2,637 patients (21.8%) required long-term dialysis and 5,094 (42.2%) died before progression to ESRD. Compared to post-AKI patients without using ACEI/ARB, ACEI/ARB users are less likely to suffer from future ESRD (adjusted HR, 0.90; 95% CI 0.83-0.99, $p = 0.022$) and all-cause mortality (adjusted HR, 0.92; 95% CI 0.86-0.97, $p = 0.003$). The renal benefit of ACEI/ARB use in post-AKI survivors was consistent across patient subgroups with different post-AKI renal function status, including those who fully recovered [non-chronic kidney disease (CKD)] and those who complicated with subsequent CKD stages 1-4.

Conclusions: For patients who experienced AKI and had hypertension, RAAS inhibitors should be the drug of choice to treat their hypertension.

The Role of Extracellular Histones in Patients with Lung-Kidney Cross-Talk: A Prospect Study

Min Gao,[1] Yizhi Cao,[3] Dawei Chen,[2] Xin Wan.[2] [1]*Department of Nephrology, Affiliated Sir Run Run Hospital, Nanjing Medical University., Nanjing, China;* [2]*Nanjing First Hospital, Nanjing, China;* [3]*Nanjing Medical University, Nanjing, China.*

Background: Extracellular histones have potential to affect distant organs when released from tissue injury. In this prospect study, we aim to investigate the impact of extracellular histones on the community-acquired pneumonia (CAP) patients with acute kidney injury (AKI), acute lung injury (ALI) or the combination of both.

Methods: Blood samples were obtained from 83 patients within 24h after admission at the hospital who were diagnosed with CAP. According to the discharge diagnosis, the patients were divided into 4 groups (AKI+CAP, ALI+CAP, AKI+ALI+CAP, and CAP). Then the subjects were split into 2 groups (histones <30 μg/ml and histones ≥30 μg/ml).

Results: Compared with the CAP group, the logarithms of the concentrations of the extracellular histones in AKI+CAP, ALI+CAP, and AKI+ALI+CAP groups were higher (P = 0.004, P = 0.029, and P < 0.001, respectively). The incidences of AKI and ALI were 39.8% and 28.9% in CAP patients. In CAP patients, Log_2 Histones (P = 0.002) and chronic kidney diseases (P = 0.039) were predictors of AKI, Log_2 Histones (P = 0.006) and surgery (P = 0.019) were risk factors of ALI. Compared with the histones <30 μg/ml group, patients in the histones ≥30 μg/ml more likely to admit to ICU (65.6% *vs* 33.3%, P = 0.004), to need mechanical ventilation (62.5% *vs* 31.4%, P = 0.005), and had longer duration of mechanical ventilation (6.9±9.5 *vs* 1.3±2.8, P = 0.002), longer ICU length of stay (6.1±7.9 *vs* 1.9±3.5, P = 0.007), and longer length of in-hospital stay (18.4±8.7 *vs* 12.7±5.9, P = 0.002).

Conclusions: Elevated extracellular histones were observed in CAP patients with AKI, ALI, and the combination of both. Our data supported that extracellular histones were a higher risk of developing AKI or ALI in CAP patients and a predictor of worse short-term outcomes.

PUB030

Effect of Hypertonic Saline and Furosemide on Urinary Markers of Kidney Injury

Frank H. Mose,[1] Marie H. Vrist,[2] Jesper N. Bech.[3] [1]*Holstebro Hospital, Holstebro, Denmark;* [2]*University Clinic of Nephrology and Hypertension, Holstebro, Denmark;* [3]*Holstebro Hospital and Aarhus University, Holstebro, Denmark.*

Background: Chloride is speculated to have nephrotoxic properties. In healthy subjects we tested the hypothesis that and acute chloride load with hypertonic saline would induce kidney injury, which could be prevented with the loop-diuretic furosemide.

Methods: The study was designed as a randomized, placebo-controlled, crossover study. Subjects were given hypertonic saline accompanied by either placebo or furosemide. Before, during and after infusion of hypertonic saline we measured glomerular filtration rate (GFR), fractional excretion of sodium (FENa), urinary chloride excretion (u-Cl), neutrophil gelatinase-associated lipocalin (u-NGAL) and kidney injury molecule-1 (u-KIM-1) as marker of kidney injury. Four days prior to each of the two examinations subject were given a standardized diet and fluid intake.

Results: U-NGAL and KIM-1 excretion increased slightly during hypertonic saline infusion. The increase in NGAL was absent when furosemide was given simultaneously, the responses in u-NGAL were not significantly different from placebo control (p = 0.214) with a general linear model (GLM)). Furosemide changed responses in KIM-1, where a delayed increase was observed. (p < 0.001 with GLM) GFR was increased by hypertonic saline, but decreased when furosemide accompanied the infusion. U-Na, FENa, u-Cl, and u-osmolality increased in response to saline and the increase was markedly pronounced when furosemide was added (p<0.001 with GLM for all variables)

Conclusions: This study shows minor increases in markers of kidney injury after hypertonic saline. Furosemide only changed response to KIM-1 and further investigations need to clarify if this is a protective renal response.

PUB031

Multiple Myeloma: An Uncommon Presentation of a Common Neurological Complication

Mansoor N. Ali. *Renal Mecdicine, Calderdale and Huddersfield Hospitals NHS Trust, Huddersfield, United Kingdom.*

Introduction: Multiple myeloma is a neoplastic proliferation of abnormal plasma cells. The clinical features of multiple myeloma depends on either direct proliferation of plasma cells resulting in extensive bony destructive lesions or indirectly related to paraprotein production mainly monoclonal immunoglobulins resulting in renal damage e.g. proteinuria, renal impairment (acute kidney injury), electrolyte disturbances and amyloid deposits. Multiple myeloma can also present with signs of spinal cord compression resulting in paraesthesia and paraplegia which can be missed and lead to delay in diagnosis and treatment.

Case Description: A 73 years old patient with past medical history of; asthma, atrial fibrillation on warfarin, bilateral knee replacements; presented to the emergency department, following recurrent mechanical falls. The patient had suffered prepatellar lacerations which was treated with suturing and discharged home. The patient further attended the emergency department with right knee pain and an inability to walk. The working diagnosis was right knee haematoma due to raised international normalised ratio (INR) since she was on warfarin. She required knee washouts and multiple blood transfusions due to anaemia and was subsequently discharged. The patient was re-admitted with recurrent falls. Further physiotherapy was arranged and plans made for discharge. During a weekend on call; the patient's husband asked the oncall consultant to review his wife as he was worried about her general decline and no one seemed to have listened so far. . The consultant listened to the husband and revisited patient's history. Upon examination; the patient appeared to have had significant neurological symptoms of spinal cord compression. A myeloma screen was requested due to anaemia. The patient underwent an urgent MRI scan and was transferred urgently to a neurosurgical centre for surgical decompression on the same day.

Discussion: Spinal cord compression from multiple myeloma, should be suspected in patients presenting with severe back pain along with weakness or paraesthesia, bladder or bowel dysfunction or incontinence, including unexplained anaemia (requiring blood transfusions). It is important to listen to patients and family when they warn us that their "loved ones" are not feeling right. Listening to patients and concentrating on their problems gives one more realistic ideas and insight into their problems

PUB032

Long-Term Outcomes After Leptospirosis: A Population Cohort Study

Chih-Hsiang Chang. *Chang Gung Memorial Hospital, Taoyuan, Taiwan.*

Background: Acute kidney injury (AKI) is a common complication of leptospirosis infection. However, the long-term outcomes following leptospirosis infection is not fully clarified. The aim of this study is to elucidate the long-term outcomes of adult patients who survived after leptospirosis.

Methods: The study analyzed datasets from Taiwan's National Health Insurance Research Database. The data of 2145 patients who survived after leptospirosis between January 1, 2003, and December 31, 2013, were analyzed. Characteristics and outcomes were compared according to the AKI or not to evaluate the impact of AKI on long-term mortality and major adverse kidney events.

Results: Of the 2145 patients, 26.0% had AKI and 3.5% received renal replacement therapy (RRT). Compared between the non-AKI, AKI and AKI-RRT, those with RRT had highest rates of all-cause mortality (22% vs 12.6% vs. 7.0%) and, advanced chronic kidney disease (0% vs. 1.09% vs 6.49%) respectively, demonstrating a significant trend (P < 0.001).

Conclusions: Patients who has leptospirosis related AKI, compared to those without AKI, have an increased risk of long-term mortality and major adverse kidney events.

PUB033

CRRT with Oxiris®: An Option for Multidisciplinary Treatment of AKI in Sepsis?

Nicoletta Pertica,[1] Alessia Corvo,[1] Paolo Ria,[2] Lorenzo Signorini,[1] Gianluigi Zaza.[3] [1]*Nephrology, AOUI - Borgo Trento, Verona, Italy;* [2]*Nephrology, Ospedale - V. Fazzi, Lecce, Italy;* [3]*University of Verona, Verona, Italy.*

Background: Septic shock is a serious cause of morbidity/mortality in ICU. MODS and AKI are common sepsis complications, burden by high mortality rates. CRRT, carried out by filters adsorbing sepsis mediators, can improve the outcome. The actual guidelines on sepsis highlights the importance of a timely start of CRRT.

Methods: We selected 27 consecutive patients with AKI in septic shock and treated through CVV-HDF with Prismaflex® and Oxiris®. We considered different laboratory parameters at regular time lapses after the CRRT start. As control group, we enlisted 20 patients from a historical cohort matched for diagnosis, treated with filter ST-150.

Results: We observed a statistically significant improvement for those treated by Oxiris®, particularly over kidney function recovery at 6 days (p =0.021) and reduction of inflammatory parameters (PCR p=0.006; PCT p=0.005). Over mortality, no difference emerged between infections caused by Gram + or Gram–, even if a better outcome was noted for Gram + related sepsis (G+ 83%vsG- 53%)

Conclusions: The use of specific filters for the treatment of sepsis with timely start of CRRT might help to improve the outcome of septic patients with AKI, not in terms of

absolute mortality, but reducing the indices of inflammation and shortening the functional recovery time.

The Anticoagulation Is the Single Most Important Factor Leading to Prolonged Filter Time on CRRT

Muhammad O. Saleem,[1] Colleen S. Boyle,[1] Azeem Mohammed,[1] N. Stanley Nahman.[1,2] Nephrons@AU *[1]Medical College of Georgia, Augusta University, Augusta, GA; [2]Norwood VAMC, Augusta, GA.*

Background: When providing continuous renal replacement therapy (CRRT) to the critically ill, circuit clotting is a key impediment to effective dialysis. Filter clotting may result from dysfunctional vascular access, inadequate anticoagulation, and/or selection of dialysis parameters that may promote clotting. To investigate the effect of these variables on filter life we performed a retrospective, performance improvement, analysis of the records of 33 CRRT patients treated in the intensive care units at Augusta University

Methods: A chart review was conducted and patients were sorted into two groups based on the presence or absence of anticoagulation. On each patient, we documented the indication for CRRT, vascular access specifications, dialysis modality, and prescription, which included therapy fluid rates, blood flow rates, and filtration fraction. The clinical characteristics of patients were also compared. Students t-test was used to compare the groups.

Results: Of the 33 patients 15 were anticoagulated with heparin, 18 received no anticoagulation. No patients received regional citrate anticoagulation in this study. The mean filter life in the first 24 hours for all patients was 16.03±11.9 hours. Patients treated with heparin had a significantly longer filter life in the first 24 hours (23.3±13.5 vs 9.9±6.8 hours for heparin vs no heparin, respectively, $p < 0.005$) The majority of patients (85%) received CVVH with the pre-filter administration of replacement fluid. The mean filtration fraction of all prescriptions was 19.40±4.03%. There was no difference in site, size, or diameter of dialysis catheters between the two groups.

Conclusions: Anticoagulation with heparin prolongs filter half life when compared to no anticoagulation. The use of heparin and prolonged filter life must be balanced with the risks of bleeding, however, substantially more dialysis can be given without interruption in heparinized patients. The role of regional citrate anticoagulation vs heparin or no therapy remains to be studied. The results support the use of heparin, when possible, to help maintain filter half life in CRRT.

PUB035

Infection in Community Acquired AKI

James Tollitt,[1] Nicola Bennett,[2] Smeeta Sinha,[1] James Ritchie,[1] Emma Flanagan,[3] Denise Darby,[1] Philip A. Kalra,[1] Dimitrios J. Poulikakos.[1] *[1]Salford Royal NHS Foundation Trust, Salford, United Kingdom; [2]University of Manchester, Manchester, United Kingdom; [3]Salford Care Organisation, Salford, United Kingdom.*

Background: The majority of acute kidney injury (AKI) is community acquired (CA). The interaction between community acquired (CA-I) and CA-AKI is incompletely understood. Recent sepsis guidance has included assessment of AKI for risk stratification to guide treatment. The aim of this study was to evaluate characteristics of CA-I and CA-AKI and their impact upon patient outcomes in general population and a care home population.

Methods: Adult, non-elective patient attendances to a single centre were analysed retrospectively. CA-AKI (AKI within 48 hrs of hospital attendance) and/or CA-I (antibiotic within 48 hrs of attendance) were recorded. Outcomes were 30-day all-cause mortality (30 DM), intensive care unit (ICU) admission and length of stay (LOS) dichotomised at median. Binary logistic regression models were created to predict the probability of the outcome variables in both patient groups.

Results: Of 61,471 attendances 4.2% were from a care home. In the total cohort 28.1% suffered CA-I and 5.7% suffered CA-AKI (3.8% AKI1, 1.1% AKI2, 0.8% AKI3). 3.4% suffered CA-I and CA-AKI. CAI-I was present in 58.9% of CA-AKI cases. 30 DM showed a stepwise increase in patients with CA-I (8.1%), with CA-AKI (11.8%) and with combination of CA-I and CA-AKI (26.2%). In the care home population 30 DM for the group with both CA-I and CA-AKI was 43.4%. In non-care home group those with both CA-I and CA-AKI had the highest rate of ICU admission (24%), followed by CA-I alone (7.2%) and CA-AKI alone (7.1%). Odds ratios (OR) for all outcome variables in non-care home population demonstrated an escalating association for poor outcomes (CA-AKI and CAI>CA-AKI alone>CAI alone) (Figure1).

Conclusions: CA-I is present in the majority of CA-AKI and their coexistence is associated with increased risk of poor outcomes.

Model for 30 Day Mortality in non care home patients

	OR	CI
Male	1.24	1.15-1.33*
Age	1.06	1.06-1.06*
CA-I	3.01	2.78-3.28*

PUB036

Transcatheter Repair of Tricuspid Regurgitation with the MitraClip Device and the Observed Rate of Post Procedure AKI

Ramy M. Hanna, James Wilson. *UCLA Health, Rolling Hills Estates, CA.*

Background: The MitraClip device was approved for transcatheter repair of significant mitral valve insufficiency instead of surgical repair. The device is now being used for non-surgical candidates with severe tricuspid regurgitation. As IV contrast dye is often not necessary for placement of the device in this subset of patients, we have sought to evaluate the risk of renal failure in patients who received the Clip in the tricuspid position.

Methods: At the University of California Los Angeles, the MitraClip is being used off-label in patients with significant tricuspid regurgitation who are not surgical candidates. We report our experience with the first five patients who have had this procedure completed at UCLA. We examine the rates of acute kidney injury post procedure in these five patients.

Results: Of the five patients, one had normal kidney function, three had underlying CKD and were not on dialysis, and one had ESRD and was on dialysis. Acute kidney injury, defined as a rise in serum creatinine by 0.5mg/dL was observed in two of four patients (50%) who underwent this procedure and were not on dialysis. The one patient without CKD did not suffer acute kidney injury but had a mild rise in serum creatinine. The one dialysis patient who underwent this procedure had no discernible change in renal function. These procedures were done without iodinated contrast

Conclusions: We examine the rate of AKI post off label tricuspid valve repair with MitraClip, further data should be sought out as this procedure is increasingly implemented.

Table 1: Clinical cases involving percuatenous tricuspid valve repair (TriClip) procedure

Renal Prognosis Is Related with Delta Neutrophil Index in Patients with Alcoholic Ketoacidosis

Jun Young Lee,[1] Jae seok Kim,[3] Seung-Ok Choi,[2] Byoung Geun Han.[1] *[1]Wonju Christian Severance Hospital, Wonju, Kangwon do, Republic of Korea; [2]Yonsei University Wonju College of Medicine, Wonju, Kangwon, Republic of Korea; [3]Yonsei wonju college of medicine, Won-ju, Republic of Korea.*

Background: Alcoholic ketoacidosis is metabolic abnormalities often diagnosed in malnourished patients chronically abuse alcohol and have a history of alcoholic binge. Delta neutrophil index (DNI), representing an elevated fraction of circulating immature granulocytes in acute infection, has been reported as a useful predictable marker for mortality in patients with sepsis. We make an attempt to reveal clinical charateristics and found prognostic factor including DNI associated with alcoholic ketoacidosis in this study.

Methods: We investigated patients diagnosed with AKA who visited the emergency department fo Wonju Severance Christian hospital from October 2009 to March 2014 retrospectively. Patients have history of alcohol abuse and recent episode of binge drinking with metabolic acidosis in ABGA and increased serum anion gap in serum chemistry were included. We categorized according to KDIGO Acute kidney injury criteria and compared groups about prognostic factors

Results: In a total of AKA cases, 95 (80.5%) were diagnosed with AKI by KDIGO criteria: 27 cases (22.9%) were classified as AKI stage 1, 15 cases (12.7%) as AKI stage 2, 53 cases (44.9%) as AKI stage 3. Mortality was reported in 38 cases (32.2%), and the mean time from admission to mortality was 6.4 ± 12.1 days. Major causes of death included uncontrolled metabolic acidosis (n=25, 21.2%), septic shock (n=10, 8.5%), and gastrointestinal tract bleeding (n=1, 0.8%). There were significant differences in pH, PCO_2, lactate, Hb, platelets, PT, PTT, Cr, albumin, AST, GGT, Total bilirubin, P, Ammonia, T3, fT4, and DNI (P<0.001) between survivors and non-survivors. DNI was higher value in AKI stage III compared with AKI 0 to 2 stage significantly (p<0.001)

Conclusions: Delta neutrophil index have a significant value in predicting alcoholic ketoacidosis with poor renal outcome and mortality.

PUB038

Obstructive Uropathy with Uremia Due to Advanced Cervical-Uterine Cancer

Héctor R. Ibarra-Sifuentes,[1,2] Raymundo Vera,[2] Edgar F. Carrizales Sepulveda,[2] Fernando G. Ruiz Hernandez,[1] Angel N. Del cueto aguilera,[2] Marco D. Del cueto aguilera,[3] Luis I. Bonilla,[1,2] Sergio Alvizures,[1,2] Michelle Morcos sandino,[1] Diego Martinez yañez,[1] Lilia M. Rizo Topete,[1,2] Giovanna Y. Arteaga Muller.[1,2] *[1]Nephrology, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico; [2]Internal Medicine, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico; [3]Ginecology, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico.*

Background: Cervical-uterine cancer (CUC) is a worldwide public health problem. Advanced CUC affects nearby regional structures causing obstruction. Rarely, obstructive uropathy can cause acute kidney injury (AKI), which leads to uremic syndrome. In extreme situations, urgent treatment such as ureteral stent placement, nephrostomies and hemodialysis, as saving life modalities, are required.

Methods: We retrospectively analyzed the characteristics of AKI patients due to obstructive uropathy caused by advanced CUC presenting to the emergency department in a teaching hospital, located in Mexico, during may 2013 to may 2018.

Results: 28 patients were analyzed, 45 years as mean age. The main identified comorbidities were Diabetes Mellitus, identified on 5 (17%) of the patients, and Hypertension identified on 5 patients also. The mean evolution of CUC period was 22 years. 60% of the patients had metastatic CUC. The mean Eastern Cooperative Oncology Group score was 2.3. The most common presenting symptom was malaise and weight loss on 57% and 46%, respectively. The mean Blood Urea Nitrogen and Creatinine was 86 ±60 mg/dL and 6.9 ± 6.5mg/dL, respectively. 46.4% of the patients underwent JJ stent placement, and 39% required nephrostomies. 96% had bilateral hydronephrosis. The mean hospitalization period was 6.7 days. 10 patients (36%) died, with a mean survival of 6 ±6 months. Survival analysis showed no difference in mortality when comparing both treatment arms (long-rank test: 0.95).

Conclusions: Advanced CUC, in our country, is a public health issue and a considerable cause of uremia and AKI. Those patients had a mean survival of 6 months irrespective of the palliative treatment modality.

From Heparin to Citrate Anticoagulation in CRRT: Efficiency and Expense Evaluation

Davide Ricci, Laura Panicali, Giuseppe Cavallari, Maria grazia Facchini, Elena Mancini. *Nephrology, Dialysis and Hypertention Unit, S.Orsola - Malpighi Teaching Hospital, Bologna, Italy.*

Background: CRRT is used as a therapy for acute kidney injury in intensive care units. Heparin has long been used as an anticoagulant during CRRT (efficacy-low cost) but, starting from the KDIGO 2012 guidelines, citrate has become first-choice anticoagulant.

Methods: From 2011 to 2017 we performed 11,109 CRRT treatments (1 treatment = 24 h CRRT) with an increasing percentage of citrate anticoagulation, from 2.9 to 73%. We performed a retrospective analysis starting from the quantity and cost of materials (Kits+solutions) and evaluated efficiency and expense.

Results: a) reduction in the number of filters used for every 72 hours of treatment, from 2.4 to 1.5; b) increase in the administered dialysis dose, from 25.7 to 37.5 ml/kg/h; c) reduction in the difference between prescribed and administered dialysis dose, from 22 to 7%; d) slight increase in the total cost for 24 hours' CRRT, from €161.03 to €184.54; e) reduction in the total cost for each 35ml of solution administered, from € 0.13 to € 0.10 (e.g. 134960000 ml solution used in 2017).

Conclusions: The limits of the study are its retrospective nature and data collection not regarding single treatments but starting from the total quantity of materials used and thus ruling out statistical analysis of significance. With citrate we observed a slight increase in the total cost but also a reduction in the cost per unit of administered dialysis dose. Furthermore, we obtained an increase in the average life of the filter and an increase in the efficiency of the treatment (prescribed dialysis dose *versus* administered dose).

An Update on the Use of Novel Biomarkers for AKI in Drug Development

Carolina Panico, Aliza M. Thompson. *U.S. Food and Drug Administration, Silver Spring, MD.*

Background: In 2008, FDA qualified 7 urinary biomarkers to be used, in conjunction with serum creatinine, BUN and histopathology, as additional evidence to identify early signals of kidney injury in the rat. Since then, there has been increased use of these biomarkers in drug development programs. The objective of this study is to characterize the data that can be leveraged on the performance of these biomarkers and use to inform decision making in drug development programs.

Methods: The FDA document archiving, reporting and regulatory tracking system was used to retrieve biomarker information contained in Investigational New Drug applications (INDs), using KIM-1 (kidney injury molecule-1) as the search term. The following information was collected: urinary biomarkers assessed, pre-analytical information, such as collection method, storage and processing of samples, information on assays, and status of the drug development program, including stage of clinical development and whether studies were still being pursued under the IND.

Results: A total of 143 INDs referenced the use of KIM-1 between 2005 and 2016. Of these, 51 INDs contained summary or patient-level data on KIM-1; 41 also contained information on other novel urinary biomarkers. In 45 INDs, the biomarkers were used in safety assessments, whereas in 6 INDs the biomarkers were used in efficacy evaluations. Among the 51 INDs, 45 reported the use of the biomarkers in preclinical studies and 11 in clinical studies (8 phase I and 3 phase II studies). 15 of 51 applications contained pre-analytical and assay information, though the granularity of that information varied greatly across the 15 INDs. Of the applications in which the biomarkers were used to assess drug-induced kidney injury, 33 were still active. In contrast, only two of 6 INDs identified as using the biomarkers for efficacy assessments were still active at the end of 2016. Based on the submitted data, it is unclear to what extent the biomarker data influenced the decision to pursue further investigation of the drug.

Conclusions: Although novel renal biomarkers are being used in drug development, most INDs do not appear to contain granular information on pre-analytical variables and assay(s) or data sets, which may limit the ability to leverage data that are currently available to FDA to learn about the performance of the biomarkers as drug development tools.

PUB041

Reduction of Inpatient Length of Stay, Readmissions, and Associated Healthcare Costs Through Early Detection of AKI Using a Urinary Biomarker: Results of an Economic Model

Mauricio Berdugo,[2] Lauren M. Scarpati,[1] Seth Toback,[2] Louise Zimmer,[2] Michael N. Stone,[1] Ross M. Dember,[1] Jody C. Wen,[1] Joshua M. Tseng-Tham,[1] Noam Y. Kirson,[1] Mark Miller.[2] *[1]Analysis Group, Inc., Boston, MA; [2]bioMérieux, Durham, NC.*

Background: [TIMP-2/IGFBP-7] NephroCheck® (NC) is a novel biomarker-based, FDA-cleared urine test to aid in assessing risk for moderate or severe acute kidney injury (AKI) in ICU patients. NC measures the levels of two urinary biomarkers indicating higher risk of AKI, and is thus able to identify AKI earlier than the existing standard of care (SOC). We evaluated via an economic model if early identification of AKI, by using NC, could reduce the severity of AKI, thereby improving patient outcomes, such as length-of-stay, readmissions and healthcare costs.

Methods: An Excel-based economic model (2017 USD) using peer-reviewed data was developed from the perspective of a hypothetical hospital system. The model estimated the impact of testing patients for AKI using SOC versus a combination of SOC plus NC over a 1-year period. Outcomes considered included lengths of ICU and non-ICU inpatient stays, 30-day readmissions, and net impact on hospital budget. Model inputs included literature-based estimates for diagnostic efficacy of NC plus SOC and for patient healthcare resource utilization associated with levels of AKI severity, as well as data on file for costs associated with NC test meters and cartridges.

Results: Assuming 500 hypothetical at-risk patients were tested, improved diagnostic efficacy using NC in addition to SOC would result in 283 fewer non-ICU inpatient days (0.6 days per tested patient [PTP]), 152 fewer ICU days (0.3 days PTP), and 5 fewer 30-day readmissions. The incremental cost of using NC is more than offset by these reductions, resulting in annual net savings of $799,479 ($1,599 PTP) or 10.1% to the overall hospital budget. Deterministic and probabilistic sensitivity analyses support improved patient outcomes and associated savings in over 99% of scenarios.

Conclusions: This model demonstrates that the addition of NC to SOC for the earlier identification of AKI is likely to result in moderate reductions in inpatient non-ICU and ICU lengths of stay, 30-day readmissions and total healthcare costs. Further studies are needed to confirm these findings in a real-world setting.

AKI Mortality Across KDIGO Classification Strata: Does Previous CKD Matter?

Maria Isabel Acosta-Ochoa, Armando Coca, Alicia Mendiluce. *Hosptal Clinico Universitario Valladolid, Valladolid, Spain.*

Background: Few works compare in-hospital mortality in individuals with previous normal (ARF) and impaired (Acute on CKD) renal function who suffer AKI, and fewer compare mortality between strata inside KDIGO stages. We hypothesize that AoCKD individuals perform distinctly across the classification.

Methods: Retrospective study of ARF and AoCKD patients classified by KDIGO guidelines. We analyzed epidemiological variables, compared the clinical outcome in-hospital mortality, and analyzed the distribution through KDIGO stages of all cohort and subanalyzed dead patients.

Results: 1269 individuals were included. Table 1 summarizes clinical characteristics and results of both groups. Compared with ARF individulals, AoCKD patients are older, have a higher Charlson's Index, are more frequently classified in Stage 1 (both criteria), lesser in Stage 2, and equal in Stage 3. Global mortality is not significantly different between groups, we checked every KDIGO Stage and mortality was significantly higher in Stage 1 (for both criteria), lower in Stage 2 and equal in Stage 3. When evaluating every component of Stage 3 we found that 29% of AoCKD individuals (vs 67% ARF) reached a 3x SCr increment, 65% (vs 42% ARF) reached a SCr ≥4.0 mg/dl (21 patients had already a basal SCr ≥4.0 mg/dl), and no difference in initiation of renal replacement therapy (RRT).

Conclusions: Although in-hospital mortality is not significantly different between groups, when analyzing KDIGO strata we found excess mortality for the AoCKD individuals in Stage 1 and 3. The smaller proportion of SCr x 3.0, and the excess in SCr ≥4.0 mg/dl may be due to diminished renal reserve and higher basal SCr. The facts that the same proportion of patients in both groups initiate RRT, and that in Stage 2 a smaller proportion of AoCKD patients died, deserves further investigation.

Incidence of AKI in a Large Retrospective Cancer Cohort Using Checkpoint Inhibitors

Ala Abudayyeh,[1] Chukwuma O. Kalu,[5] Laila S. Lakhani,[2] Biruh Workeneh,[3] Amit Lahoti,[4] Sheldon Chen,[5] Farhad R. Danesh,[6] Maen Abdelrahim.[7] *[1]The University of Texas MD Anderson Cancer Center, Houston, TX; [2]UT Houston, Houston, TX; [3]MD Anderson Cancer Center, Houston, TX; [4]M D Anderson Cancer Center, Houston, TX; [5]MD Anderson, Houston, TX; [6]UT MD Anderson, Houston, TX; [7]Houston Methodist Cancer Center, Houston, TX.*

Background: With the advent of the era of immunotherapy there has been marked increased survival in several cancers such as advanced melanoma, renal cell carcinoma, non-small cell lung cancer (NSCLC), urothelial carcinoma, and head and neck cancers. Although the incidence of renal toxicity is reported 3.8%, we believe that it is much higher. In this study we sought to retrospectively review a 10 year experience at MD Anderson Cancer Center of patients with cancer and treated with CPI and evaluate incidence of AKI, CKD, and overall survival.

Methods: We performed a retrospective chart review from 2008-2018 and extracted all patients treated with Ipilimumab, Nivolumab, Pembrolizumab, Atezolizumab, Durvalumab, and Avelumab. We identified 6412 unique patients and extracted all avaliable creatinine and GFR. We have defined AKI based on KDIGO guidelines excluding urine output. We also are also interested in evaluating the overall renal outcomes looking at CKD as persistent GFR over three month period at end of the study. Variables to be studied basic demographics, type of cancer, type of CPI, number of doses, dosages, and CKD stage at beginning of the study period. We have three primary endpoints: incidence of AKI, stage of CKD, and overall survival. We will perform Cox proportional hazards regression models to estimate unadjusted and adjusted cause-specific hazards ratios (HR) of risk factors for all three endpoints.

Results: We have identified 6412 patients with diagnosis melanoma, sarcoma, lung cancer, renal cell cancer, and hematological malignancies. The patients have been categorized as either single agent CPI or combinations. Based on our preliminary data and further verification is underway the incidence of AKI is higher than reported in the literature and estimated at >25%. Since patients with Renal cell cancer maybe predisposed to having AKI and CKD in setting of solitary kidneys we will be perform a subpopulation analysis.

Conclusions: With such a large population of patients treated with CPI we would be able to understand the variables associated with renal toxicities, such as type of CPI, combinations, or dosage and help create more accurate guidlines. This would impact renal survival which would impact ultimately patients overall survival.

PUB044

AKI in the Setting of Coronarography Procedures: A Monocentric Analysis

Matteo Floris,[1] Maria Rosaria Concas,[1] Nicola Lepori,[1] Andrea Angioi,[1] Maurizio Porcu,[2] Bruno Loi,[2] Gianfranca Cabiddu,[1] Antonello Pani.[1] *[1]Nephrology, Ospedale Brotzu, Cagliari, Italy; [2]Cardiology, Ospedale Brotzu, CA, Italy.*

Background: Acute Kidney injury (AKI) is a common complication of coronarography, PTCA and TAVI, with a literature reported incidence ranging from 7 to 12%. This study investigates incidence, risk factors and outcomes of AKI in patient who undergo to coronarography procedures with intraarterial administration of contrast medium.

Methods: We retrospectively reviewed data from all the adults who underwent to diagnostic or therapeutic coronarography procedures at the Cardiology Department of Brotzu Hospital in 2016 and had least one creatinine value 7 days before and 72 hours after the procedure. Patients who were on dialysis at the time of the procedure and those who underwent to cardiac catheterization were excluded from the analysis.

Results: 375 patients were included in our analysis. Among them a total of 57 (15.2%) developed AKI (according KDIGO definition): 30 patients (8%) developed CI-AKI. 49 patients reached stage 1 AKI (according KDIGO definition), 2 and 6 developed stage 2 and stage 3 AKI respectively. Diagnosis of AKI was associated with older age (73.6 vs 65.7), lower eGFR before procedure (53 ml/min vs 81.5 ml/min), preexisting CKD (OR 5.3), hypertension (OR 1.86), CHF (OR 2.20) and higher Mehran score (8.47 vs 5.01). AKI required begin of renal replacement treatment in 3 patients. The mean contrast medium dose was not significantly different between patient who developed AKI and those who did not, while radial access was associated with a lower incidence of AKI. At 12 months follow-up 7 patients of AKI group were on dialysis, while only 1 patient from non-AKI group needed RRT (12.3% vs 0.03% OR 44.4); risk of mortality was significantly higher in patients who developed AKI (17.5% vs 3.7% OR 5.42). No significative difference were found between who developed CI-AKI and those who developed AKI but did not meet criteria for CI-AKI.

Conclusions: Our analysis describes risk factors who should evaluated in patients who should undergo to coronarography procedures: older age, previous CKD, hypertension, CHF. Since criteria for CI-AKI were met in 52% of AKI cases, 48% of patients developed a kidney damage with no clear correlation with contrast medium: hemodynamic factors, renal atheroembolism and drug nephrotoxicity should, therefore, be considered as further kidney injury cause in these patients

PUB045

The Location of the Short Term Catheter for Continuous Renal Replacement Therapy Does Not Affect the Patient's Short Term Outcome

Ha nee Jang,[1] Tae won Lee,[3] Ji-Hye Kwak,[1] Eunjin Bae,[3] Hyun Seop Cho,[1] Hyun-Jung Kim,[1,2] Dong Jun Park,[3,2] Se-Ho Chang.[1,2] *[1]Gyeongsang National University Hospital, JINJU, Republic of Korea; [2]School of Medicine, Gyeongsang National University, Jinju, Republic of Korea; [3]Gyeongsang National University Changwon Hospital, Changwon, Republic of Korea.*

Background: Many severe acute kidney injury (AKI) patients in the intensive care unit(ICU) has received renal replacement therapy and the patients with hemodynamic instability receive the continuous renal replacement therapy (CRRT). The vascular access for CRRT is usually performed using a short term catheter. In KDIGO guidline., When choosing a vein for insertion of a dialysis catheter in patients with AKI, consider these preferences.: 1st choice: right jugular vein (RJV); 2nd choice: femoral vein(FV); 3rd choice: left jugular vein(LJV); Last choice: subclavian vein(subV). But, There are many patients who have access to the FV more than the Internal JV in the clinical setting, The aim of this study was to investigate the relationship between catheter location and patient prognosis and norepinephrine(NE) dose changes.

Methods: We retrospectively studied on patients who received CRRT in the ICU on our hospital from January 5, 2016 through December 31, 2016. Among these patients, We excluded patients under 18 years, End stage renal disease, without central venous catheterization, not using NE, using NE and other additional vasopressors and using Extracorporeal membrane oxygenation. They were divided two groups based on the double lumen catheter insertion site. Femoral vein insertion was assigned to group 1 and the other site was assigned to group 2. The 28-day mortality and NE dose changes were compared between the two groups. We calculated the difference by measuring the amount of NE injection at the start of CRRT and the amount of NE injection after 6 hours.

Results: All patients who received CRRT in the ICU on our hospital was initially screened.(n=186). We excluded 124 patients according to exclusion criteria. A total of 62 patients were included in the analyses. The median age of patients is 68(21-90) year-old and men were 67.7% (n=42). 28-day mortality rate was 56.5% and the septic shock was the main cause of CRRT (n=46, 74.2%). The 28-day mortality rate was not different between the two groups. [48.4%(n=15) vs.64.5% (n=20), P=0.2]. And NE dose changes were also not different between the two groups. [-1.3699(-44.99 – 128.74) vs. 0.0000(-66.67 – 97.86) ug/kg/hr, P=0.767.].

Conclusions: The insertion site of the catheter in patients with CRRT does not affect the patient's short term out coming.

PUB046

A Novel Hemodialysis System, Deployed in an Acute Setting, Provides Volume Management at Lower Cost Than CRRT

Sevag Demirjian,[3] Glenn M. Chertow,[2] Luis Alvarez.[1] *[1]Palo Alto Medical Foundation, Palo Alto, CA; [2]Stanford University School of Medicine, Palo Alto, CA; [3]Cleveland Clinic, Cleveland, OH.*

Background: There is an increasing prevalence of AKI requiring renal replacement therapy. Care of this patient population is challenging to health care systems (HCS) both in costs and logistics. HCS increasingly face nursing shortages and flat reimbursement rates for care of this patient population, straining abilities to provide effective dialysis.

Methods: As part of a QAPI project, we first examined the number of dialytic therapies, grouped by modality, conducted in intensive care settings at the Cleveland Clinic between 2013 and 2016. Secondly, we piloted the use of novel, simple to use hemodialysis system (Tablo) as a transitional modality, in 80 patients ready to transition off CRRT, but that remained clinically volume overloaded. This is a cost-effectiveness analysis of our PIRRT experience using Tablo compared to existing options.

Results: During 4 years of study, the number of intermittent dialysis treatments in the ICU stayed stable, however the number of continuous dialysis treatment days increased (Table 1). 80 patients were dialyzed using Tablo, for 6-8 hour treatments at QB of 200-300 ml/min and QD of 300 ml/hr. The cost of PIRRT using Tablo is presented in Table 2.

Conclusions: Treating this critically ill cohort at the Cleveland Clinic, we demonstrate that Tablo can enable transitional hemodialysis while markedly reducing staffing costs. These data suggest that Tablo can provide increased functionality and flexibility to cost and staff constrained ICUs.

Clinical Study and Outcome of Patients with AKI Following Exposure to Various Poisons with Special Emphasis on Paraquat Poisoning

Renu M. Bharne,[1] Muntazir Ali P. Sayed.[2] *[1]RCSM Government Medical College and CPR Hospital, Kolhapur, Maharashtra, India, Thane, India; [2]RCSM Government Medical College Kolhapur, India., Mumbai, India.*

Background: Exposure to compounds like pesticides, herbicides and insecticides have hazardous effects. ARDS, AKI, multiorgan failure are the frequent causes of mortality. Paraquat is a weedicide used commonly for suicide in southern Maharashtra. It is always fatal as there is no specific antidote. Current study highlights the occurence of Acute kidney injury and its outcome after exposure to various poisons amongst patients admitted to RCSM GMC and CPR Hospital, a tertiary care centre in Kolhapur, Maharashtra.

Methods: We carried out a retrospective observational study where data was collected from case records of patients admitted from May 2015 to April 2018 and their outcome was noted. The aim was to study the morbidity and mortality rates of different poisons with special focus on Paraquat compound. Almost all patients included required hemodialysis, especially with Paraquat poisoning and associated mortality was compared with other poisons combined. Adequate statistical test was used and a p-value <0.05 was considered statistically significant

Results: During the study period we found 347 patients of poisoning who developed AKI requiring dialysis. The largest group was from Paraphenyline diamine (PPD) of 94 patients followed by Organophosphorus compound (73), Paraquat (66), Copper sulphate (42) Methanol (20) and other poisons (52). The outcome of ingestion of these poisons is summarized in Table 1. Mortality associated with Paraquat was 86.36% (N=57) whereas it was 43.82% (N=78) among other poisons combined. This difference was statistically significant ($x^2 = 69.70$, $p < 0.0001$)

Conclusions: It is important to report all the poisonous substances. causing nephrotoxicity to increase awareness among general population and health care providers. Of all registered herbicides, Paraquat is the most fatal and despite early hemodialysis, the mortality rates remained high. Newer treatment options like early hemoperfusion may help to reduce the mortality in future.

AKI and Complete Heart Block in Hepatitis E Infection

Prof Narinder P. Singh, Purneetha Singh, Swapan Deep Singh Nagpal, Anish Gupta. *Max Super Speciality Hospital, Ghaziabad, India*.

Introduction: Hepatitis E is a benign, usually self-limiting viral infection with primary symptoms of fever, myalgia, fatigue, nausea and vomiting. Acute kidney injury is uncommon in hepatitis E infection and hence not frequently anticipated. We present a patient with type II diabetes mellitus (DM) with two episodes of syncope. Investigation revealed AKI, hyperkalemia and complete heart block, all secondary to Hepatitis E infection.

Case Description: A 71 year male, presented with two episodes of syncope and fall, decreased urine output and complete heart block. Temporary pacemaker implantation was done. On detailed evaluation, he gave history of fever, vomiting, fatigue and loss of appetite for the last 1 week. Examination revealed bradycardia, right hypochondrial tenderness and decreased breath sounds in bilateral intrascapular regions. Initial investigations revealed grossly elevated cardiac enzymes, leukocytosis, hyperglycemia, hyperkalemia (Serum potassium - 6.4 mEq/L) and markedly deranged renal, liver and coagulation profiles. Measures to counter hyperkalemia, broad spectrum antibiotics and insulin therapy were initiated. Ultrasound was suggestive of ascites and bilateral pleural effusion; and possible underlying chronic kidney disease. 2D Echocardiography showed hypokinesia of the basal inferior and infero-lateral walls with ejection fraction of 50%. He was hemodialysed in view of the decreased urine output and hyperkalemia. Investigations done to rule out the cause of acute liver injury revealed serology positive for hepatitis E infection. After clinical and symptomatic improvement, the pacemaker support was withdrawn and there was reversion to sinus rhythm. The patient was discharged in a stable condition after over a fortnight in the hospital. He was followed up in OPD where he was asymptomatic and had a normal renal profile.

Discussion: Acute Kidney Injury is an uncommon manifestation of Hepatitis E infection. Complete heart block due hyperkalemia secondary to AKI (with a serum potassium of 6.4 mEq/l) is unlikely and may occur due to myocarditis or an underlying coronary artery disease. The clinician should be aware of the extra hepatic manifestations of hepatitis E infection including AKI and arrhythmias, which, if identified in time could be treated promptly with good outcomes.

PUB049

Nonagenarians in Northern Jordan Are at Risk for AKI: A Retrospective Case-Control Study

Sameeha A. Alshelleh,[1] Ashraf O. Oweis.[2] [1]*University of Jordan, Amman, Jordan;* [2]*Jordan University Of Science and Technology, Amman, Jordan*.

Background: Improvements in healthcare systems worldwide have had notable effects on the life expectancy of older individuals. As a result, nonagenarians are emerging as a separate age group with distinct healthcare needs. We evaluated the incidence and outcome of acute kidney injury (AKI) in nonagenarians who were admitted to one regional city hospital in Jordan

Methods: In our retrospective chart review, we included all patients 90 years of age and above who were admitted to the floor at our University hospital, between January 2010 and December 2013. Patients with Stage I, II or III chronic kidney disease (CKD) were included in the analysis. Our exclusion criteria included those patients with Stage IV and V CKD. The incidence of AKI was determined by using data from the Acute Kidney Injury Network Classification (AKIN). Primary outcome variables included length of in-hospital stay and mortality rates.

Results: Of the total 283 patients who were evaluated during the study period, 48 patients with end stage renal disease (ESRD) were excluded. In the 253 patients who were included, the mean age was 91.5 years, 61 of the patients developed AKI (25.9%), and 41 patients were in Stage 1 AKI (66.1%) according to AKIN criteria. A total of 57 patients died during the study period and 33 of these patients (57.9%) had AKI. Hospital stay was longer in patients with AKI with a mean length of stay of 8.1 days. Congestive heart failure, cancer, and use of non-steroidal anti-inflammatory drugs were the main risk factors for AKI in our patients.

Conclusions: AKI is common in nonagenarians with increased risk for mortality and increased hospital stays.

The Kinetics of Fluid Overload Are Associated with Outcomes in Critically Ill Patients

Rajit K. Basu,[1] Shina Menon,[2] Stuart Goldstein.[3] [1]*Children's Healthcare of Atlanta, Atlanta, GA;* [2]*Seattle Children's Hospital, Seattle, WA;* [3]*Cincinnati Children's Hospital Medical Center, Cincinnati, OH*.

Background: Recent data indicate fluid accumulation in critically ill patients, termed fluid overload (FO), is associated with poor outcome. There is little discussion of how timing and rate of fluid accumulation associate with morbidity. We hypothesized how fluid accumulates is associated with patient morbidity.

Methods: We performed a post-hoc analysis of a prospective observational study of patients requiring mechanical ventilation admitted to a pediatric intensive care unit (PICU). Fluid accumulation was studied using three definitions. Absolute FO was calculated as a percentage (%FO). Delta FO was the defined as the change in %FO on consecutive days (e.g., %FO Day 2 - % FO Day 1). Fold FO was defined as the fold difference in %FO between days (e.g., % FO Day 2 / % FO Day 1). The maximum value identified in the first seven days of ICU was used and FO were definitions separated into strata. The primary outcome of interest was mechanical ventilation (MV) duration. Other outcomes of interest included length of stay (LOS), renal replacement therapy (RRT) use, and mortality. All outcomes were assessed at 28-days.

Results: 124 patients (64 male) aged 8.6 ± 6.5 years were studied (Figure 1). While there was no difference in MV duration for patients based on Absolute %FO (f-ratio=0.22, p=0.79), MV duration steadily increased between the Delta FO strata and also in the Fold FO strata (f-ratio=1.99, p=0.13 and f-ratio=2.55, p=0.08, respectively). Absolute %FO was not associated with ICU LOS (f-ratio=0.7, p=0.49), but there was a significant LOS difference with both escalating Delta FO and Fold FO (f-ratio=3.2, p=0.04 and f-ratio 3.3, p=0.04, respectively). RRT utilization and mortality were not associated with absolute % FO, delta % FO, or % fold FO.

Conclusions: Our data suggests how fluid accumulates in critically ill patients affects morbidity. Rapid accrual fluid through ICU course, even after initial resuscitation, demonstrates a greater association with poor outcome than absolute maximum fluid overload. Expanded study of our initial findings is warranted.

Index	N (%)	MV Duration (Days)	ICU LOS (Days)	RRT Use N (%)	Mortality N (%)

Functional Investigation of miR-17-5p Inhibition in Kidney Ischemia-Reperfusion Injury in Mice

Peter Hamar,[2,3] Tamás Kaucsár.[1] [1]*Semmelweis University, Budapest, Hungary;* [2]*Institute for Translational Medicine, University of Pécs, Pécs, Hungary;* [3]*Clinical Experimental Research Institute, Semmelweis University, Budapest, Hungary*.

Background: One of the most common causes of acute kidney injury (AKI) is ischemia-reperfusion (IR), which increases the risk of renal fibrosis and chronic kidney disease. Our group has previously described the activation of the pro-proliferative and anti-apoptotic miR-17-5p in IR induced AKI. Our aim was to investigate the function of miR-17-5p in IR-induced renal fibrosis in mice.

Methods: AKI was induced in the left kidneys of C57BL / 6N mice with 20-minute ischemia, without the removal of the right intact kidney. One day before the IR operation, mice were given miR-17-5p silencing (17-LNA-IR group, N = 10) or scrambled sequence (SCR-

IR group, N = 10) locked nucleic acid (LNA) modified antisense oligonucleotides[EO1] (30 mg / kg, ip). On the 7th reperfusion day, the efficacy of the miR-17-5p inhibition was evaluated in the injured and control kidneys (qPCR). In addition, we investigated the extent of tubular damage in histological sections (PAS, HE), the miR-17-5p-target p21 mRNA expression, the tubular damage (KIM1 mRNA), fibrosis (FN1 mRNA), inflammation (TNFα mRNA), the oxidative stress response (NRF2 mRNA), and the proliferation (PCNA mRNA) with real-time PCR.

Results: At the 7th reperfusion day, specific LNA inhibition prevented the increase in miR-17-5p expression (1.62x, p <0.01, SCR-IR vs. non-IR) in the damaged kidneys (0.49x, p < 0.0001; 17-LNA-IR vs. SCR-IR). The inhibition of miR-17-5p following IR had no[EO1] significant effect either on the histological damage, or on increased KIM1 (83.2x, p <0.0001), FN1 (8.6x, p <0.0001), TNFα (5.8x, p < 0.0001), NRF2 (1.4x, p <0.01), PCNA (1.3x, p <0.05), and p21 (3.8x, p <0.0001) mRNA levels.

Conclusions: While miR-17-5p could have renoprotective effects, our findings suggest that miR-17-5p inhibition has no significant effects on the IR-induced AKI outcome. New National Excellence Program (Immuno Pathophysiology) OTKA (114619), Kispál Gyula Program 30021

Intestinal Apoptosis, but Not Tight Junctions, Contributes to the Translocation of Bacteria/Endotoxin in a Rat Model of Non-Ischemic AKI

Jiangtao Li,[1] Chen Yu,[1] Lirui Wang,[2] Kun Zhang.[1] *[1]Nephrology, Shanghai Tongji Hospital,Tongji University School of Medicine, Shanghai, China; [2]Tongji Hospital of Tongji University, SHANGHAI, China.*

Background: To investigate whether translocation of bacteria and endotoxin develops in acute kidney injury (AKI), and, if so, what are the mechanisms behind it.

Methods: Sprague–Dawley (SD) rats were subjected to bilateral nephrectomy (BNx) or sham-operation (n=5/group) and observed for 24h. The pathology of ileum was scored. Apoptosis in ileum was detected by TUNEL staining and DNA fragmentation ELISA. Gut mucosal permeability was evaluated in vivo and ex vivo. Serum endotoxin levels were measured by LAL method. Bacterial load in liver was measured by 16srDNA analysis. The expression of tight junctions(TJs) in ileum, including zonula occluden-1, Occludin and Cludin-1 was measured by Western blot. Transmission electron microscopy was used to detect the alterations of cell-cell junction.

Results: Compared with the sham rats, the BNx rats showed elevated intestinal damage scores (Fig.A-B), accelerated apoptosis in ileum (Fig.C-D), increased serum levels of D-lactate (FigE) and promoted intestinal clearance of FITC-dextran (Fig.F). Serum levels of endotoxin and bacterial load in liver increased significantly after 24h nephrectomy (Fig.G-H). BNx did not reduce the expression of the selected epithelial TJ proteins(Fig.I), but resulted in the disruption of cell-cell junction(Fig.J).

Conclusions: Our study shows that non-ischemic AKI causes impairment of intestinal functions and histology, which in turn promotes the translocation of gut-derived bacteria and endotoxin. Accelerated intestinal mucosal apoptosis and the disruption of cell-cell junction are the most likely mechanisms for the translocation of bacteria and endotoxin.

Insulin-Dependent Diabetes Mellitus Aggravates the Systemic Inflammatory Response

Daniel Patschan. *Medical School of Brandenburg, Brandenburg, Germany.*

Background: Acute Kidney Injury significantly worsens the prognosis of hospitalized patients. Diabetes mellitus (DM) affects a growing number of individuals in the western world. DM subjects are at higher risk for aquiring AKI during the stay at the hospital, in addition the long-term prognosis of kidney function is particularly poor in subjects suffering from this metabolic condition. The most frequent cause of AKI, renal ischemia typically induces tubulopathy, microvasculopathy, and interstitial inflammation. The latter has extensively been investigated in recent years. The current study intended to quantifiy serum levels of certain immunomodulatory cytokines in diabetic mice suffering from AKI.

Methods: DM was induced in male C57/Bl6N mice by repeated systemic injections of beta cell-toxic streptozotocine. Animals underwent bilateral renal ischemia (45 minutes) 6 weeks later. Mice were either injected with native or preconditioned (zVAD or MD132 - autophagy inducers) syngeneic murine proangiogenic cells (PACs). Two days after surgery, mice were harvested and analyzed. Beside kidney function and morphology, serum levels of numerous (n=18) immunomodulatory cytokines were quantified.

Results: Post-ischemic diabetic mice showed significantly different serum concentrations of the majority of all analytes as compared to untreated controls and to non-diabetic (post-ischemic) animals. Cell therapy did not modulate cytokine patterns in a consistent manner.

Conclusions: Together, our data suggest significant DM-associated immunoactivation in AKI. One may suppose that inadequate stimulation of the humoral / cellular immune response potentially contributes to the higher ischemia-susceptibility of the organ in DM.

PUB054

Antioxidative and Antiapoptotic Effects of (+)-Clausenamide on Acetaminophen-Induced Nephrotoxicity in Mice

Fanna Liu. *The First Affiliated Hospital of Jinan Universtiy, Guangzhou, China.*

Background: Renal insufficiency occurs in nearly 1–2% of patients with APAP overdoses. We assumed that oxidative damage caused by reactive oxygen species (ROS) might be involved in APAP-induced renal injury, and available antioxidative agents, clausenamide (CLA) might be able to reduce the adverse effects. The aim of the study was to evaluate the protective effect of (+)-CLA against APAP-induced nephrotoxicity and to elucidate the mechanisms of the protective effect of (+)-CLA

Methods: Mice were divided into control, APAP, high-dose (+)-CLA, and low-dose (+)-CLA groups. Then, mice were preadministered (+)-CLA (50 and 100 mg/kg) for 5 consecutive days. After the last treatment, the animals received a single intraperitoneal injection of APAP (600 mg/kg). Renal histopathology was evaluated by staining with hematoxylin and eosin. The levels of MDA and GSH and the activities of CAT and SOD were determined using corresponding kits. Western blotting was used to analyze the expression of apoptosis-related proteins in renal tissue.

Results: Administration of APAP increased Scr and BUN levels in comparison with the control group. Renal MDA level increased, GSH, CAT and SOD activities reduced in renal tissue. The expressions of Bax and caspase-3, cleavage of caspase-3, and cytoplasm cytochrome c (Cyt c) levels were up-regulated in renal tissue, whereas Bcl-2 expression and mitochondrial Cyt c levels were down-regulated in the APAP group. The histopathology of kidney tissue supported these biochemical mechanisms. (+)-CLA can reverse changes in most of the abovementioned parameters and nearly restore the normal structure of the kidney.

Conclusions: Oxidative stress and apoptosis are considered to be the mechanisms underlying APAP-induced nephrotoxicity. (+)-CLA could be a promising antidote for APAP-induced AKI owing to its antioxidative and antiapoptotic effects.

A Case Imitating Thrombotic Microangiopathy

Golriz Jafari,[1] Phuong-Chi T. Pham,[1] Raghu Konanur venkataram,[2] Thuan V. Nguyen,[3] Anita Kamarzarian.[4] *[1]UCLA-Olive View Medical Center, Los Angeles, CA; [2]Olive View- UCLA Medical Center, Porter Ranch, CA; [3]UCLA-Olive View Nephrology, North Hills, CA; [4]UCLA -Olive View Medical Center, La Canada, CA.*

Introduction: The combined finding of hemolytic anemia, thrombocytopenia and organ injury, in particular AKI, are the hallmark signs of thrombotic microangiopathies (TMA). The differential is broad, presentations are diverse and most cases severe and life threatening. Risks associated with therapy must be calculated accordingly.

Case Description: A 44 year old female presented with fatigue and body aches 1 week after a motor vehicle accident. Hemoglobin 7.6 g/dl and platelets 16K. Prior to accident she had left knee pain, nausea, poor oral intake and weight loss for 2-3 weeks. No major trauma or injuries resulting from the accident. Only past medical history was a neck plaque like rash 9 months prior that was treated with antibiotics. Later she reported dysuria, fever and chills. Social history positive for prior cocaine use and current marijuana. Initially afebrile, then developed a temp 37.9 BP 115/92 HR 108. Exam was notable for suprapubic/costovertebral tenderness, left knee erythema, warmth and pain and a macular erythematous rash. WBC 6.4K, BUN 107 mg/dl Cr 4.59 mg/dl Albumin 1.6 g/dl UA: 182 WBC 112 RBC, Urine Protein/Cr ratio 3.7 gm Blood cultures and Urine cultures positive for E coli. Orthopedic evaluation ruled out septic joint. She was treated with antibiotics, fluids and platelet transfusion. Central venous catheter was placed for plasmapheresis. Blood smear revealed that schistocytes present, however haptoglobin values were high and bilirubin was normal. Therefore patient was managed medically and plasmapheresis was not implemented. Cr gradually improved to 1.82 mg/dl, on day 4 platelets>50K. ADAMTS13 levels were within normal range and serologies were negative: ANA, ANCA, HBV, HCV, HIV.

Discussion: The differential for the presentation of thrombocytopenia, hemolytic anemia and organ dysfunction is broad including TMAs such as TTP, HUS (shiga toxin or complement mediated) but also include other etiologies that augment complement activation such as sepsis, auto-immune disorders, malignancy, malignant hypertension and pregnancy. Treatment options such as plasmapheresis for TTP or complement cycle immune modulators such as eculizumab for aHUS are available however risks must be calculated based on clinical judgement. In this case the findings were due to E. Coli sepsis due to pyelonephritis rather than TTP or HUS and patient improved with sepsis treatment.

PUB056

The Effect of L-Carnitine in Contrast-Induced Nephropathy in Diabetic Rats

Natalia A. Oliveira,[2] Sheila M. Fernandes,[1] Maria De Fatima Vattimo,[1] Mirian Watanabe,[3] Karina B. Peres,[4] Cassiane D. da Fonseca.[1] Experimental laboratory on animal models *[1]University of São Paulo, Carapicuíba, Brazil; [2]Organization University of São Paulo, São Paulo, Brazil; [3]University of Sao Paulo, Sao Paulo, Brazil; [4]EEUSP, São Paulo, Brazil.*

Background: Contrast-induced nephropathy (CIN) has been defined as an abrupt reduction in renal function, resulting from iodinated contrast (IC) use. Studies show that Diabetes Mellitus is an important predisposing factor for CIN. It is known that L-carnitine is a lipidic metabolism compound and antioxidant effect is one of its major mechanisms. The aim of this study was evaluated the L-carnitine effect on CIN in diabetic rats.

Methods: Adult male Wistar rats was sorted into four groups: Citrate (control), Diabetes Mellitus (DM), Diabetes + iodinated contrast (DM+IC) and DM + IC+L-Car. Renal function (Inulin clearance); hemodynamics (renal blood flow; renal vascular resistance) and oxidative profile (urinary peroxides, urinary TBARS, thiols in renal tissue and urinary nitric oxide- NO) were evaluated.

Results: Diabetes was associated with significant decrease in inulin clearance that was additionaly reduced after the infusion of IC. DM+IC group also showed a significant increase in the urinary peroxides, TBARS and NO, a reduction in the thiols levels. Considering the renal hemodynamics parameters, this group showed a reduction in renal blood flow and increase in renal vascular resistance when compared with DM group. These parameters were significantly changed by L-carnitine in diabetic rats and those that received IC. Supplementation with L-carnitine resulted in an antioxidant protection in this IC model.

Conclusions: Our data reinforced that DM is an important risk factor for contrast-induced nephropathy. Supplementation with L-Carnitine showed a renoprotective effect in diabetic animals submitted to CIN, sugesting a possibility of a novel role of L-carnitine promoting anti-oxidant responses in the CIN.

PUB057

Deficiency of IKKα in Kidney Tubular Epithelial Cells Alleviates TGFβ1-Induced Kidney Fibrosis via Wnt/β-Catenin

Zhang Hao,[1] Feng Zhang,[1] Xin Wan.[2] *[1]Nanjing Medical University, Nanjing, China; [2]Nanjing First Hospital, Nanjing, China.*

Background: Nuclear transcriptional factor NF-κB plays an important role in inflammation, and the activation of NF-κB is mediated by IκB kinase (IKK) which is consisting of two subunits IKKα and IKKβ. Previously, we found that IκB kinase α (IKKα) protects against kidney ischemia/reperfusion(IR) injury.

Methods: However, its regulation and role in the pathogenesis of CKD remain poorly defined. To study this, we initially treated HK-2 cells with TGFβ1 and found that TGFβ1 activated IKKα and Wnt/β-catenin signaling in cultured cells. Blocked with IKKα small interfering RNAs (siRNA) markedly inhibited TGFβ1-induced vimentin and α-smooth muscle actin(α-SMA).

Results: Ensuing western blotting or immunostaining results showed that IKKα and Wnt/β-catenin signaling was activated in kidney tubular epithelial cells (TECs) in mice kidney ischemia/reperfusion(IR) injury. We found that IKKα in mouse model with TECs deletion was reduced. Compared with control group, the kidneys of IKKα knockout mice developed less interstitial extracellular matrix deposition and inflammatory cell infiltration at 2 weeks after-ischemia/reperfusion injury.

Conclusions: Our study suggests that IKKα activation mediated TGFβ1-induced kidney fibrosis and up-regulated Wnt/β-catenin signaling. In addition, IKKα contributes to the development of kidney fibrosis. This may provide a therapeutic target for chronic kidney diseases.

PUB058

The Association Between Urinary Markers of Fibrosis and Tubular Injury and Recovery of Kidney Function After Moderate to Severe AKI

Alexander Bullen,[1] Christina T. Saunders,[3] Jeffrey Blume,[3] Lorraine B. Ware,[4] Joachim H. Ix,[1] Edward D. Siew.[2] *[1]UCSD, San Diego, CA; [2]Vanderbilt University School of Medicine, Nashville, TN; [3]Vanderbilt University Medical Center, Nashville, TN; [4]Vanderbilt University, Nashville, TN.*

Background: Acute kidney injury (AKI) is a risk factor for chronic kidney disease (CKD). Tubulointerstitial fibrosis is strongly associated with urine collagen type III amino-terminal propeptide (PIIINP) in patients with CKD. We examined if urine collagen fragments, or other markers of kidney injury, were associated with renal recovery post-AKI.

Methods: The VALID study is a prospective study of critically ill adults. Among the first 1732 patients enrolled with available biosamples, we identified 147 with stage 2/3 AKI and urine available <48 hours of peak serum creatinine and at least 1 serum creatinine available between peak SCr and 9 months. We excluded patients with ESRD, no creatinine before enrollment, and stage 1/no AKI. We measured PIIINP, alpha-1 microglobulin, IL-18, MCP1, YKL-40, NGAL, and KIM-1 using multiplex panels, except for PIIINP (radioimmunoassay). Biomarkers were indexed to urine creatinine. 118 patients had complete measurements available, 26 with dialysis-requiring AKI and 92 patients without dialysis-requiring AKI. Renal recovery was defined as a return to <20% of baseline creatinine within 9 months. Relaxed Lasso logistic regression models were used to examine the association between biomarkers levels and renal function recovery.

Results: Among the 92 individuals not requiring dialysis, median age was 56(47,71), baseline creatinine 0.96 (0.72, 1.23), and peak creatinine of 2.5 (1.9,3.6) mg/dL. Fifty-seven (62%) recovered kidney function. Statistical modeling did not reveal any relationships between biomarker levels and odds of renal recovery in univariate or multivariable analyses adjusted for age, gender, race, baseline creatinine, peak creatinine, presence of sepsis and APACHE score. Biomarker information did not contribute to predictive ability for renal recovery beyond baseline creatine. Among the 26 dialysis, twenty-one (81%) were able to discontinue dialysis. None of the biomarkers were associated with dialysis discontinuation. There was also no association of biomarker levels with death.

Conclusions: Among a broad panel of biomarkers of kidney injury and fibrosis, we did not observe an association or predictive ability between biomarker measurements at the time of peak injury and renal recovery.

PUB059

AKI and Hemolytic and Uremic Syndrome (HUS) After Bothrops Envenomation - Interest of Renal Biopsy: About an Observation

Jean-Marc R. Dueymes-Laporte,[1] Herve Gbaguidi,[2] Timoté Davodoun,[3] Ahozegni T. Gbaguidi,[3] Hommel Didier.[4] *[1]Nephrology, General Hospital, Cayenne, French Guiana; [2]CHAR/, CAYENNE, France; [3]CHAR, CAYENNE, France; [4]General hospital. Cayenne. french guiana, Cayenne, France.*

Introduction: The snakebite by a Bothrops (Viperidae, Crotalinae, Botrops) is responsible for severe complications, and especially AKI whose origin is multifactorial. We report an observation of AKI following a bite by a Bothrops in which a renal biopsy could be performed to assert the mechanism of renal damage.

Case Description: 42-year-old patient was hospitalized 4 days after a bite by Bothrops Atrox, during which time she was treated only with traditional decoctions (no administration of antivenom). At the entrance, the patient was anuric, serum creatinine was 1077 µmol / l (SOFA score: 8). She had haemolytic anemia (Hg 6.8 g / dl, 25% schizocytes), haemostasis disorders (TP 71%, hypofibrinogen), thrombocytopenia, rhabdomyolysis. In front of this viperian envenomation complicated by HUS and anuria, without hypovolemic

shock, plasmapheresis sessions (4 liters plasma exchanges replaced by diluted albumin and fresh frozen plasma) associated with sessions hemodialysis were performed to control the HUS, correct hemostasis disorders. Resumption of diuresis was observed on D8 and the patient came out of resuscitation unit at D16. The evolution was made towards the recovery of the renal function, the disappearance of the hemolytic syndrome. A renal biopsy puncture was performed at day 30.

Discussion: The sample concerned 35 glomeruli all permeable. No image of thrombotic microangiopathy or inflammatory infiltrate was noted. Marinozzi and PAS stains showed only a thickening of Bowman's capsule and on one glomerulus a flocculo capsular synechiae draft. The tubes were lined with a flattened, regenerative epithelium showing sequelae of tubular necrosis. The immunofluorescence study was negative. In total, the renal biopsy was in favor of tubular necrosis associated with a discrete interstitial inflammatory reaction. There were no glomerulopathy lesions apart from discrete podocytosis lesions and no evidence of thrombotic microangiopathy. The clinical history of this patient was initially in favor of renal impairment secondary to intra-renal thrombotic microangiopathy in the context of HUS and described after Viperidae envenomation. The kidney renal biopsy allowed to rule out this hypothesis showing only tubular necrosis lesions secondary to a direct toxic attack of Bothrops' venom.

PUB060

Primary Cilium Length and Urine Primary Cilia Can Be Indicative of Cisplatin-Induced AKI

Min Jung Kong,[1] Jee in Kim,[3] Kwon Moo Park.[2] *[1]Kyungpook Nationcal University, Daegu, DaeJeon, Republic of Korea; [2]Kyungpook National University, Daegu, Republic of Korea; [3]Keimyung University, Daegu, Republic of Korea.*

Background: The primary cilium protrudes to kidney epithelial cell surface and is associated with the pathogenesis of many kidney diseases including acute kidney injury (AKI). During cell cycle, the length of primary cilium dynamically alters; when cell proliferates cilium is shortened by retraction into the cell body, whereas when cell is matured cilium is lengthened. In addition, during the progression of diseases, the length of primary cilium is changed; shortened or elongated, indicating that primary cilium length reflects cell and tissue conditions. Cisplatin nephrotoxicity limits its administration and is associated with increased oxidative stress. Here, we investigated whether cisplatin nephrotoxicity is associated with primary cilium and the alteration of primary cilium length can be indicative kidney injury.

Methods: Cisplatin was injected with the presence or absence of (2-(2,2,6,6-Tetramethylpiperidin-1-oxyl-4-ylamino)-2-oxoethyl) triphenylphosphonium chloride monohydrate (Mito-TEMPO, a mitochondria-specific antioxidant).

Results: Cisplatin increases kidney tubular injury in dose-dependent manner, shortening of primary cilia, and shedding of primary cilia fragments into the urine together with increased ROS production/oxidative stress. Cisplatin did not induce the cell proliferation when evaluated by BrdU incorporation assay. In addition, cisplatin did not induce significant changes in p21 and proliferation cell nuclear antigen (PCNA) expression in the kidney. Cisplatin-induced those changes were prevented by Mito-TEMPO, a mitochondria-targeted antioxidant, treatment.

Conclusions: Taken together, these results indicate that cisplatin nephrotoxicity is associated with primary cilia and cisplatin-induced shortening of primary cilia is due to disruption of primary cilia via increasing oxidative stress, suggesting that cisplatin nephrotoxicity is related with the alterations of renal primary cilia length and urine primary cilia protein can be a useful indicative of kidney injury.

PUB061

Kidney Injury Molecule-1 Staining Reflecting Proximal Tubule Injury Is a Common Finding in Pediatric and Adult Kidney Diseases

Ping L. Zhang,[1] Wenqing Yin,[2] Xu Zeng,[3] Joseph V. Bonventre.[2] *[1]William Beaumont Hospital, Royal Oak, Royal Oak, MI; [2]Brigham and Women's Hospital, Boston, MA; [3]University of Florida, Gainesville, FL.*

Background: Proximal tubules (PT) are known to be vulnerable to ischemic and toxic injury due to their high metabolic activity. The PT is also sensitive to hypoxic injury due to reduced post-glomerular blood supply. Kidney injury molecule-1 (KIM-1) is an injury marker specific for the PT. The purpose of this study was to determine whether KIM-1 expression was observed in human renal biopsies in a variety of kidney diseases where PT injury may be secondary to a primary disease process.

Methods: We randomly selected 184 renal biopsies from patients with various forms of kidney diseases and excluded cases with severe interstitial fibrosis. Biopsies were divided into three groups: 63 pediatric patients (< 20 years of age), 64 adults < 65 yr and 57 senior patients (> 65 yrs of age). All biopsies were stained using immunochemical techniques for KIM-1 (AKG7 monoclonal antibody) and examined by light microscopy. The intensity scores of KIM-1 in non-atrophic PT, ranging from 0 to 3+, were correlated with serum creatinine (sCr) levels.

Results: The patients' ages ranged from 2 to 82 years old. Regardless of primary etiology of injury (vascular or glomerular), positive staining of KIM-1 was seen in the majority of biopsies (80% to 91% in each age group). In all three groups, the KIM-1 staining scores were significantly positively associated with levels of sCr ($p < 0.05$). Compared to adult renal biopsies, there was a high KIM-1/sCr ratio in pediatric renal biopsies.

Conclusions: Our data indicate that acute damage in PT, determined by enhanced KIM-1 expression in non-atrophic proximal tubules, is a common finding in wide variety of pediatric and adult intrinsic kidney diseases. A high KIM-1/sCr ratio could be a potential repair and regenerative predictor in the early phase of acute kidney injury (AKI), reflecting active synthetic function of the PT cells with potential for PT recovery after injury. Thus, KIM-1 can serve as a sensitive and reliable biomarker for identification of acute tubular injury in non-atrophic PT of pediatric and adult renal biopsies.

Inhibition of Rac1-GTPase Attenuates Renal Ischemia/Reperfusion-Induced Injury by Suppressing Macrophage Infiltration

Mi Ra Noh,[1] Jee in Kim,[2] Kwon Moo Park.[3] *[1]Department of Anatomy and BK21 Plus, School of Medicine, Kyungpook National University, Daegu, DAEGU, Republic of Korea; [2]Keimyung University, Daegu, Republic of Korea; [3]Kyungpook National University, Daegu, Republic of Korea.*

Background: Migration of inflammatory cells is a pivotal for numbers of diseases including ischemia/reperfusion (I/R) injury. Rac1, a member of the Rho-family of small GTPase, plays a critical role for activation of NADPH oxidase, a major ROS producing enzyme. Rac1 also regulates the cell migration. However, the role of Rac1 on the macrophage migration after renal ischemia remains to be defined. Here, we investigated the role of Rac1 in the kidney ischemia/reperfusion injury and its mechanism focusing on macrophage migration.

Methods: Mice were intraperitoneally injected with either a single dose of NSC23766, an inhibitor of Rac1, or vehicle for 3 days before surgery and subjected to either ischemia or sham operation.

Results: Thirty-minutes bilateral renal ischemia in the kidney induced renal functional and morphological impairments along with the increase of Rac1 expression in the kidney. After ischemia, Rac1 was strongly expressed in the interstitial cells rather than renal tubular epithelial cells. Rac1-positive interstitial cells were mostly F4/80, a marker of macrophage, -positive. The treatment of NSC23766, an inhibitor of Rac1 activity, significantly inhibited the increase of F4/80-positive cell number after I/R together with reduced renal morphological and functional impairments. NSC23766 hindered the migration of RAW264.7 cell, a mouse monocyte/macrophage cell line cell, after treatment of MCP-1, a chemoattractant cytokine. Furthermore, Rac1 inhibition by NSC23766 also suppressed MCP-1-induced lamellipodia and filopodia of RAW264.7 cells.

Conclusions: These results indicate that I/R increases Rac1 expression, enhancing migration of monocytes/macrophages into the injured site. This suggests that Rac1 represents a potential therapeutic target protein for the treatment of acute kidney injury.

PUB063

Is It Possible to Prevent Contrast Induced Nephropathy with Dexpanthenol?

Osman Sutcuoglu,[1] Mehmet K. Derici,[2] Ozge T. Pasaoglu,[3] Burak Dumludağ,[4] Ipek isil Gonul,[1] Serpil muge Deger,[5] Ozant Helvaci,[6] Ulver Derici.[1] *[1]Gazi University Faculty of Medicine, ANKARA, Turkey; [2]Kirikkale University, Faculty of Medicine, KIRIKKALE, Turkey; [3]gazi University Faculty of Medicine, ANKARA, Turkey; [4]Erzurum Hinis State Hospital, ANKARA, Turkey; [5]Yuksek Ihtisas University Faculty of Medicine Department of Nephrology, ANKARA, Turkey; [6]Gazi University, Ankara, Turkey.*

Background: To demonstrate the effect of dexpanthenol, known to be antioxidant, in contrast-induced nephropathy(CIN) rat model.

Methods: Sprague Dawley rats, 12 weeks old, were kept without water for 3 days to produce contrast nephropathy. Thereafter L-NAME (10mg / kg), tenoxicam (0.5mg / kg) and sodium amidotrizoate (10ml / kg) were administered via the tail vein. Rats were euthanized after 48 hours (CIN group). Dexpanthenol (Dxp) was administered intraperitoneally at a dose of 500 mg/kg for 3 days, as the day prior, on the day and next day of contrast administration. The rats in this group were also euthanized at the 48th hour after the contrast administration (CIN + Dxp group). While Dxp was administered intraperitoneally for 5 days at equal doses to the Dxp group, control rats were administered saline solution. All rats were observed for 5 days and euthanized on the 6thday after blood draw.

Results: The comparison of contrast+dexpanthenol group and the contrast-only group showed that dxp provided significant decline at acute tubular injury and necrosis histopathologically (Figure 1). Serum creatinine levels were found similar amongst the groups, whereas cystatin C level was the highest in the CIN group (Figure 2). There was no statistically significant difference between the groups in total oxidant and antioxidant level evaluations.

Conclusions: Dexpanthenol, which has been demonstrated as a significant inhibitor on renal ischemia reperfusion model, did not show any significant effect on biochemicemistry on this CIN model. However, it has ameliorated histopathological findings of CIN.

Severe Renal Failure After Immunoglobulin Transfusions Requiring Dialysis as a Life Saving Measure

Ravi K. Thimmisetty, Frank W. Braxton. *Nephrology Associates, Cape Girardeau, MO.*

Introduction: We are presenting a rare cause of renal failure developed after Intravenous Immunoglobulin (IVIg) infusions given for acute exacerbation of Myasthenia gravis requiring dialysis

Case Description: 72 year-old-lady with h/o of Myasthenia gravis admitted with 5 days of progressive dysphagia, dysphonia, fatigue and bilateral ptosis. Diagnosed Myasthenia gravis exacerbation and treated with 5 days of IVIg infusions. Home medications were pyridostigmine and prednisone. Vitals on admission were blood pressure 159/61, temperature 98, heart rate 81, respiratory rate 16, saturating 97% on room air. Physical examination was with in normal limits. Laboratory results on admission were sodium 145, potassium 3.5, chloride 104, bicarbonate 26, bun 30, creatinine is 1.0 mg/dl, calcium 9.3, phosphorus 3.1, wbc 6, Hemoglobin is 13 .3 g/dl and platelets 212 x 10^3. After finishing 5-day course, bulbar symptoms were improved, but she developed severe anemia, Jaundice and Renal failure. Further labs include hemoglobin dropped 6.5, platelets 186 x 10^3, reticulocyte count 4.4%, wbc 11.8, LDH 2148, CPK 230, haptoglobin <10, direct coombs test negative, bicarbonate 11, creatinine 9.50 mg/dl, BUN 204 mg/dl, total bilirubin 5.1, direct bilirubin 0.40, total protein 11.5 g/dl, albumin 2.7 g/dl, ratio of kappa/lambda ratio 1.56, C3 135, C4 7, negative for MPO and PR3 antibodies, p-ANCA <1:20, c-ANCA 1:80, peripheral blood smear showed rouleaux and no significant schistocytes, serum IFE and SPEP showed no monoclonal proteins, urinalysis revealed cloudy red colored urine, numerous WBC's, 30-40 RBC, 3+ blood, 1+ protein, 1+ leukocyte esterase, negative for bilirubin, urine eosinophils and nitrite. Hospital course was complicated with atrial fibrillation with rapid ventricular rate and pulmonary edema requiring intubation. Emergent dialysis was started for refractory metabolic acidosis, fluid overload and 4 units of PRBC was transfused. Patient was stabilized hemodynamically and discharged with intermittent dialysis follow up and renal function tests

Discussion: Our case strongly suspects any undetected passive antibodies might have trigger acute hemolytic reaction causing renal failure. It's a rare complication of IVIG that is estimated to occur less than 1 % of infusions. Anecdotal reports showed elderly age, preexisting renal disease, and non-O blood group recipients have high risk

PUB065

Female Spontaneous Hypertensive Rats (SHR) Have Better Recovery in Response to Renal Ischemia Reperfusion (IR) Injury Than Males

Riyaz Mohamed,[1] Gene R. Crislip,[2] Sarah C. Ray,[1] Qingqing Wei,[1] Jennifer C. Sullivan.[1] *[1]Augusta University, Augusta, GA; [2]University of Florida, Gainesville, FL.*

Background: Experimental and clinical evidence suggests that normotensive males are more susceptible to acute kidney injury (AKI) vs females. Hypertension is a known risk factor for AKI, however if hypertensive males and females respond comparably to AKI is unknown. Present study tested hypothesis that hypertensive males have worse renal outcomes than females following renal IR

Methods: 13wk old male and female Sprague Dawley (SD) and SHR were subjected to sham or 25min warm bilateral IR (n=6). Blood and urine were collected at 1 and 7 days; kidneys were isolated at 7 days for histological analysis

Results: IR increased plasma creatinine (Pcr) and BUN in all groups compared to respective sham at 24 hrs, although increases in Pcr and BUN were greater in male vs female (SHR-Pcr: $P_{Sex}*_{IR}$=0.03; BUN: P<0.05; SD-Pcr: $P_{Sex}*_{IR}$<0.05; BUN: P<0.05). At 7 days Pcr and BUN remained elevated in male SHR compared sham (Pcr P_{IR}=0.03; BUN P_{Sex}<0.05); Pcr and BUN returned to baseline levels in all other groups. Histological examination of SHR kidneys following 7 days of reperfusion showed significant increase in vascular congestion ($P_{Sex}*_{IR}$=0.002), damaged tubules ($P_{Sex}*_{IR=}$0.001) and tubular cell apoptosis ($P_{Sex}*_{IR}$=0.001) compared to sham only in males. Since IR induced vascular congestion has been implicated in loss of renal function, additional male and female SHR were pretreated with heparin (1500U/kg) prior to IR. Pretreatment with heparin reduced IR induced vascular congestion and improved renal function in male SHR at 7 days (Pcr-$_{IR}*_{Hep}$<0.05; BUN: P=0.02).

Conclusions: Our data suggest that persistent vascular congestion in hypertensive male SHR results in delayed recovery following IR

Diverse Gene Expression Patterns of Renal Transporters in AKI

Hadi Fattah,[1] Alana Shigeoka,[2] Winnie Huang,[1] Rohit Patel,[1] Sashi Kasimsetty,[2] Prabhleen Singh,[1] Dianne B. McKay,[2] Volker Vallon.[1] *[1]Department of Medicine, University of California, San Diego & VA San Diego Healthcare System, San Diego, CA; [2]UCSD Nephrology/Transplantation, La Jolla, CA.*

Background: Restoration of tubular function may be a prerequisite for recovery of GFR and overall kidney function after acute kidney injury (AKI). We performed RNA sequencing (RNA-seq) to gain more insights on the expression pattern of tubular transporters in a murine model of AKI.

Methods: We induced ischemia/reperfusion (IR) injury by bilateral clamping of the renal arteries for 10 or 15 minutes (min) vs sham in C57BL/6J males. On days 1, 3 and weeks (wks) 2 and 14 after reperfusion, we assayed glomerular filtration rate (GFR) (by FITC-sinistrin plasma elimination kinetics in awake mice, n= 4-5/group) and harvested kidneys for RNA-seq analysis (n= 3-5/group).

Results: GFR in the 10 min IR group did not change while the 15 min IR group showed a sharp decrease on day 1 with partial recovery at 14 wks. The mRNA expression pattern seen in most tubular transporters was an ischemia time-dependent decrease on day 1 followed by subsequent gradual normalization with close to sham levels by 14 wks. This included Na transporters such as Nhe3, Nkcc2, Ncc, Enac, and Na-K-Atpase. An initial reduction on day 1 was also observed for Sglt2, Sglt1 and Glut2, which together mediate transcellular glucose reabsorption in proximal tubules. In contrast, Glut1, which in tubular epithelial cells can mediate the basolateral uptake of glucose used for glycolysis, showed an initial ischemia time-dependent increase in expression followed by eventual normalization. The phosphorous (Pi) transporters Pit1 and Pit2 showed a similar pattern to Glut1.

Conclusions: The mRNA expression of the main renal Na transporters and GFR are both reduced on day 1 after 15 min IR, and partially or fully recovered by 14 wks. Initial tubular cell loss and eventual restoration, and the kidneys' need to conserve energy during AKI may contribute to this pattern. In contrast, Glut1 is upregulated initially, potentially as part of the shift from fatty acid oxidation to glycolysis in early AKI. Upregulation of Pit1 and Pit2 may serve to conserve intracellular Pi availability including the uptake of extracellular Pi derived from cell lysis.

Double-Negative αβ T Cells in Murine Cisplatin-Induced AKI

Jing Gong,[1,2] Sanjeev Noel,[1] Sul A Lee,[1] Mohanraj Sadasivam,[1] Johanna T. Kurzhagen,[1] Abdel Hamad,[1] Hamid Rabb.[3] *[1]Johns Hopkins University, Baltimnore, MD; [2]The Second Affiliated Hospital of Nanjing Medical University, Nanjing, China; [3]Johns Hopkins University School of Medicine, Baltimore, MD.*

Background: Cisplatin treatment for malignancies is limited by nephrotoxicity. Though T cells have been implicated in cisplatin induced acute kidney injury (AKI), the role for $CD4^-CD8^-$ (double-negative, DN) T cells is unknown.

Methods: 8-week-old C57BL/6 male mice (n=8) were administered 30 mg/kg cisplatin and followed for 72 h. Serum creatinine (SCr) and histologic examination were assessed to confirm AKI. Kidney mononuclear cells (KMNCs) and splenocytes from cisplatin-treated mice were analyzed for DN T cell proliferation (Ki67, BrdU), immune cell trafficking/activation (CD69, CD62L), apoptosis (Annexin v) and differentiation (NK1.1, PD1) by flow cytometry.

Results: Cisplatin administration led to significant (p<0.0001) increase in SCr at 72 h (2.1 ± 0.4 mg/dl). DN T cell frequency increased at 24 h (52.6 ± 3.0%, p<0.001) after cisplatin treatment and subsequently decreased at 72 h (30.0 ± 3.0%, p<0.001) compared to 72 h vehicle treated mice (33.2 ± 3.2%) as well as the absolute number (vehicle: 1295.0 ± 194.1 versus 24 h: 2602.4 ± 295.7 versus 72 h 488.2 ± 118.4)(vehicle versus 24 h, p<0.001; 24 h versus 72 h, p<0.001). Kidney $CD4^+$ T cells were activated after cisplatin treatment (p<0.05), but not DN T cells. DN T cell proliferation decreased at 24 h (p<0.05) but increased (p<0.05) at 72 h. In contrast to ischemic AKI which showed expansion of the $PD1^+$ DN T cell subset, cisplatin-induced AKI increased both $NK1.1^+$ and $PD1^+$ DN T cell subsets (p<0.05).

Conclusions: Kidney DN T cells respond rapidly to cisplatin induced AKI, but in distinct ways compared to CD4 and CD8 T cells. Furthermore, there are key differences between DN T cell responses to nephrotoxin versus ischemia, including differentiation characteristics. Ongoing studies are investigating the role of DN T cells during early injury and recovery from cisplatin-induced AKI.

PUB068

The Use of Renal Doppler Ultrasonography in Critically Ill Patients with AKI

Rogerio Passos,[1] Juliana R. Caldas,[1] Joao G. Ramos,[1] Érica B. Melo,[2] Paulo benigno P. Batista.[3] SAPIENS MI *[1]Hospital Sao Rafael, Salvadir, Brazil; [2]Hospital Português da Bahia, Salvador, Brazil; [3]Hospital São Rafael, Salvador, Brazil*.

Background: Acute kidney injury is one of the major organic dysfunctions that occur in critically ill patients. Ultrasonography of the kidneys and urinary tract is always a tool used by nephrologists as a way of evaluating this pathology. Despite this practice, its clinical utility in determining the cause of acute kidney injury is poorly established.

Methods: Retrospective cohort study of critically ill patients that underwent renal ultrasound for acute kidney injury over a 5-year period at Hospital Portugues da Bahia. Renal Resisitive Index was determined by the doppler sonography.

Results: Over the 5-year period, 350 renal ultrasounds were performed for evaluation of acute kidney injury. Renal ultrasound was normal in 76% of patients. Hydronephrosis was detected in only 6% of studies and in only 2% of the cases was obstructive uropathy considered the cause of acute kidney injury.. Less than 1% of patients had urinary tract obstruction on ultrasound without a suggestive medical history. Median renal RIs were 0.68 (0.62-0.75) in patients with sepsis related AKI and 0.74 (0.72-0.80) in patients with non sepsis related AKI (P = 0.001). RIs were 0.72 (0.70-0.79) in transient AKI and 0.76 (0.70-0.80) in persistent AKI (P = 0.64).

Conclusions: The role of renal ultrasonography in every critically ill patients with acute renal injury still needs to be determined In patients with history suggestive of urinary tract obstruction renal ultrasound for evaluation of acute kidney injury should be indicated. The use o renal resisitive index could to be a tool to reflect vasomotor tone in patients with AKI related to sepsis.

PUB069

Effects of Properdin Associated with EPOR/βcR on Repair Post Renal Ischaemia-Reperfusion Injury

Yuanyuan Wu,[1,2] Nigel J. Brunskill,[1] Bin Yang.[1] *[1]University of Leicester, Leicester, United Kingdom; [2]University of Nantong, Nantong, China*.

Background: Ischaemia-reperfusion injury (IRI)-induced acute kidney injury is common with high mortality. Properdin is an only positive regulator of the alternative pathway of complement activation, while it could also act as a pattern recognition molecule. Our previous study has demonstrated more severe damage in properdin deficient (P^{ko}) mice than wild type (WT) mice upon IRI. However, its mechanisms, especially its association with tissue protective EPO receptor/β common receptor (EPOR/βcR) in kidney repair post IRI are not clear.

Methods: The bilateral occlusion of renal pedicles for 30 min (n=7-9) and sham control (n=4-5), was performed in WT and P^{ko} male C57BL/6 mice, followed by 72-h reperfusion. EPOR/βcR protein in kidneys was detected, together with mitosis, apoptosis and inflammation markers. Moreover, apoptosis and phagocytosis were measured in proximal tubular epithelial cells (PTECs) isolated from both WT and P^{ko} mice and stimulated with H_2O_2.

Results: The expression of EPOR/βcR was significantly increased by IRI in both WT and P^{ko} mice compared with that in the sham controls. Interestingly, renal EPOR/βcR was further increased in P^{ko} mice after IRI in comparison with WT mice. EPOR/βcR was positively correlated with, proliferating cell nuclear antigen (PCNA) and mitosis, active caspase-3, apoptosis, $F4/80^+$ cells, tubulointerstitial damage (TID) and renal function. Moreover, apoptotic cells in tubular lumens of the IRI kidney were significantly increased by P^{ko}. Apoptotic cells were higher in P^{ko}-PTECs subjected to H_2O_2 stimulation compared with that in WT-PTECs. The phagocytic ability of PTECs to engulf apoptotic cells was compromised by P^{ko}. Both apoptosis and phagocytosis were not affected by additional WT or P^{ko}-serum.

Conclusions: Properdin might be associated with EPOR/βcR to facilitate the clearance of apoptotic cells by the phagocytosis of PTECs and initiate repair and remodeling of the kidney post 72-h IRI. The precise role and mechanism of properdin and EPOR/βcR in IRI and repair are worthy to be further studied.

PUB070

Contrast-Induced Acute Renal Oxalosis with Sustained AKI in Enteric Hyperoxaluria

Glenn R. Kershaw. *Renal Medicine, UMass Memorial Medical Center, Worcester, MA.*

Introduction: Intratubular deposition of calcium oxalate crystals induces chronic renal disease in settings of primary hyperoxaluria (chronic renal oxalosis). Acute oxalosis is reported with extreme oxalate or Vitamin C intake and renal transplant settings.

Case Description: A 65-year-old W/M w creatinine 4.62 on chemotherapy screening (CS). Creatinine 1.3 six weeks prior to screening (PTS). CT scan w contrast 4 weeks PTS. **PMH**. adenocarcinoma of caecum (2013) treated w cytoreduction, HIPEC, right hemicolectomy + resection 2 feet terminal ileum. Chemo-Rx last 6 months was capecitabine-bevacizumab. **ROS**: No oliguria, flank pain, hematuria, dysuria, fever. Reports 2-4 loose stools/day since 2013 surgery. Serum HCO3 normal, urine SG ≥ 1.020 x 12 months. **Med:** lisinopril, loperamide, citalopram, ferrous sulfate. Recently took amoxicillin\clavulanic acid x 7 days for "toe infection." No NSAIDS **PE**: BP 130/80 no orthostasis, no edema; H/L/A normal. **Lab and imaging**: BUN 43, creatinine 4.33, bicarbonate 20, uric acid 10.4. Lytes, Ca, Mg, LFTs, CBC normal. Noncontrast CT: normal-sized kidneys, no hydro. U/A: pH 5.5, SG 1.009, P/B/leuk. negative. Sediment: no casts, cells or crystals. UNa 64, Ucreat 82. **Renal biopsy**: Acute tubular injury with intratubular calcium oxalate deposits DCT c/w oxalate nephropathy. **Treatment**: 3 L fluid intake, low oxalate diet, Calcium + citrate supplements. **Subsequent course**: 14 d after peak Creat and prior to therapy, Creat ↓to 3.08, 24 hr U oxalate elevated (58 mg), U citrate undetectable. Plasma oxalate undetectable.

Discussion: Proposed mechanisms: PRE-EXISTING CONDITIONS: 1) ***Enteric mechanisms***;↑ Ox permeability, ↓Ox secretion (intact ileum, proximal colon are net oxalate secretors), ↑ Ox availability (Ca binding to FFA). 2) *chronic diarrhea*; ↑U osm, ↓U citrate. CONTRAST INDUCED CONDITIONS: 1) ***Acute supersaturation:*** a) subclinical tubular injury → systemic Ox accumulation → acute ↑ filtered Ox. b) early osmotic diuresis ↓washout/tubular stasis. 2) Contrast binding to Tamm-Horsfall protein→↓***inhibitor crystallization***. OTHER: eradication of oxalate degrading gut flora (***Oxalobacter formigenes***) by antibiotics. **Teaching point:** Contrast loads in patients with Enteric hyperoxaluria and diarrhea following bowel resection may induce acute secondary oxalosis with sustained AKI. Appropriate screening, prophylaxis, imaging alternatives are advised.

PUB071

Cannabidiol-Induced Regulation of Innate Lymphoid Cells in AKI

Babak Baban, Mahmood S. Mozaffari. *Augusta University, Augusta, GA.*

Background: Cannabidiol, a non-psychoactive cannabinoid, is increasingly believed to be of therapeutic potential for several conditions including those accompanied with inflammation. Intense immune and inflammatory responses are pivotal to the pathogenesis and manifestation of acute kidney injury (AKI). We recently showed renoprotective effects of cannabidiol in the murine model of AKI prompting us to explore cannabidiol-induced regulation of immune and inflammatory responses in this condition. Innate lymphoid cells (ILCs) have emerged as a new class of lymphocytes capable of regulating and amplifying the immune response through a variety of effector functions that parallel those of the T lymphocytes. Based on expression of signature molecular markers and cytokine expression, ILCs are classified into three groups: ILC1s, ILC2s and ILC3s. While ILC1s and ILC3s are linked to pro-inflammatory effects, ILC2s exert counter-inflammatory roles. Thus, we tested the hypotheses that AKI is associated with significant changes in frequency of each subset of ILCs and b) cannabidiol treatment restores frequencies of ILCs subsets to normal levels.

Methods: male mice were subjected to either bilateral renal ischemia (20 min)-reperfusion (24 hrs.) injury (IRI), a model of AKI, or sham operation; sham-operated mice and those subjected to IRI were further subdivided to receive either cannabidiol (10 mg/Kg; i.p.) or the vehicle (DMSO) 10 min before restoration of renal blood flow. Thereafter, kidney cells were prepared for subsequent flow cytometry analyses of subsets of ILCs.

Results: Induction of IRI markedly increased frequencies of ILC1s and ILC3s but significantly reduced ILC2s. Cannabidiol treatment of sham-operated animals did not affect frequency of each ILCs subsets. However, cannabidiol treatment of animals subjected to IRI resulted in restoration of frequencies ILCs subsets to levels of sham-operated animals although a differential persisted for ILC1s.

Conclusions: Collectively, our observations indicate that cannabidiol-induced regulation of ILCs contributes importantly to its renoprotective effect in AKI.

PUB072

Hypoxia-Induced Long Non-coding RNA Malat1 Is Dispensable for Renal Ischemia/Reperfusion-Injury

Malte Kölling,[1] Andreas D. Kistler,[4] Harald Seeger,[1] Roland Schmitt,[2] Hermann G. Haller,[2] Jan T. Kielstein,[3] Rudolf P. Wuthrich,[1] Johan Lorenzen.[1] *[1]University Hospital Zurich, Zurich, Switzerland; [2]Hannover Medical School, Hannover, Germany; [3]Academic Teaching Hospital Braunschweig, Braunschweig, Germany; [4]Cantonal Hospital Frauenfeld, Frauenfeld, Switzerland.*

Background: Renal ischemia/reperfusion (I/R) injury represents a major socioeconomic health problem. Non-coding RNA are crucially involved in pathophysiology. Long non-coding RNA *Malat1* (Metastasis Associated Lung Adenocarcinoma Transcript 1) was upregulated in renal I/R injury. We elucidated the functional role of *Malat1 in vitro* and its potential contribution to kidney injury *in vivo*.

Methods: *In patients*, kidney biopsies and plasma samples were collected. *In vivo*, *Malat1* knockout- (KO) and wild-type (WT) mice were subjected to unilateral and bilateral I/R. Histopathology-, gene expression-, kidney function- and survival studies were performed. *In vitro*, *Malat1* was silenced by antisense oligonucleotides in endothelial cells (EC) and tubular epithelial cells (TEC) subjected to hypoxia/reoxygenation. Transcriptional activation- and functional studies were implemented. Genome-wide RNA analysis was performed.

Results: *Malat1* was upregulated in human kidney biopsies and plasma and in murine kidney tissue, EC and TEC and mainly nuclear-chromatin associated. *In vitro*, *Malat1* inhibition reduced EC in the S-phase of the cell cycle. Proliferation decreased. Less EC were apoptotic after *Malat1* silencing. TEC were not functionally altered. *Malat1* was transcriptionally activated in EC and TEC by Hypoxia-inducible factor 1-alpha. *In vivo*, *Malat1* KO- and WT mice showed similar degrees of tubular epithelial injuries and proliferating cells. Capillary rarefaction was not affected. Kidneys of *Malat1* KO- and WT mice expressed more pro-inflammatory (IL-1beta, IL-6, MIP2a, MCP-1) and pro-fibrotic (Col1a2, Col III, TGF-beta) genes. Similar amounts of macrophage-, T-cell infiltration and tubulointerstitial collagen were detected. mRNA- and smallRNA expressions showed only minor differences. The reduced kidney function was not altered by *Malat1* KO. *Malat1* KO mice showed no survival benefit.

Conclusions: *Malat1* plays a pivotal role in hypoxia/reoxygenation induced endothelial cell pathology. Even though previous studies have suggested a prominent role of *Malat1* in

the induction of disease, we did not confirm an effect of *Malat1* loss on the progression of renal I/R-inury.

PUB073

Detection of Erythropoietin (Epo) Protein Expression by Western Blot

Hiroshi Nonoguchi,[1] Yukiko Yasuoka,[2] Yuichiro Izumi,[6] Takanori Nagai,[7] Yushi Nakayama,[5] Hideki Inoue,[10] Masayoshi Nanami,[3] Tomomi Oshima,[9] Takeshi Nakanishi,[4] Masashi Mukoyama,[5] Yuichi Sato,[2] Katsumasa Kawahara.[8] *[1]Kitasato University Medical Center, Kitamoto, Japan; [2]Kitasato University, Sagamihara, Japan; [3]Internal Medicine, Division of Kidney and Dialysis, Nishinomiya, Japan; [4]Hyogo College of Mediicne, Nishinomiya, Japan; [5]Kumamoto University Graduate School of Medical Sciences, Kumamoto, Japan; [6]Kumamoto University, Kumamoto, Japan; [7]Internal Medicine, Nagai Clinic, Nishinomiya, Japan; [8]Dept of Physiol, Kitasato Univ School of Med, Sagamihara, Japan; [9]Kitasato University, School of Medicine, Sagamihara-shi, Japan; [10]Kumamoto University School of Medicine, Kumamoto, Japan.*

Background: It has been believed that erythropoietin is secreted into plasma soon after the production by the erythropoietin producing cells in the kidney probably because of the difficulty of immunohistochemistry and Western blot analysis. We investigated the expression of Epo protein by Western blot analysis using the monoclonal and polyclonal antibodies against Epo.

Methods: Both the polyclonal and monoclonal antibodies against Epo were used for the detection of Epo protein by Western blot analysis. Antigen-peptide absorption tests using recombinant rat Epo and the antibodies were used to check the specificity of the band. Since Epo is known to be a glycoprotein, deglycosylation of the recombinant rat Epo and produced Epo using N-glycosidase F was performed.

Results: Both the polyclonal and monoclonal antibodies against Epo showed recombinant Epo as a broad band at 34-43 kDa. The kidney and liver from control rat showed a broad but faint band at 36-40 kDa and a narrow band at 42 kDa. The polyclonal antibody was used for immunohistochemistry and the monoclonal antibody was used for Western blot analysis. Severe hypoxia increased an expression of a broad band at 36-40 kDa in the kidney but reduced a band at 42 kDa in the liver. Antigen-peptide absorption test using recombinant rat Epo largely decreased the expression of the bands of recombinant Epo and kidney/liver Epo. Deglycosylation of recombinant Epo and hypoxia-induced kidney sample showed a shift of the bands to 22 kDa, which is identical to the size of Epo by LC/MS analysis. These data clearly show that the bands at 36-40 and 42 kDa correspond to Epo protein.

Conclusions: In conclusion, Epo protein can be detected at 36-40 and 42 kDa by Western blot analysis using the monoclonal antibody.

PUB074

The Effect of Ferric Citrate (Auryxia) on Hemoglobin, Iron Levels, As Well As, Phosphorus Management in Dialysis Patients

Mahmoud Algharabli,[1] Shelley L. Munch,[3] Ahmed M. Awad.[2] *[1]Clinical Research Consultants, KAnsas city, MO; [2]Nephrology, UMKC, KANSAS CITY, MO; [3]Davita Kidney Care, Parkville, MO.*

Background: Hyperphosphatemia in end stage renal disease is associated with increased morbidity and mortality. Ferric Citrate (FC) is indicated for hyperphosphatemia in patients with CKD on dialysis and in the treatment of iron deficiency anemia in adult patients with CKD III and IV. We present real-world serum phosphorus, hemoglobin and other iron-related data from patients treated with FC in one dialysis center compared to second group of patients from the same center on other phosphorus binders.

Methods: Retrospective chart review in one dialysis center of two study groups, each with 19 patients. One group was prescribed FC for hyperphosphatemia for an average of 9.89 months. The second group was prescribed other phosphorous binders for one year. FC and control group treatment data collected: Treatment Duration, Average Daily Prescribed Pill Count, Average Monthly Intravenous (IV) Iron Dose, Start and End for the following parameters: Serum Phosphorus, Iron Saturation (ISAT), Serum Ferritin and Hemoglobin (Hgb).

Results: We compared 19 patients who were prescribed FC as a phosphorus binder to 19 patients prescribed other phosphorus binders. Both groups had similar characteristics: Gender (26.3% F/ 73.6% M vs 42.1% F/57.8% M), Age (52 vs 60.5), Diabetic Status (63.1% vs 68.4%), BMI (27.5 vs 33.1). The mean daily prescribed pill burden was FC 5.1 vs Control 6.9. There was net reduction of serum phosphorus by more than 1 mg/dL reaching the goal of 5.5 mg/dL compared to the control group where there is an increase in phosphorus by ~1 mg/dL reaching 5.72 mg/dL. The patients taking FC showed an increase in HgB of 1 gm/dL FC group vs decrease HgB ~0.4gm/dL, ISAT of 14% FC group vs no significant change in control group, Average IV venofer need per month 110.8 mg in FC group vs. average IV venofer need per month 145.2 mg in control group.

Conclusions: The use of Ferric Citrate as a phosphorous binder for patients on Hemodialysis showed a decrease of total monthly IV iron requirements by 25% with an average increase in the HgB by 1 gm/dL, and an increase in ISAT by 13.4%. In addition, FC Group reached the target phosphorus level of 5.5mg/dL. The Control Group showed no significant changes in either HgB or ISAT and an increase in phosphorus levels.

PUB075

Efficacy of Intravenous Ferumoxytol Compared to Sodium Ferric Gluconate for Anemia Management in Outpatient Hemodialysis Population

Wasim El Nekidy,[1] Derrick Soong,[2] Maher M. El-Masri,[4] Albert Kadri.[3] *[1]Cleveland Clinic - Abu Dhabi, Windsor, ON, Canada; [2]Windsor Regional Hospital, Windsor, ON, Canada; [3]Windsor Regional Kidney Care Center, Windsor, ON, Canada; [4]University of Windsor, Windsor, ON, Canada.*

Background: Intravenous iron is one of the main therapies for anemia management in hemodialysis dependent patients. Data comparing the efficacy of ferumoxytol versus other parenteral iron supplements are scarce. The objective of the study was to compare the efficacy and safety of ferumoxytol as compared to sodium ferric gluconate in hemodialysis patients

Methods: A prospective observational study was conducted on hemodialysis outpatients who received ferumoxytol 510 mg once or twice quarterly compared to sodium ferric gluconate 125 mg weekly in a single center southwestern Ontario community hospital between Oct 2013 and June 2014. Patient demographics, iron indices, hemoglobin levels, iron doses, and erythropoiesis stimulating agent (ESA) doses were collected

Results: The study sample consisted of 291 observations from 173 patients. Generalized estimating equations of multiple linear regression modeling was conducted to compare the outcomes while adjusting for baseline scores. About 25% of the study participants received ferumoxytol while 75% received sodium ferric gluconate. Males (58.4%), mean age was 68.73 (SD ± 13.03) years. Both groups did not show significant difference in their hemoglobin levels (*Wald* $z = 0.54$; $p = 0.46$), ESA utilization at 3 months (*Wald* $z = 0.20$; $p = 0.65$) and TSAT levels (*Wald* $z = 3.45$; $p = 0.06$). However, the iron levels (*Wald* $z = 4.24$; $p = 0.04$) and ferritin levels (*Wald* $z = 5.14$; $p = 0.02$) were higher in the ferric gluconate group (*Wald* $z = 58.78$; $p \leq 0.001$) and patients who received ferumoxytol received more blood transfusion as compared to those who received sodium ferric gluconate ($\chi^2 = 16.71$; $p \leq 0.001$)

Conclusions: Both iron products maintained hemoglobin levels with those receiving ferumoxytol had lower iron indices and received more blood transfusions compared to sodium ferric gluconate

PUB076

Effect of the Paricalcitol on the Hemoglobin Variability and Anisocytosis Degree in Hemodialysis Patients

Miguel Uriol Rivera,[1] Joan M. Gasco,[2] Angel Garcia-Alvarez,[3] Gonzalo Gómez marqués,[4] Manuel Luque-Ramírez.[5] *[1]Hospital Universitario Son Espases, Palma de Mallorca, Spain; [2]Hospital Universitari Son Espases, Palma de Mallorca, Spain; [3]Hospital Comarcal de Inca, Inca, Spain; [4]Hospital Universitario Son Espases, Palma De Mallorca, Spain; [5]Hospital Universitario Ramón y Cajal, Madrid, Spain.*

Background: Hemoglobin variability(Hb-V) and higher red cell distribution width (RDW- a marker to describe the amount of anisocytosis-) are two factors associated with higher mortality in dialysis patients. A potential benefit of the selective vitamin D receptor activator (paricalcitol) lowering ESA doses was described; however its effect on Hb-V and RDW is unknown. **Objective:** To describe the influence of the paricalcitol on Hb-V and RDW in hemodialysis patients.

Methods: This is cross-sectional study. Patients with paricalcitol(N=56) and without paricalcitol (N=41) were compared. Prevalent hemodialysis patients with the following inclusion criteria were included: Hb ≥ 9g/dl, transferrin saturation(TSAT) ≥20% and/or plasma ferritin levels ≥200pg/ml. Hb stability range was defined as Hb within 10-12g/dl. Higher RDW values >15%. Hemoglobin and RDW relationship was evaluated by regression analysis.

Results: Median parathyroid hormone was higher in group A in comparison with group B (234 pg/ml versus 154 pg/ml, P>0.001). Hb, RDW, TSAT, ferritin, albumin, cholesterol, iron supplements and ESA doses showed no differences between groups. The percentage of patients with diabetes, hypertension, were similar between groups. As a whole, a quadratic regression model explained the relationship between Hb and RDW (R^2:0.09, P=0.01). No association between the percentage of patients treated with paricalcitol and Hb stability, or higher RDW was observed. However, a negative relationship between Hb and RDW (r: -0.28; P=0.03) was observed in those with paricalcitol, while it was positive in those without paricalcitol (r:0.41; P=0.006). Those patients with PRC and higher RDW showed lower Hb levels than those with lower RDW (mean difference: 1,20g/dl, P = 0.01); while in those without PRC patients with higher RDW, no differences in Hb values respect to those with lower RDW values were observed (mean difference: -0.88 g/dl, P=0.07).

Conclusions: The use of the paricalcitol in patients with Hb stability was associated with a decrease in the anisocytosis, while in those without paricalcitol an opposite association was observed. These data suggest a direct effect of the paricalcitol on the hematopoiesis process.

Effect of Ferric Citrate on Iron Parameters in ESRD Patients with Elevated Ferritin: Interim Report of a Pilot Pragmatic Clinical Trial

Monica Rodriguez,[1] Derian Lai,[1] Cindy Gomez,[2] Medha Airy,[1] Sreedhar A. Mandayam.[1] *[1]Baylor College of Medicine, Houston, TX; [2]Baylor College Of Medicine, Houston, TX.*

Background: Iron deficiency is prevalent in ESRD patients. Patients with elevated Ferritin (>1000 mcg/dL) are poorly responsive to IV Iron & may be at risk of infection. We investigated the efficacy of oral Ferric Citrate on Iron parameters in ESRD patients with

low transferrin saturation (TSAT) but elevated ferritin in a pragmatic pilot clinical trial at a single dialysis center in the US.

Methods: This is an un-blinded, open label study to determine the effect of Ferric Citrate on iron parameters in ESRD patients with elevated ferritin & low TSAT. All ESRD patients on hemodialysis for at least 3 months at the US Renal Care Baylor Scott Street Dialysis unit were eligible to participate. Patients were included in the trial if they satisfied the following criteria: 1) Mean Serum Ferritin >1000mcg/dL on 2 consecutive samples 3 months apart 2) TSAT <30% on 2 consecutive samples 3 months apart 3) Able to tolerate phosphate binders We collected the following information pre-enrollment into the trial: Ferritin, TSAT, hemoglobin, ESA dose, Calcium, Phosphorus, and PTH. Subjects were given Ferric Citrate 210 mg 2 tabs with meals (minimum 6/day) for 3 months. Clinicians could change the dose as clinically indicated. Management of IV Iron & ESA was per the standard clinic anemia management protocol. Labs were monitored monthly This is an interim report after completion of 9 patients in the trial.

Results: Mean serum Ferritin & TSAT at enrollment were 1246 ng/ml & 23.7 %. After completion of 90 days of Ferric Citrate the mean ferritin and TSAT increased to 1303 ng.ml (4% increase) and 38.29% (38% increase) respectively. ESA use decreased from 38 units/week of Darbepoetin to 15 units/week (60% reduction) after 90 days.

Conclusions: Oral Ferric Citrate appears to be an effective iron supplement that increases iron stores in ESRD patients with high Ferritin & low TSAT. Further studies with larger numbers of patients are needed to investigate its impact on ESA use in ESRD patients.

Anemia parameters

Parameter (mean)	Baseline	Visit 3
Hemoglobin (g/dL)	10.2	10.5
TSAT (%)	23.74	38.29
Ferritin (ng/ml)	1246	1303
Iron (mcg/dL)	59.3	85.4
ESA (dose units/week)	38.3	15

PUB078

Effect of Ferric Citrate on KDQOL-36 Scores in ESRD Patients with Elevated Ferritin: Interim Report of a Pilot Pragmatic Clinical Trial

Derian Lai,[1] Cindy Gomez,[2] Monica Rodriguez,[1] Medha Airy,[1] Sreedhar A. Mandayam.[1] *[1]Baylor College of Medicine, Houston, TX; [2]Baylor College Of Medicine, Houston, TX.*

Background: Iron deficiency is prevalent in ESRD patients. Patients with elevated Ferritin (>1000 mcg/dL) are poorly responsive to IV Iron and have higher risk of infection. We investigated the efficacy of oral Ferric Citrate on KDQOL-36 scores in ESRD patients that have low TSAT but high Ferritins in a pragmatic pilot clinical trial at a single dialysis center in the US

Methods: This is an unblinded, open label study to determine the effect of Ferric Citrate on anemia management in ESRD patients with elevated Ferritin and low TSAT. Primary end point was change in weekly ESA use. Secondary end points were changes in TSAT and KDQOL scores. All ESRD patients on hemodialysis for at least 3 months at the US Renal Care Baylor Scott Street Dialysis unit were eligible to participate. Patients were included if they satisfied the following criteria: Serum Ferritin >1000 on 2 consecutive samples 3 months apart, TSAT <30% on 2 consecutive samples 3 months apart, and able to tolerate phosphate binders. Subjects were given Ferric Citrate 210 mg 2 tabs with meals (minimum 6/day) for 3 months. Treating clinicians were allowed to change the dose of Ferric Citrate as clinically indicated. Anemia management was per the standard clinic protocol. KDQOL 36 scores were collected upon enrollment and again at 90 days at the end of trial. This is an interim report after completion of 9 patients in the trial.

Results: Mean Physical Health Composite and Mental Health Composite at enrollment were 37.98 and 44.72. After completion of 90 days of Ferric Citrate, the mean Physical Health Composite and Mental Health Composite increased to 48 and 50.86 respectively. Notably 2 of the 9 patients had self-reported low compliance with Ferric Citrate (18% and 14%) and had worsening of KDQOL scores.

Conclusions: Ferric Citrate appears to be a safe and effective phosphate binder in ESRD patients with high Ferritin and low TSAT. Further large scale studies are need to be conducted to study its impact on Quality of Life in ESRD patients.

Funding: Commercial Support - Keryx Biopharmaceuticals

KDQOL-36 subscale scores

Subscale	Mean scores (baseline)	Mean scores (90 day follow up)	Standard Deviation
Physical Health Component	37.98	48	13.58
Mental Health Component	44.72	50.86	10.87
Burden of Kidney Disease	61.49	59.38	23.48
Symptoms of Kidney Disease	81.25	80.89	19.43
Effect of Kidney Disease on Daily Life	69.79	67.19	23.48

Association Between Renal Function, Serum Levels of Interleukin-6 and Stroke in Nondialysis CKD Outpatients

Caroline Makay Silva,[3,1] Bruna Hernandez,[1] Thais D. Takahashi,[2] Marcella A. Barros,[3,1] Guilherme B. Barbosa,[1] Miguel Angelo Goes.[4] *[1]Faculdade das Américas, São Paulo, Brazil; [2]Iniciação Científica Unifesp Poá, Brazil; [3]UNIFESP, Sao Paulo, Brazil; [4]Federal University of Sao Paulo, Sao Paulo, Brazil.*

Background: Cardiovascular disease is the leading cause of mortality and stroke is a frequent complication inchronic kidney disease (CKD) patients. Inflammation is associated with cardiovascular disease. To assess if serum renal function and inflammatory cytokines are associated with stroke in nondialysis CKD outpatients.

Methods: We retrospectively analyzed a database with 100 nondialysis CKD outpatients and identified 20 patients with stroke up to 96 months after enrolment in nephrology office. Demographic data, eGFR, blood count, ACEi, erythropoiesis-stimulating agents (ESAs) use, serum sFas, and inflammatory cytokines levels from baseline were recorded. We performed comparisons between stroke group (n=20) and non-stroke group (n=80). Binary logistic regression was used to determine the impact of factors on stroke.

Results: The primary cause of CKD was diabetes followed by hypertension. Stroke occurred after 37±8 months. Transient ischemic attack-9, ischemic-7 and hemorrhagic stroke-4 patients. We observed lower eGFR (37.8±20.8, 25.5±8.7 mL/min; p=0.01), Hb (12.4±2.1, 11.2±2.4 pg/mL; p=0.04) and platelets [(227±56, 200±50)x10^3; p=0.04)] in stroke group. We found higher levels of serum sFas levels (4007±1668, 2985±940 pg/mL; p=0.001) and serum IL-6 levels (10.1±5.8, 5.6±4.2 pg/mL; p=0.002) in stroke group. We did not observed difference in smokers, diabetes and hypertension, ACEi and ESA use. Serum IL-6 (b = 1.133, 95%CI 1.002-1.131; p=0.04) and GFR (b = 0.911, 95%CI 0.844-0.983; p=0.01) were independently associated with stroke.

Conclusions: In this study lower GFR and higher serum IL-6 were predictors of stroke in nondialysis CKD outpatients within 96 months.

PUB080

Nephrology and Biodesign: Using the Needs Finding Process for Nephrology Innovation

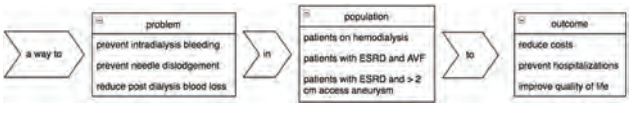
Dimitri A. Augustin, Glenn M. Chertow, Dan Azagury. *Stanford University School of Medicine, Palo Alto, CA.*

Background: There is renewed demand to accelerate innovation in nephrology and both public and private sectors are creating programs to support its growth. The Stanford biodesign innovation process, first developed in 2000, provides a roadmap for health technology innovation. The program includes three phases: identify, invent, and implement. There is insufficient published guidance on the application of this process in the generation of novel devices to address nephrology clinical needs. We present our process of needs identification in a hemodialysis unit, using the biodesign innovation process.

Methods: We applied the identify phase of the biodesign innovation process in two stages: 1. needs finding and 2. needs screening. We performed a qualitative retrospective review of observations within a hemodialysis unit, generated needs statements, actively tested those needs, and validated them. The needs finding stage includes background research, direct clinical observations, interviews, documenting those observations, and development of multiple needs statements. The needs screening stage includes a deeper review of the disease state, an analysis of stakeholders and market, and ranking of needs statements.

Results: A dozen retrospective observations were reviewed to create needs statements. One of the twelve observations were utilized to generate multiple related needs statements. The figure is based on observations of a cannulated hemodialysis access within a hemodialysis unit.

Conclusions: We conclude that the needs finding and needs screening stages of the biodesign innovation process can be used to identify meaningful unmet clinical needs in nephrology and foster new device inventions.



Need statement scoping (actively testing and refining need statement) with multiple problems, populations, and outcomes

Vascular Calcifications in Animal Models: Can They Be Compared to Those in Humans?

Geert J. Behets,[1] Miquel D. Ferrer,[2] Carolina Salcedo,[2] Joan Perelló,[2] Patrick C. D'Haese.[1] *[1]University of Antwerp, Antwerp (Wilrijk), Belgium; [2]Laboratoris Sanifit, Palma de Mallorca, Spain.*

Background: Rat models of vascular calcification are an important tool to evaluate safety and efficacy of compounds aimed at reducing vascular calcifications in humans. Calcifications in rats can be detected using μCT imaging of the aorta, bulk calcium analysis and/or Von Kossa (VK) staining of vessels. In renal failure patients, calcifications are generally detected using the CAC score which has been shown to be associated with cardiovascular morbidity/mortality in these patients. An important question in translational

studies on vascular calcification is the extent to which CAC scores, and thus vascular calcification, in humans can be correlated to calcifications observed in animal models.

Methods: Vascular calcifications were induced in 15 male Wistar rats using the adenine-low protein model. After 4 weeks, all animals underwent both in-vivo and post-mortem μCT imaging of the aorta, using a Skyscan 1076 μCT, with a 35μm voxel size. Scans were also made of 12 human blood vessels, obtained during transplant surgery. Additionally, VK staining and bulk Ca analyses were performed in all rat and human samples.

Results: Seven animals showed clear calcification (bulk Ca > 10 mg/g). A good correlation (R=0.885, p<0.05) was found between the in-vivo and post-mortem scans. Both bulk Ca levels (16.32 ± 5.74 mg/g) and VK positive area (10.96 ± 4.43 %) correlated well with the in vivo scan (R=0.829, p<0.01 and R=0.813, p<0.001). Six out of the 12 human samples showed detectable calcifications using μCT. Four of these had bulk Ca levels > 10 mg/g. In the human samples, a good correlation was also found between the μCT scan and both bulk Ca levels (56.5 ± 40.3 μg/g) and VK positive Area (7.2 ± 4.83%) (R=0.991, p<0.001 and R=0.932, p<0.001). Both bulk Ca levels and VK positive area were similar in the human and animal samples (p > 0.05).

Conclusions: In summary, we found a good correlation between μCT, bulk Ca and VK staining in both animal and human samples. Furthermore, bulk Ca levels and VK staining in human and rat samples were similar. In order to evaluate whether CAC scores in humans correlate with the various parameters of vascular calcification, sample collection of patients with known CAC scores is currently ongoing.

Osteoblastic Differentiation of Bone Marrow-Derived Mesenchymal Stem Cells in Uremic Rats with Secondary Hyperparathyroidism

Tadashi Kato,[1] Masahide Mizobuchi,[2] Ryutaro Kamijo,[4] Fumihiko Koiwa,[3] Hiroaki Ogata.[1] *[1]Division of Nephrology, Department of Internal Medicine, Showa University Yokohama Northern Hospital, Yokohama, Japan; [2]Division of Nephrology, Department of Medicine, Showa University, Tokyo, Japan; [3]Division of Nephrology, Department of Medicine, Showa University Fujigaoka Hospital, Yokohama, Japan; [4]Division of Biochemistry, Department of Dentistry, Showa University, Tokyo, Japan.*

Background: Although severe secondary hyperparathyroidism (SHPT) represents a high turnover bone disease, osteitis fibrosa, but the pathogenesis of osteitis fibrosa is not fully clarified. We examined the characteristics of bone marrow-derived mesenchymal stem cells (BMSCs) differentiation into osteoblasts in uremic rats with SHPT.

Methods: We bred 5/6 nephrectomized (Nx) rats with a high phosphorus (P) diet (containing 1.2 % phosphate) to progress SHPT (Nx+high P diet (HP) group, n=10), or Nx (Nx+normal P diet (NP:containing 0.6 % phosphate) group, n=6) and normal rats (Normal+NP group, n=5) with a standard diet. After 8 weeks all rats were sacrificed and BMSCs (obtained from femur), tibia, and serum were analyzed. BMSCs were confirmed by flow cytometry for the expression patterns of the cell surface marker (CD90+, CD29+, CD45-, and CD31-). Osteoblastic differentiation was induced by an osteogenic medium containing 10mM β- glycerophosphate, 50 μg/mL ascorbic acid and 10 nM dexamethasone in minimal essential medium α (MEMα). The osteoblastic differentiation was assessed by ALP mRNA expression and alizarin red staining.

Results: Serum creatinine (Cre) levels were significantly elevated in the Nx+NP rats compared with the Normal+NP rats. The Cre levels in the Nx+HP rats showed levels similar to those in the Nx+NP rats. Serum P and PTH levels were significantly elevated in the Nx+HP rats compared with the Nx+NP rats (P level: 11.1±2.4 vs 7.3±1.3 mg/dL, PTH level: 1820.6±665.1 vs 197.8±151.9 pg/mL). Bone morphometrical analysis showed an increase in both osteoid volume and eroded surface in the Nx+HP but not in the Nx+NP rats. The population of harvested BMSCs were similar in all three groups. The ALP mRNA expression in the BMSCs from the Nx+HP rats was significantly suppressed compared with that in the other rats. Alizarin red staining showed a tendency similar to the ALP mRNA expression.

Conclusions: These results suggested that the BMSCs differentiation into osteoblasts was disturbed in the SHPT rat. The discrepancy between the high osteoblastic activity in the bone and impaired differentiation of the progenitor cells were found. P load might contribute to this differentiation impairment.

Bone Morphogenetic Protein-7 Upregulates Collagen I, Sp7, and IBSP Genes in Human Mesenchymal Stem Cells

Jun-Beom Park,[1] Hye Min Choi.[2] *[1]The Catholic University of Korea, Seoul, Republic of Korea; [2]Myongji Hospital, Seonam University College of Medicine, Goyang-si, Republic of Korea.*

Background: Bone morphogenetic proteins are reported to be associated with proliferation and differentiation of various types of cells. This study was performed to evaluate the effects of short-term application of bone morphogenetic protein-7 on human mesenchymal stem cells with next-generation sequencing.

Methods: Stem cells were treated with a final concentration of 100 ng/ml bone morphogenetic protein-7. Sequencing of mRNA and analysis of data were performed. Gene ontology and pathway analysis were done. Quantitative real-time polymerase chain reaction of mRNA of ColI, Sp7, IBSP and Western blot analysis of collagen I, osterix and bone sialoprotein and β-actin were performed.

Results: A total of 25,737 mRNAs were differentially expressed and up and down-regulated mRNAs were documented based on the related pathway. Expression of collagen I, Sp7 and IBSP were increased with the application of BMP-7 at 3 hours and this was confirmed with Western blot analysis.

Conclusions: The short-term application of BMP-7 produced increased expression of collagen I, Sp7 and IBSP and this was related with target genes chosen for osteoblast differentiation. This study provided new insights into role of bone morphogenetic protein-7 using mRNA sequencing.

PUB084

Study of Fibroblast Growth Factor 23 in Patients with CKD in Indian Population

Girish V. Kumthekar. care hospital *Care Hospital, Banjara Hills,Hyderabad,INDIA, Beed, Maharashtra, India.*

Background: Historically there are four main 'Players' in CKD-MBD, namely calcium, phosphate, parathyroid hormone (PTH) and vitamin D endocrine system. The treatment strategies are designed to keep all four parameters within defined ranges in an attempt to maintain bone and vascular health in a patient with CKD. FGF-23 is pivotal as a marker of progression of CKD as well as a therapeutic target for assessing response to treatment.

Methods: Total 64 patients were enrolled over a period of 18 months after obtaining consent. The blood samples were collected for serum calcium, phosphorous, PTH, Vitamin

D and haemoglobin. The statistical significance in the difference in the outcome variables between the groups was assessed using Kruskal -Wallis for FGF-23. Data was analysed using STATA 13 software.

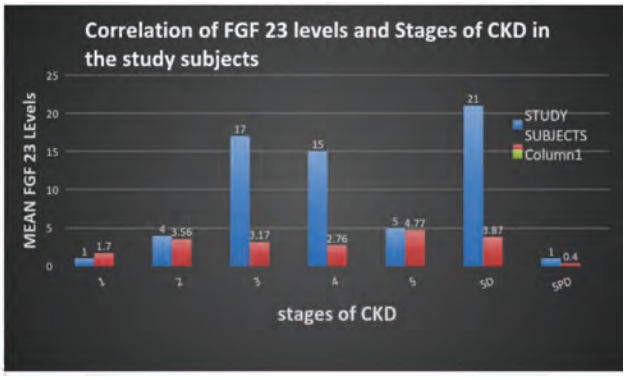
Results: The mean value for FGF 23 was found to be highest in CKD stage 5 (4.77) followed by stage 5D (3.87) and stage 2 (3.56). This was not statistically significant. FGF-23 was compared with existing markers of CKD MBD and except for marginal significance for phosphorus (P value 0.09); there was no statistically significant correlation. The drop in haemoglobin level with CKD progression was correlated negatively with FGF 23 level. (p=0.01)

Conclusions: The FGF-23 levels do not correlate with present markers of CKD-MBD. FGF-23 values were observed to be lower in low turnover disease and higher in high turnover bone disease. But estimating CKD-MBD severity by utilising FGF-23 as a marker may not be helpful as majority CKD population has low PTH in our study.

FGF-23 correlation with existing markers

Variables	FGF-23	P-Value
Calcium	-0.03	0.79
Phosphorus	0.22	0.07
Vitamin D	0.11	0.37
PTH	-0.01	0.58
Calcium x phosphorus	0.2	0.09

There is no statistical significance between FGF-23 and existing markers of CKD-MBD.



Levels of FGF 23 among different stages of CKD

PUB085

Correlation of Vitamin D and Islet β Cell Function Among Calcium Kidney Stone Formers

Pulkit Gandhi,[1] Roopali G. Gandhi,[2] Jie Tang.[1] *[1]Brown University, Providence, RI; [2]RIH, Providence, RI.*

Background: Existing evidence suggest that low vitamin D store affects normal release of insulin from β-islet cells after glucose intake, hence could play a role in the pathogenesis of glucose intolerance and type 2 diabetes mellitus. However, the interaction between 25(OH)-vitamin D (25D) with β cell function has not been studied in calcium kidney stone formers, a unique population whose 1,25(OH) vitamin D (1,25-D) action seems to be hyperactive.

Methods: Prevalent non-diabetic calcium kidney stone formers from 2015 to 2018 were enrolled in this study. We assessed the association between serum 25D and β cell function measured by HOMA- β [(360 × fasting insulin (μU/L)/(fasting glucose (mg/dl)–63)] using univariate analysis and multivariate regression model adjusting for demographics and important clinical covariates. P values less than 0.05 were considered significant.

Results: A total of 94 non-diabetic calcium kidney stone formers were enrolled in this study. Among them, 51% were male, 86% were Caucasian, 38% had history of hypertension and 29% had history of dyslipidemia. Mean age was 54 years, mean creatinine clearance (CrCl) was 131 ml/min, mean body mass index (BMI) was 31.3 kg/m^2, mean serum 25D was 28 ng/ml, mean serum 1,25D was 52 pg/ml, and mean serum parathyroid hormone level was 66 pg/ml. As a measure of islet β-cell function, mean HOMA β was calculated to be 270. In univariate analysis, CrCl, BMI and history of hypertension and dyslipidemia, associated significantly with HOMA- β ($p<0.05$), but 25D did not have a significant association ($p=0.2$). After adjusting for demographics, 25D associated significantly with HOMA- β ($p=0.02$). Likewise CrCl, BMI, history of hypertension and dyslipidemia continued to carry significant associations with HOMA- β ($p<0.05$). After adjusting for demographics, histories of hypertension and dyslipidemia, CrCl, BMI and serum uric acid, the association between 25D and HOMA- β remains significant ($p=0.01$). Unlike 25D, serum 1,25D levels have no association with HOMA- β in univariate and multivariate analyses.

Conclusions: Like the general population, low serum 25D levels, not 1,25D levels, associate strongly with islet β cell function measured by HOMA- β in calcium kidney stone formers.

PUB086

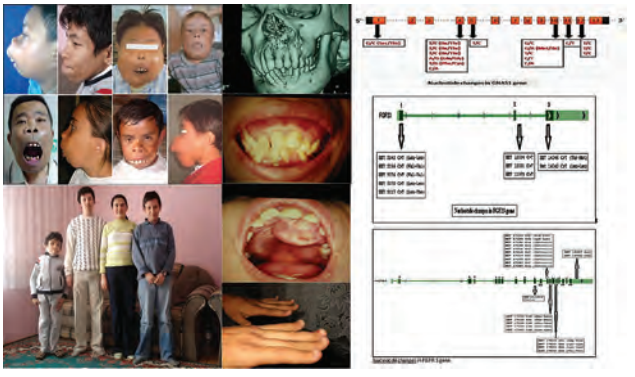
Multiple GNAS1, FGF23, FGFR3 Genes' Striking Mismutations in CKD with SH: Brand New Bone Dysplasia and Uglifying Human Face Appearances - Sagliker Syndrome (SS)

Yahya Sagliker. *Sagliker Hypertension Unit, Adana, Turkey.*

Introduction: SS so far, seems to be related to chronic kidney disease (CKD) and consequent secondary hyperparathyroidism (SH). SS starts and develops particularly before puberty, while CKD reaches stage III level with overt SH. Since it occurs only in some patients (%1), it is plausible to think SS is genetically predisposed. Genes' mismutations on the genesis of SS is unclear and no data are available so far.

Case Description: We conducted clinical studies and screening for mismutations in GNAS1 gene in 23, FGF23 and FGFR3 genes in 17 patients. DNA isolations performed from blood samples and mismutation regions were amplified by PCR. In 73.9% (17/23) patients, 17 different abnormalities in GNAS1 were detected.58.3% (7/12) nucleotide alterations comprised novel mismutations in different manners. There were 6 heterozygous tranversion polymorphism in exons.6 were introngenic mismutations found in introns 65626, 70387, 70817. We found 10 different mismutations in FGF23 gene. 8 were novel mismutations defined first in our study. 3 were in intronic region near exon 2. In FGFR3 gene we found 22 different mismutations. 16 were novel mismutations defined first in our study. 12 mismutations were found in exons. 8 were found in introngenic region near exon 11. 2 were found in non-coding exonic regions of exon 18.1 was in the exon-exon junction region between exon 11 and 12. 3 were nonsense Therefore mismutations might be preventing splicing of introns.

Discussion: There are plenty mismutations on 3 genes consistent with an insufficiency of genes playing a role in clinical phenotype of loss of function mutations with functional alleles having predominant roles in preventing hormonal resistance. Since incidence of CKD stage 3 is around 8% in world but the incidence of SS is around 1% and although our patients were not resembling any of them, but they could be in between and SS might be a combination-compulsion of Genetical Bone displasias such as McCune-Albright syndrome, Achondroplasias etc and SH and CKD.



PUB087

Warfarin Based Anticoagulation Is a Major Risk Factor for Calciphylaxis

Philipp G. Russ, Martin Russwurm, Joachim Hoyer. Nephrology Department Marburg *Marburg Philipps-University, Marburg, Germany.*

Background: To assess clinical risk factors, altered laboratory parameters, epidemiology and survival rates of patients suffering from calciphylaxis, we conducted a retrospective study of patients with biopsy-proven calcific uremic arteriolopathy (CUA).

Methods: In an eight year period from 2008-2016 we included 15 patients in a single center retrospective study for final analyses. Only patients with both, strong clinical suspicion of calciphylaxis and confirmative histological patterns such as intimal hyperplasia, micro thrombi or van Kossa stain positive media calcification, were included. Patients with clinical suspicion but lacking dermatohistological evidence were excluded.

Results: The mean age of patients was 64.8 years. 9 patients (60%) were female; 12 (80%) were obese with a Body-Mass-Index above 30 kg/m2; 3 (20%) did not have chronic kidney disease (CKD); 12 (80%) had stage 4 or 5 CKD and 10 (66.7%) were on dialysis (CKD 5D). One-year mortality in the entire cohort was 73.3%. With respect to medication history, the majority of patients (n=13 (86.7%)) received Vitamin-K-Antagonists (VKA); 10 (66.7%) weretreated with Vitamin D; 6 (40%) were supplemented with oral calcium; 5 (33.3%) had been treated with corticosteroids; 12 (80%) were on protonpump inhibitors. 13 (86.7%) patients showed hyperparathyroidism. The serum-phosphate level was elevated in 9 (60%) patients and the serum-calcium level was reduced in 7 (46.7%) patients. Ten (66.7%) patients presented with hypoalbuminemia at diagnosis.

Conclusions: Calciphylaxis is a rare disease with high mortality associated with female sex, obesity, severe chronic kidney disease and hyperparathyroidism. Especially treatment with VKAs and liverdysfunction are important risk factors for the development of calciphylaxis.

PUB088

Rationale, Design, and Characteristics of EPISODE Trial

Yoshitaka Isaka,[1] Hideki Fujii,[2] Yoshihiro Tsujimoto,[4] Satoshi Teramukai,[3] Takayuki Hamano.[1] *[1]Osaka University Graduate School of Medicine, Suita, Japan; [2]Kobe University Graduate School of Medicine, Kobe, Japan; [3]Kyoto Prefectural University of Medicine, Kyoto, Japan; [4]Inoue Hospital, Osaka, Japan.*

Background: In dialysis patients, mortality risk due to cardiovascular diseases is remarkably high and prognosis is poor; coronary artery calcification is considered one of the major contributing factors. It is known that hyperphosphatemia is associated with coronary artery calcification. Therefore, controlling serum phosphate levels and thereby mitigating vascular calcification could improve the poor prognosis of dialysis patients. However, the optimal phosphate range in dialysis patients remains unknown; hence, this study was planned to compare the effects of two types of non-calcium-based phosphate binders, and examine the effect of strict control of phosphate on coronary artery calcification.

Methods: EPISODE is a randomized, open-label, multi-center, interventional trial with a two-by-two factorial design. We enrolled 160 hemodialysis patients (men 109, women 51, diabetes 59, hypertension 116) with a pre-dialysis serum phosphate level of at least 5.0 mg/dL or at least 6.1 mg/dL, respectively, in those taking or not taking a phosphate binder, as measured during the observation period. Registered patients were randomized to the sucroferric oxyhydroxide or lanthanum carbonate arm in order to reduce serum phosphate to two target ranges (3.5 - 4.5 mg/dL in strict arm and 5.0 - 6.0 mg/dL in standard arm) for 12 months. The primary endpoint will be percent change in coronary artery calcification score (CACS), and the secondary endpoints will include change in serum phosphate and calcium levels, change in renal anemia-related factors, etc.

Results: At baseline, the median CACS was 840 (IQR; 270-2705).

Conclusions: This study may show the optimal phosphate range in dialysis patients.

PUB089

Calciphylaxis: What Are These Patients Dying from? A Single Centre Study

Ester Casillas, Haridian Sosa Barrios, Laura V. Blanco, Sofia Ortego, Victor Burguera, Milagros Fernandez lucas, Maite Rivera. *Ramón y Cajal Hospital, Madrid, Spain.*

Background: Calciphylaxis is a rare metabolic entity most commonly associated to chronic kidney disease, with a mortality rate over 80% in the first year after diagnosis. The optimal treatment for calciphylaxis continues to be discussed. There is not one healing treatment that works in every case, although there is many that can be useful for avoiding the progression of the lesions and in some cases even lead to curation (ulcer debridement, Paracalcitrol, sodium thiosulfate, biphosfonates and paratiroidectomy are some of them.) We present a series of 23 patients diagnosed of calciphylaxis in our center and review the treatment regimen and survival in each case.

Methods: From January 2002 to october 2017 our Nephrology department attended 2131 patients with chronic kidney disease, 23 of them (1%) developed calciphylaxis: 11 men/12 women with a mean age of 58 years (range 32 to 87 years). At the time of diagnosis, 13 patients were receiving treatment with hemodialysis, 7 were on peritoneal dialysis and 3 had a functioning transplant. The mean risk factors identified in these patients were: severe hyperparathyroidism in 11 cases (PTH>600), oral anticoagulants in 10 patients., steroid treatment in 8 patients, active-D-vitamin supplements in 4 patients, severe hyperphosphatemia in 6 patients (P> 6 mg/dl). In 11 patients calciphylaxis occurred coincidental with a decompensation of another illness. All of them were treated by trained nurses who performed ulcer debridement and applied antiseptic and healing bandages. Other treatments were Paracalcitrol (n=12), parathyroidectomy (n=4), Biphosphonates (n=3), Sodium thiosulfate (n=3).

Results: During the follow-up 13 patients died, 2 were lost and 8 are alive. 3 patients died as a result of calciphylaxis (13%), improving the skin lesions in the remaining 20. However, in the first year after diagnosis, another 9 patients died due to pathology not related to calciphylaxis (5 cardiac, 1 lung transplant rejection, 1 gastrointestinal hemorrhage, 1 pneumonia, 1 HD withdrawal), thus total mortality was 52%.

Conclusions: Secondary hyperparathyroidism and oral anticoagulants were the most prevalent risk factor in our series. Although calciphylaxis is associated to a very high mortality rate, the main cause of death was the decompensation of unrelated illnesses.

PUB090

Early Detection of Mineral Abnormalities in Patients with CKD Stage 3-4

Eleni Chelioti,[1] Eleni Theodoropoulou,[2] Kyriaki Stamatelou,[3] Evdokia Efthimiou,[4] Maria Tsilivigou.[5] *[1]Dept. of Nephrology, Tzaneio, General Hospital of Pireaus, Athens, Greece; [2]Dept. of Nephrology, General Hospital of Athens "Alexandra", Athens, Greece; [3]Athens Medical, Dafni Clinic, Vrilisssia, Greece; [4]Renal Unit "Frontis", Piraeus, Greece; [5]Dept. of Nephrology, Tzaneio General Hospital of Piraeus, Athens, Greece.*

Background: Mineral and Bone Disorders (MBD) are highly prevalent in all stages of chronic kidney disease (CKD). Secondary hyperparathyroidism (SHPT) and hyperphosphatemia (HP) are the most prominent mineral abnormalities. Progression of CKD has been associated with increased iPTH, phosphorus (P) and Calcium x Phosphate product (CaxP) and with decreased calcium (Ca) and 1,25 dihydroxyvitamin D levels. Our aim was to determine the prevalence of mineral disorders in our outpatient CKD stage 3-4 patients.

Methods: We studied 336 CKD stage 3-4 patients (190 men, 56.5% and 146 women 43.5%, mean age 65±14 years). Patients were not receiving Ca supplements, phosphate binders, or vitamin D. Mean eGFR was 34±9.5 ml/min/1.73m2. The parameters determined and analyzed were: Ca, P, iPTH and CaxP.

Results: The percentage of patients with Ca, P, iPTH and CaxP within the recommended targets are presented in the Table. 58% of our patients had iPTH>110 pg/ml (95%CI ∑49.8-65.2), 34.2% had P>4.6mg/dl (95%CI 25.8-40.4), 86.3% had CaXP>55mg2/dl2 (95%CI 79.9-90.9) and 22.3% had Ca<8.4mg/dl (95%CI 15.6-28.5). P correlated positively with iPTH and CaxP (r=0.25 p=0.001 and r=0.41 p=<0.001 respectively), and negatively with Ca (r=0.85 p<0.001). (Table)

Conclusions: In patients with CKD stages 3-4, out-of target mineral parameters are highly prevalent. Early detection of mineral abnormalities is critical for timely and effective treatment of SHPT in pre-dialysis patients and could delay the progression of CKD-MBD.

Funding: Government Support - Non-U.S.

Biochemical Parameter	Target Value	% of patients within target	95% CI
P	2.7 - 4.6 mg/dl	61%	(52.2 - 67.5)
Ca	8.4 - 9.4 mg/dl	38.7%	(30.2 - 45.3)
iPTH	50 - 110 pg/ml	32.7%	(24.7 - 39.2)
Ca X P	<55 mg2/dl2	14.3%	(9.0 - 20.0)

PUB091

Relationship Between Young Adult Mean and Vascular Calcification in Patients with CKD on Maintenance Hemodialysis

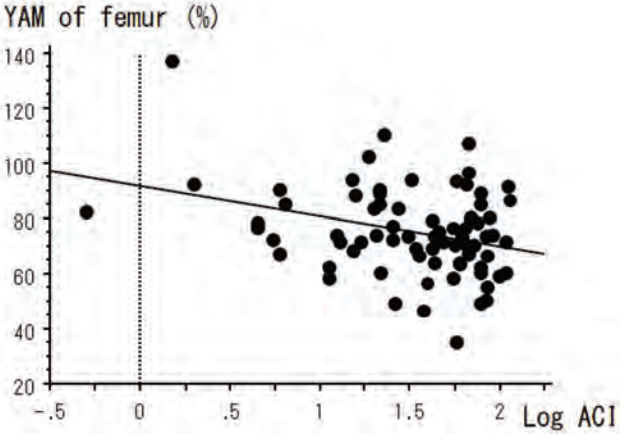
Wataru Fukao,[1,2] Yukiko Hasuike,[1] Tomoko Kimura,[1] Kosuke Mizusaki,[1] Yasuyuki Nagasawa,[1] Takahiro Kuragano.[1] *[1]Hyogo College of Medicine, Nishinomiya, Japan; [2]Takarazuka City Hospital, Takarazuka, Japan.*

Background: Patients with chronic kidney disease (CKD) often have osteoporosis and a high risk of bone fracture. Mineral bone disorder in CKD is associated with cardiovascular disease, although the mechanism remains unclear. The purpose of this study was to clarify the relationship between lower bone mineral density (BMD) and vascular calcification in patients with CKD on maintenance hemodialysis (MHD).

Methods: A total of 78 MHD patients were examined. BMD at the lumbar vertebral spine and femur were measured via dual-energy X-ray absorbsiometry by young adult mean (YAM). Factors related to bone marker (tartrate-resistance acid phosphatase 5b [TRACP 5b], bone specific alkaline phosphatase [BAP]), Ca, P, intact parathyroid hormone and 25-hydroxycalciferol [25(OH)D] were measured. Aortic calcification index (ACI) were measured by computed tomography, as previously reported.

Results: The patients' mean age ± SD was 66.1±11.1 years, and mean dialysis vintage was 7.4 years. YAM of femur was significantly lower than YAM of vertebra (YAM of femur [74.9±14.9%]; YAM of vertebra [91.3±18.0%], p<0.0001). YAM levels positively correlated with body weight, Ca, creatinine, albumin and 25(OH)D, and negatively correlated with TRACP 5b, BAP and ACI (r=-0.319, P=0.0044).

Conclusions: Lower BMD correlated with ACI in patients with CKD on MHD. These findings suggest that BMD is related ectopic calcification.



PUB092

Improving Control of Mineral Bone Disease in Peritoneal Dialysis Patients

Ryan Marinovich,[1] Robin Wigen,[2] Han Wang,[2] Nancy I. Woodcock,[4] Arsh Jain,[3] Elena Qirjazi.[2,3] *[1]Schulich School of Medicine, London, ON, Canada; [2]Schulich School of Medicine and Dentistry, London, ON, Canada; [3]London Health Sciences Center, London, ON, Canada; [4]London Health Sciences Centre, London, ON, Canada.*

Background: Peritoneal dialysis (PD) patients often have difficulty regulating their calcium (Ca), phosphate (PO4) and parathyroid hormone (PTH) levels, placing them at risk for mineral bone disease (MBD). Following Ca/PO4/PTH trends is key in evaluating the effectiveness of different treatments. However, out-patient laboratory blood work and physician shared-practice models in PD units make following these trends challenging. We

aim to increase the number of PD patients at our centre who meet targets for Ca/PO4/PTH levels by 15% within 9-12 months using quality improvement methods.

Methods: We developed a simple tracking tool which includes: a) the trend of individual patients' Ca/PO4/PTH values and subsequent interventions, and b) a treatment guide for MBD. The latter was generated from a combination of National Kidney Foundation KDOQI guidelines and local expert opinion. This tracking tool was rolled out at our PD Unit in October 2017. The primary outcome was the change in the proportion of patients (at clinic) who meet all three targets, before and after implementation of our tool. Baseline data was collected from a 12-week look-back window and an opinion survey of the stakeholders at our PD Unit. Post-implementation, we tracked uptake of our tool and elicited specific feedback from care-givers. We used Plan-Do-Study-Act (PDSA) quality improvement methodologies to continuously adjust the tool and its implementation.

Results: The opinion survey was completed by 16 health care professionals. 87.5% of respondents felt MBD management is poorly defined and 56% believed patient adherence is the biggest barrier. Baseline data indicated that 34.5% of our patients met targets for Ca/PO4/PTH. During PDSA cycle#1, 69.8% of charts utilized our tool and 37.2% of patients met targets (p=0.62). For PDSA cycle#2, the dietitian was recruited to champion our tool and uptake increased to 90.7%. The proportion of patients meeting targets rose to 44.2% (p<0.05, compared to baseline).

Conclusions: We achieved a 9.7% increase in the PD patients meeting Ca/PO4/PTH targets within 6 months by adjusting care-givers' behaviors, rather than patient factors. We will continue using PDSA methodologies to achieve our objective within 9-12 months.

PUB093

Change of Bone and Mineral Metabolism in Kidney Donors After Uninephrectomy: Prospective Observational Study

Eun jeong Ko,[1] Bumsoon Choi,[2] Cheol Whee Park,[3] Chul Woo Yang,[4] Byung ha Chung.[4] *[1]Seoul St.Mary's Hospital, Seoul, Republic of Korea; [2]Division of Nephrology, Department of Internal Medicine, Seoul, Republic of Korea; [3]The Catholic University of Korea, Seoul, Republic of Korea; [4]Seoul St. Mary's Hospital, Seoul, Republic of Korea.*

Background: The aim of this study is to investigate whether uninephrectomy for kidney donation cause change of bone and mineral metabolism and also investigate factors associated with it in prospective kidney donors after uninephrectomy.

Methods: Serum and urine creatinine, calcium, phosphorus, and serum intact parathyroid hormone (iPTH), 25(OH) vitamin D values were obtained pre-donation and postoperatively in 32 donors. Renal fraction excretion rate of phosphate (FEpi) was calculated with 24-hour urine collection. Pre- and post-donation GFR was measured by DTPA scan in all donors. We defined post-donation chronic kidney disease-mineral bone disorder (CKD-MBD) as higher serum iPTH level than median (59.7 pg/ml) of all donors at post-transplant, and investigate factors associated with the development of CKD-MBD.

Results: After donor nephrectomy, MDRD eGFR declined (93.1 to 61.2 ml/min/1.73m^2) and remnant kidney's GFR measured by DTPA scan increased (53.9 to 63.8 ml/min), significantly. (both p<0.001) Post-donation serum iPTH increment was marked (56.8 Vs 47.4 pg/ml, p=0.055), and 25(OH) vitamin D level also rose (27.0 to 30.2 ng/ml, p=0.364). After donation, serum Ca was changed from 9.19 to 9.26 (p=0.181), serum phosphate changed from 3.4 to 3.3 (p=0.434). Renal fraction excretion rate of phosphate (FEpi) was increased after donation. (14.4 to 21.4, p<0.01) Compared with no-CKD group, CKD group showed higher increment of GFR by DTPA scan (15.1 Vs 8.6 ml/min/1.73m^2, p=0.069), higher increase of serum P level (+0.12 Vs -0.19, p=0.044), and higher change in serum Ca X P (1.4 Vs -1.7, p=0.04) In logistic regression analysis, after adjusting sex, age, BMI, pre-donation eGFR, the predictors of development of CKD-MBD was pre-donation FEpi. (OR 0.811, 95% CI 0.658-0.998, p=0.048)

Conclusions: Donor nephrectomy caused a significant change in bone and mineral metabolism in prospective kidney donors and pre-donation FEpi couble be a good predictive marker for early expecting development of CKD-MBD.

PUB094

Serum Osteoprotegerin Is Associated with an Increased All-Cause Mortality in CKD Patients

Marek Stopinski,[1] Joanna Kaminska,[1] Krzysztof Mucha,[2,3] Anna Jedrzejczak,[2] Marta P. Soboniak,[2] Rafal Staros,[2] Monika A. Niewczas,[4,5] Leszek Paczek,[2] Bartosz Foroncewicz.[2] *[1]Department of Internal Diseases and Dialysis Unit, West Hospital of Saint Paul II, Grodzisk Mazowiecki, Poland; [2]Department of Immunology, Transplantology and Internal Diseases, Warsaw Medical Univeristy, Warsaw, Poland; [3]Institute of Biochemistry and Biophysics, Polish Academy of Sciences, Warsaw, Poland; [4]Joslin Diabetes Center, Boston, MA; [5]Department of Medicine, Harvard Medical School, Boston, MA.*

Background: Bone related cytokines were reported to be linked to cardiovascular risk in chronic kidney disease (CKD) patients. The aim of this study was to assess the usefulness of osteopontin (OPN), osteocalcin (OC), osteoprotegerin (OPG) and fibroblast growth factor 23 (FGF23) as predictors of 5-year mortality in patients with different CKD stages.

Methods: The following study groups were enrolled: end stage renal disease (ESRD, n=38), stage 3 and 4 CKD (CKD3-4, n=19) and healthy controls (n=19). Blood samples were obtained at baseline to measure OPN, OC, OPG and FGF23 (ELISA or Luminex platform). 64-row computed tomography was performed to assess the calcium score. Patients were prospectively followed for 5 years to evaluate their all-cause mortality.

Results: All bone related cytokines concentrations significantly correlated positively with each other and had an inverse correlation to eGFR. Moreover, OPN and OPG were significantly correlated positively to calcium score, whereas OPG was associated with an increased risk of death in subjects with CKD3-4 or ESRD. The univariate logistic and Cox proportional hazard models analysis of incident all-cause mortality revealed odds and hazard ratios >4,4. whereas death hazard ratio in multivariate Cox analysis was 2,1 (Table).

Conclusions: We found that OPG correlated with declining eGFR, calcium score, other bone related cytokines and was associated with increased risk of all-cause mortality in patients with CKD3-4 or ESRD. Previous studies, mostly carried out in diabetic patients, suggested that OPG could be a biomarker for CKD progression. Our findings from the mixed population of diabetic and non-diabetic subjects at different CKD stages, provided new arguments to use OPG as a mortality predicting factor in CKD patients.

Logistic analysis and Cox proportional hazard models of incident all-cause mortality in subjects with CKD3-4 or ESRD at baseline (* p<0,05).

Medial Arterial Calcification: A Predictive Survival After Kidney Transplantation

Ekamol Tantisattamo,[1,2] Siroj Dejhansathit,[3] Possawat Vutthikraivit,[3] Haritha R. Mopuru,[4] Praveen Ratanasrimetha,[5] Rungwasee Rattanavich,[6] Raghavesh Pullalarevu,[2] Nattawat Klomjit.[7] *[1]Division of Nephrology and Hypertension, Department of Medicine, University of California Irvine School of Medicine, Orange, CA; [2]Multi-Organ Transplant Center, Division of Nephrology, Department of Internal Medicine, Oakland University William Beaumont School of Medicine, Royal Oak, MI; [3]Phramongkutklao College of Medicine, Mahidol University, Bangkok, Thailand; [4]Multi-Organ Transplant Center, William Beaumont Hospital, Royal Oak, MI; [5]Department of Internal Medicine, Texas Tech University Health Sciences Center, Lubbock, TX; [6]Division of Nephrology, Department of Medicine, Washington University school of Medicine, St. Louis, MO; [7]John A. Burns School of Medicine, University of Hawaii, Honolulu, HI.*

Background: Calcification detected from mammogram (MG) is exclusively medical arterial calcification (MAC) which is associated with morbidity and mortality in ESRD patients. The predictive value of MAC in kidney transplant recipients is unknown.

Methods: A retrospective cohort study of 305 kidney transplant recipients from 2012 to 2015 was reviewed and 51 female patients with ≥1 MG during pre-transplant period were included in this study. MAC is determined by linear calcified breast arteries detected in MG. The association between MAC and mortality was tested by using binary logistic regression analysis.

Results: Mean age±SEM is 57.08±1.47 years and mean duration of follow-up was 3.84±0.18 years. Of 51 patients, 20 patients had MAC prior to kidney transplantation. All laboratory related to mineral and bone metabolism were not different between MAC and non-MAC groups. Six patients died during study period with an incidence rate of 0.0306 person-years [Figure 1]. Five patients in MAC and 1 patient in non-MAC groups died. Patients in MAC group had 10 times higher the odd of death compared to non-MAC group (OR 10.000; 95%CI 1.070 to 93.437, p 0.043). After adjusted for presence or absence of diabetes, MAC group remains having higher mortality (OR 10.148; 95%CI 1.043 to 98.738, p 0.046).

Conclusions: Similar to non-transplant patients, kidney transplant recipients with MAC have significant higher mortality compared to those without MAC. Although kidney transplantation can reverse metabolic disarrangement, this may not be the main factors contributing to survival benefit of successful kidney transplantation.

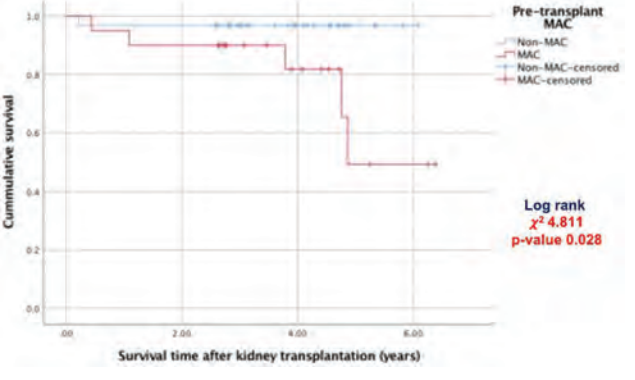

Figure 1: Kaplan-Meier curve demonstrates a significant higher mortality after kidney transplantation in patients with pre-transplant breast MAC compared to those without pre-transplant MAC.*MAC, medical arterial calcification*

PUB096

Arterial Stiffness Evaluated by Cardio-Ankle Vascular Index (CAVI) in Type 2 Diabetes Patients

Silverio Rotondi,[1] Lida Tartaglione,[2] Marzia Pasquali,[3] Gaetano Leto,[4] Daniela Mastroluca,[1] Maria luisa Muci,[1] Sandro Mazzaferro.[2] *[1]Nephrology and Dialysis Unit, ICOT Hospital, Polo, Pontino Sapienza University of Rome, Latina, Italy; [2]Department of Cardiovascular, Respiratory, Nephrologic, Anesthesiologic and Geriatric Sciences., Sapienza University of Rome, Italy, Rome, Italy; [3]Nephrology and Dialysis Unit, Policlinico Umberto I, Rome, Rome, Italy; [4]Department of Experimental Medicine, Sapienza University of Rome, Rome, Italy*.

Background: Identification of early involvement of cardiovascular (CVD) and renal disease in type 2 diabetic patients (T2DM)is challenging. Cardio-Ankle Vascular Index (CAVI), a measurement of arterial stiffness with minimal operator dependence, could help recognize early vascular damage and the resultant CKD. We evaluated CAVI in T2DM patients who had no evidence of macrovascular diseaseand/orrenal insufficiency (estimated Glomerular Filtration Rate or eGFR≥60 ml/min/1.73m2).

Methods: CAVI was measured by VaSera1500 (Fukuda Denshi Co.) in 174 non old (≤ 60 years) T2DM patients (M/F = 100/74) diagnosed since <10 years and never on insulin therapy, and with CKD-EPI estimated GFR ≥60 mL/min /1.73 m2.

Results: Patients were 55.4±4.8 y.o., had a disease duration of 5.2±3.7 y, HbA1c of 6.4±0.9 % and eGFR of 93.5±10.8 ml/min /1.73 m2. None hadeGFR>125ml/min. Systolic blood pressure (SBP) was143,4±19,6 and diastolic (DBP) 87,6±8,7 mmHg. ACR averaged 21.9±58.3 mg/gr with pathologic values (≥30 mg/gr, indicative of CKD) in 11%. CAVI averaged normal values (7.9 ± 0.9) and was pathologic (higher than reference values for age) in 18%. Univariate analysis showed that CAVI correlated positively with age (p=.450; p<.001), Pulse wave velocity (r=.830; p <.001), Hb1Ac (r=.164; p<.05), and DBP (r=240; p<.01). Multivariate analysis confirmed age (p=7.41e-07) and DBP (P=0.014), and selected ACR (p=0.004) but not diabetes duration nor HbA1c as most predictive factors of CAVI.

Conclusions: In our population, age, ACR, and DBP are most relevant factors of arterial stiffness as measured by CAVI. Better than glycemic control and disease duration, CAVI could be a potential marker of early vascular damage indicating poor BPcontrol, endothelial dysfunction and/or CKD (as reflected by ACR).

PUB097

Identifying Patient Centered Strategies for Improving Cinacalcet Adherence

Ruchi H. Naik,[1] Tanvi Rege,[2] Avrum Gillespie,[1] Swati Rao,[1] Jean Lee.[1] *[1]Nephrology, Temple University, Philadelphia, PA; [2]Center for Kidney Disease and Hypertension, Lemoyne, PA.*

Background: Cinacalcet is an effective pharmacological means of treating secondary hyperparathyroidism in patients with ESRD. However, high rates of non-adherence (50% to 85%) and discontinuation (67%) have been reported, limiting the potential benefits. We sought to investigate the underlying reasons for non-adherence and elicit patient directed interventions for improved adherence.

Methods: A sample of 25 patients from in an urban in-center hemodialysis unit who were prescribed Cinacalet for at least a month were administered a 16-item questionnaire during dialysis. These items addressed patient's self-reported adherence, barriers and potential targets for improving adherence. Demographic and laboratory data were extracted from medical records.

Results: All 25 patients were African American. Fifty-six percent were females and the mean age was 63 years. Despite 85% of patients reporting moderate to good adherence, only 5 (20%) had iPTH <600pg/ml. 20 patients (80%) were aware of the prescription, of these 17(85%) were able to identify the pill. Five patients (20%) were unaware of the medication and were unable to identify the pill. Medication refills was not a barrier for any patient. However, 6 (24%) were unable to afford medication due to high copay. Only 1 patient reported non-adherence due to diarrhea. Five patients (25%) identified medication administration during dialysis and 1 patient suggested more education as potential strategies to improve adherence. The majority of the patients did not think that additional education, pill-box management, medication reconciliation, or nursing reminders would achieve better adherence.

Conclusions: The majority of patients reported good to moderate adherence, yet very few had an iPTH at goal. Although 1/3rd of the patients were either unaware of the medication or were unable to identify it, they did not believe further education will be helpful. Unaffordability contributed to non-adherence in 25% patients. The common intervention suggested by the patients was administration during dialysis. As uncontrolled hyperparathyroidism has significant morbidity, we believe that administration of calcimimetics during dialysis and lower cost may hold the key to improved outcomes.

PUB098

Quantitative Systems Pharmacology Approach to Pharmacologic Management of Metabolic Bone Disorder in CKD

Adam E. Gaweda,[1] Eleanor D. Lederer,[2] Michael E. Brier.[1] *[1]University of Louisville, Louisville, KY; [2]University of Louisville; Robley Rex VA Medical Center, Louisville, KY.*

Background: Metabolic Bone Disorder (MBD) is a frequent comorbidity and a risk factor in Chronic Kidney Disease (CKD). Achieving established goals for MBD-CKD treatment is challenging. We show a proof-of-concept feedback controller for pharmacologic management of MBD-CKD and test its feasibility *in sillico* across late stages of CKD.

Methods: In the management of MBD-CKD, the three therapeutic goals are serum concentrations of Calcium (Ca), Phosphorus (PO4), and Parathyroid Hormone (PTH). Here we focus on targeting PTH using a calcimimetic and a vitamin D analog. Based on a Quantitative Systems Pharmacology (QSP) model of Ca-PO4-PTH metabolism in a healthy human (GFR = 100), we developed a Model Predictive Control (MPC) algorithm for determining therapeutic concentrations of Cinacalcet and Calcitriol. We tested the feasibility of the algorithm at CKD stage IV-V (GFR = 30,20,10) targeting PTH concentration ≤ 100 pg/mL.

Results: The MPC algorithm successfully achieved target PTH concentration for all simulated CKD stages. Therapeutic concentrations of Cinacalcet and Calcitriol and the equivalent daily Cinacalcet doses are shown in the table below. An example of simulated of Ca, PTH, Cinacalcet and Calcitriol trajectories over time is shown in the figure. Concurrent dosing of Cinacalcet and Calcitriol results in a dose reduction of the calcimimetic.

Conclusions: We developed a control algorithm for supporting pharmacologic management of PTH levels in MBD-CKD. *In silico* simulations at late stages of CKD demonstrate the algorithm feasibility. Our results also show the synergy between the calcimimetic and vitamin D.

Effect of Secondary Hyperparathyroidism on Bone Turnover Markers in ESRD

Yaomin Wang,[1,2] Lan Lan,[1,2] Cui Yu.[1,2] *[1]The kidney disease center, The first affiliated hospital, College of Medicine, Zhejiang University, Hangzhou, China; [2]Zhejiang University, Hangzhou, China.*

Background: To investigate the effect of secondary hyperparathyroidism (SHPTH) with higher parathyroid hormone (iPTH) on the markers of bone turnover in maintenance dialysis patients.

Methods: The bone turnover markers in 38 patients with maintenance dialysis patients combined with secondary hyperparathyroidism were investigated. Twenty men and eighteen women, aged 28-72 years (median 50.61y), including 22 cases with hemodialysis, 16 cases with peritoneal dialysis, dialysis time 36~125 months (median 84.89). 38 cases with parathyroid nodule or adenoma, 15 cases (39.47%) were diagnosed of bone osteoporosis by X ray. 26 cases (68.4%) accompanied by arterial vessels, and or heart valves calcification, soft tissue calcification.

Results: Serum calcium was 2.32 ±0.16(range 1.87n2.64) mmol/L, and serum phosphorus was 2.17±0.51 (range 1.23~3.11) mmol/L. The level of serum iPTH was 1712.60±635.51(range 1009.00~3864.40)pg/ml, The iPTH of hemodialysis patients (1997.60±147.73 pg/ml) was significantly higher than that of peritoneal dialysis patients (1320.90 ±50.79pg / ml) (P < 0.01). Osteoclast biomarkers: β-CTX degradation products 5486.80 ±849.96 (range 3248.00 ~6025.00) pg/ml. Type I collagen amino terminal propeptide was 1135.90 ±173.34 (range 590.80~1223.00)ug/L. Osteocalcin N-terminal molecular fragment 267.30 ±56.81(range 104.80 ~ 326.00) ng/ml. Serum alkaline phosphatase 277.42 ±211.71(range 84.00~976.00)U/L. Alkaline phosphatase (ALP) in hemodialysis patients (349.18 ±252.97 U / L)was significantly higher than that in peritoneal dialysis patients (178.75±55.09U/L)(P<0.01). 1 month after Parathyroidectomy and autologous forearm transplantation in 3 patients, serum PTH:6.7~2.9pg/ml, β-collagen degradation product: 729.8~800.1pg/ml, Type I collagen amino terminal prepeptide: 138~789.3 ug/L, osteocalcin N-terminal molecular fragment: 17. 38~280.9 ng / ml.

Conclusions: The markers of osteoclasts and osteoblasts were significantly increased, suggesting that the increase of parathyroid hormone level in secondary hyperparathyroidism

significantly promoted bone turnover and made the patients in a state of high transport bone metabolism. The increase of parathyroid hormone and the excess of osteolysis may be an important cause of CKD-MBD osteoporosis in dialysis patients. The monitoring of bone turnover markers can provide a convenient method for dynamic assessment of bone transport status in dialysis patients.

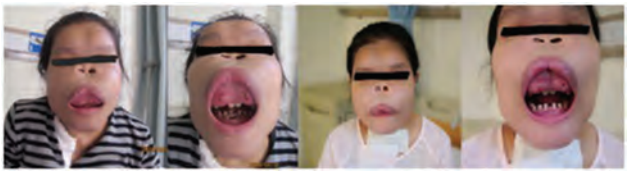
Total Parathyroidectomy Combined with Autotransplantation Under Tracheotomy for the Fatal Uremic Leontiasis Ossea (ULO): A Rare Case Report

Bing Tang,[1] Bei Hou,[1] Yong Xu,[2] Yuanming Li,[2] Xinxin Liu.[1] *[1]Medicine, Renal Division, Jewel Hospital, Changsha, China; [2]Hemodialysis Center, The Third Affiliated Hospital of Xiang Ya School of Medicine, Central South University, Changsha, China.*

Introduction: ULO is a rare medical condition, which is characterized by overgrowth of the facial and cranial bones. The severe airway and esophageal deformities can lead to respiratory depression and eating difficulties. Here we report a rare case of parathyroidotomy with complications of ULO.

Case Description: A 25.Y.O Asian woman with ESRD due to glomerulonephritis had undergoing regular hemodialysis for 6 years. She has uncontrolled SHPT with developed severe ULO for 2 years. The level of serum iPTH was 3724pg/ml, serum calcium, phosphate and alkali phosphatase were 2.32mmol/L, 2.53mmol//L and 1155u/L, respectively. The ultrasonography showed four hyperplastic parathyroid glands. Facial deformity of patient was progressing and experienced difficulties with speaking, breathing, swallowing and chewing. Maintenance of the airway during procedural sedation is quite a challenging task for the anesthesiologist. Total parathyroidectomy was successfully carried out with the general anesthesia by tracheostomy. PTH values 24 hours after surgery was 11.9pg/ml, serum calcium 1.7mmol/L, phosphate was 1.11mmol/L, Patient bone pain disappeared and nasal airway improved right away after surgery. The tracheal tube was removed after 15 days intensive care for complications of tracheostomy. Patient has been discharged with improvement of facial deformation and will be close followed up.

Discussion: ULO of this condition is rare, the patientdeveloped numerous comorbid conditions including airway obstruction. Surgical intervention has been the only option. Because of the lack of cases published so far in the literature, proper surgical management is not developed. This is a unique case to show total parathyroidectomy can be successfully carried out under tracheotomy support for severe ULO.



Preoperative and postoperative comparison of frontal and lateral view of the 25-year-old woman with leontiasis ossea.

The state and parathyroid tissue after general anesthesia under endotracheal intubation.

PUB101

The Value Contribution of an Innovative Remote Monitoring of Longitudinal Estimated Glomerular Filtration Rate Trajectories in CKD Patients

Macaulay A. Onuigbo. *Medicine, The Robert Larner, M.D. College of Medicine, University of Vermont, BURLINGTON, VT.*

Background: CKD affects over 20 million Americans. Existing CKD prediction models are not generally applicable. Most CKD patients remain stable over the years; therefore repeated provider office visits represent expensive unnecessary care. CKD prediction is an inexact science. Current CKD prediction models are cumbersome and generally untested. Individual eGFR trajectories have increasingly become recognized as underutilized diagnostic/prognostic tools. The general consensus is that eGFR trajectories remain mostly linear. A new IT product, The CKD Express ©, developed in a 2012 University of Wisconsin Consortium MBA Class by a team including this author enables remote tracking of serum creatinine/eGFR trajectories. A retrospective study of eGFR trajectories in a patient database will demonstrate the practicality of this innovative CKD Care approach. This system would monitor CKD status of subjects in real-time, determine lab testing frequency using established algorithms and initiate appropriate referrals, as needed, for a population cohort that could involve thousands of subjects. Vermont with a mostly rural-based population, and given the Vermont State-UVMC ACO model of care, would benefit maximally from this efficient, effective, cost-effective yet affordable and very convenient, patient-centered and patient-friendly CKD Care paradigm.

Methods: A retrospective analysis of EMR-based patient records at the University of Vermont Medical Center, January 2008 - December 2017, of CKD III patients. Standard demographics including co-morbidities will be extracted. All serum creatinine/eGFR values will be recorded.

Results: Smoothed linear regression-based eGFR trajectories with spline models evaluated by Bayesian approach would be completed for every patient and correlated with observed renal outcomes: stable, progressive and need for RRT. Our hypothesis of accurate CKD prediction would be confirmed. This would be followed by the development of the new Software prototype, The CKD Express ©, utilizing intrinsic algorithms derived from the eGFR trajectories' analysis, decision support systems (DSS) tools, and artificial intelligence (AI).

Conclusions: The result would be a new innovative approach to CKD Care that is convenient, efficient, effective, affordable, patient-centered, patient-friendly, integrated and cost-saving.

PUB102

Albuminuria Is a Risk Factor for White Matter Hyperintensities on Brain MRI in Elderly Japanese: The Hisayama Study

Keisuke Yamasaki,[1,2] Jun Hata,[1,2] Naoki Hirabayashi,[1,3] Yoshihiko Furuta,[1,2] Tomoyuki Ohara,[1,4] Yoichiro Hirakawa,[1,2] Keita Takae,[1,2] Toshiaki Nakano,[2] Takanari Kitazono,[2] Toshiharu Ninomiya.[1] *[1]Department of Epidemiology and Public Health, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; [2]Department of Medicine and Clinical Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; [3]Department of Psychosomatic Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; [4]Department of Neuropsychiatry, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.*

Background: Albuminuria and kidney dysfunction, which are determinants of chronic kidney disease, are acknowledged as independent risk factors for stroke. Similarly, white matter hyperintensities (WMH), which are often seen in cerebral magnetic resonance imaging (MRI) among the elderly, are reported to be associated with an increased risk of symptomatic stroke. The aim of the present study was to investigate the association of albuminuria and kidney dysfunction with WMH volume in a general Japanese elderly population.

Methods: A total of 1,214 community-dwelling Japanese subjects aged ≥65 years underwent brain MRI scans and a comprehensive health examination in 2012. Urine albumin-creatinine ratio (UACR) was categorized as normoalbuminuria (<30 mg/g) and albuminuria (≥30 mg/g). Subjects with normoalbuminuria were further divided into the following tertile categories: low-normal (≤7.3 mg/g), medium-normal (7.4-12.8 mg/g), and high-normal (12.9-29.9 mg/g). Kidney dysfunction was defined as estimated glomerular filtration rate (eGFR) <60 mL/min per 1.73 m^2. The severity of WMH was evaluated with the ratio of WMH volume to intracranial volume (WMHV/ICV). The association of UACR levels or kidney dysfunction with WMHV/ICV ratio was estimated using the analysis of covariance.

Results: The age- and sex-adjusted geometric mean value of the WMHV/ICV ratio increased significantly with higher UACR levels (low-normal: 0.18%, medium-normal: 0.21%, high-normal: 0.25%, albuminuria: 0.27%; P for trend <0.001). This association remained significant after additional adjustment for hypertension, diabetes mellitus, total cholesterol, body mass index, eGFR, electrocardiogram abnormalities, smoking habits, alcohol intake, regular exercise, and cerebrovascular lesions on MRI (P for trend =0.001). In contrast, there is no evidence of a clear association between kidney dysfunction and WMHV/ICV ratio.

Conclusions: Our data suggest that albuminuria, even within the normal range, is a significant risk factor for larger WMH volume in a general Japanese elderly population.

PUB103

Cardiometabolic Risk Factors Associated with Renal Function in Apparently Healthy Young: Cross Sectional Study

L. M. Perez-Navarro,[1] Rafael Valdez-Ortiz,[2] Araceli Alegría Díaz.[2] *[1]Hospital General de México Dr. Eduardo Liceaga, México, Mexico; [2]Hospital General de Mexico, Mexico City, Mexico.*

Background: The Presence throughout life of hypertension, hypertriglyceridemia, diabetes mellitus, BMI ≥ 30, hyperuricemia and proteinuria, increase risk up to 7 times for the development and progression of CKD. The objective was to identify the prevalence and strength of association between cardiometabolic risk factors and kidney function in young adults (18-25 years of age).

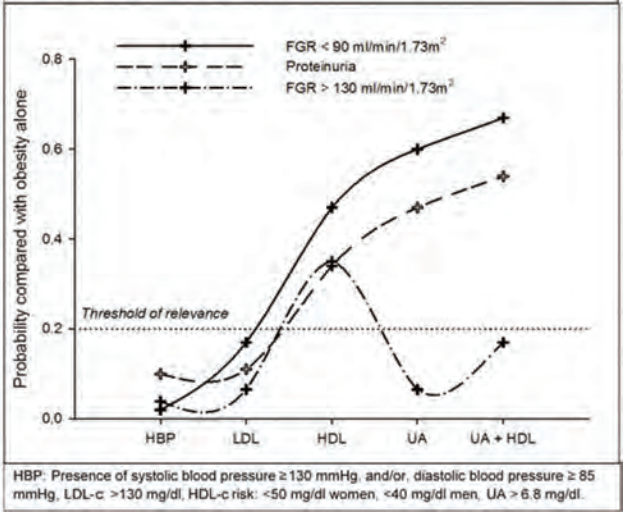
Methods: We included 5,531 apparently healthy young adults, with measurements of waist circumference, overweight and obesity (Ow/OB) by BMI, blood pressure risk systolic and diastolic (≥130/85 mmHg); hyperglycemia (≥100 mg/dl); hypertriglyceridemia (≥150mg/dl), HDL of risk (<40 mg/dl men, <50 mg/dl women), LDL of risk (> 130 mg/dl), hyperuricemia (> 6.8 mg/dl), insulin resistance (HOMA-IR,> 2.9 M,> 2.3 W),

and glomerular filtration rate (GFR) by CKD-EPI. Logistic regression was performed for adjusted OR (95%CI, p <0.05).

Results: The mean age was 19.3±1.6 years old; 76% (4130) presented at least 1 cardiometabolic risk factor for the development of CKD. Out of them 33% (1705) had GFR ≥130 ml/min/1.73m^{2}sc, 3% (157) GFR <90 ml/min/1.73 m^2, and 3% (170) proteinuria. Factors associated with GFR ≥130 were Ow/OB ORa 1.3 (95%IC 1.14-1.47), hyperuricemia ORa 0.2 (95%IC 0.15-0.26), HDL ORa 1.4 (95%IC 1.2-1.6) and IR ORa1.3 (95%IC 1.05-1.7). While hyperuricemia ORa 1.8 (95%IC 1.3-2.6), LDL ORa 1.66 (95%IC 1.05-2.6) and proteinuria ORa 3.4 (95%IC 2.07-5.7) were associated with GFR <90. Proteinuria was associated with hyperuricemia ORa 1.59 (95%IC 1.01-2.5) and LDL ORa 1.8 (95%IC 1.031-3.18). The coexistence of hyperuricemia, Ow/Ob and HDL of risk predict up to 70% the present of GFR> 90 or proteinuria. Fig 1

Conclusions: The coexistence of hyperuricemia, Ow/Ob and HDL of risk predicts the presence of renal failure in young adults. Early detection of cardiometabolic risk factors associated with CKD and the implementation of public health programs that favor its modification will contribute to the reduction of the risk of progression and development of CKD.

Figure 1. Probability of presenting alterations in renal function according to the presence of cardiometabolic risk factors



HBP: Presence of systolic blood pressure ≥ 130 mmHg, and/or, diastolic blood pressure ≥ 85 mmHg, LDL-c >130 mg/dl, HDL-c risk: <50 mg/dl women, <40 mg/dl men, UA > 6.8 mg/dl.

Triglycerides and Cardiovascular Disease in Patients with CKD: Results from the SHARP Trial

Julio A. Lamprea,[1] Natalie Staplin,[3] William G. Herrington,[5] Richard Haynes,[5] Jonathan R. Emberson,[4] Colin Baigent,[5] Ian H. de Boer.[2] *[1]University of Washington, Seattle, WA; [2]Division of Nephrology and Kidney Research Institute, University of Washington, Seattle, WA; [3]Clinical Trial Service Unit, University of Oxford, Oxford, United Kingdom; [4]Clinical Trial Service Unit, Oxford, United Kingdom; [5]University of Oxford, Oxford, United Kingdom.*

Background: Triglycerides (TG) may contribute to the high cardiovascular disease (CVD) risk of patients with chronic kidney disease (CKD). This study evaluated associations of TGs and other lipids with CVD in patients with CKD.

Methods: Analyses were conducted in 9,270 participants with CKD in the Study of Heart and Renal Protection (SHARP) including 3,023 participants on dialysis. Cox regression methods were used to evaluate the association of selected lipids and lipoproteins with incident atherosclerotic (AVE) and non-atherosclerotic vascular events (NAVE).

Results: Median TG concentrations were 1.9 mmol/L (168 mg/dl). During a median follow up of 4.9 years, 1406 participants experienced at least one AVE. Higher baseline TGs were modestly associated with AVE (hazard ratio (HR) per 1.5x higher concentration 1.07; 95% CI 1.00-1.13) with no evidence of effect modification by kidney function (p=0.95). The TG to high-density lipoprotein cholesterol ratio (TG/HDL) was significantly associated with AVE (HR per 1.9x higher TG/HDL 1.10; 95% CI, 1.03-1.18). Significant inverse associations with NAVEs were found for TG (HR per 1.5x higher concentration 0.86, 0.81-0.92) and TG/HDL (HR per 1.9x higher ratio 0.88, 0.82-0.94).

Conclusions: High TG concentrations and TG/HDL ratio were independently associated with AVE. The observed inverse associations with NAVE may reflect non-causal associations. Future studies should determine if treatments targeting TG and TG-rich lipoproteins decrease atherosclerotic cardiovascular risk in patients with CKD.

PUB105

Effect of Diabetes Mellitus on Incidence and Progression of CKD in General Japanese

Tetsuhiko Yasuno,[1,2] Kosuke Masutani.[2,1] *[1]Fukuoka university, Fukuoka, Japan; [2]Fukuoka University, Fukuoka, Japan.*

Background: To study the effects of diabetes mellitus on incidence and progression of chronic kidney disease (CKD) in general population of Japanese.

Methods: This is a retrospective cohort study using health checkup data in Iki City, Nagasaki Prefecture, Japan. The participants of the study included 5,554 residents aged 40 years or older who attended health checkups twice or more over 8 years. This study consists of 2 sets of analyses: (1) the effects of diabetes mellitus on new-onset CKD (defined by an estimated glomerular filtration rate (eGFR) less than 60 mL/min or positive urinary protein) among 4,571 subjects who did not have CKD at the initial health checkup, and (2) the effect of diabetes mellitus on progression of CKD (defined as exacerbation of the GFR category or the proteinuria category) in 983 subjects with CKD at the initial health checkup.

Results: Over a mean follow-up period of 4.6 years, 746 patients with new-onset CKD and 189 patients with CKD progression were confirmed. The incidence of CKD (per 1,000 person-years) in individuals with diabetes mellitus was 55.1%, which was higher than those without diabetes mellitus (33.9%). This correlation was significant (multivariate adjustment [hazard ratio (HR)] 1.44, 95% confidence interval [CI] 1.13-1.84) even after adjusting for the effects of other risk factors. The population attributable fraction was 3%. Similarly, the risk of CKD progression was also significantly higher in individuals with diabetes mellitus than in those without (HR 2.24, CI 1.57-3.19), and the population attributable fraction was 13%.

Conclusions: Diabetes mellitus is a significant risk factor for both new-onset CKD and CKD progression in general population of Japanese. Approximately one-sixth of CKD progression was likely to be attributable to diabetes mellitus.

PUB106

Renal Function Is Preserved During Ketoanalogue Supplementation but Declines After Supplementation Is Withdrawn - A Follow-Up of Randomized Clinical Trial

Anita Saxena,[1] Amit Gupta.[2] *[1]Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India; [2]Department of Nephrology, Lucknow, India.*

Background: We reported preservation of renal function and nutritional status in patients who were noncompliant to vLPD supplemented by ketoanalogues. The aim of the study was to evaluate i) if very low protein diet (vLPD) given along with ketoanalogue in CKD patients retards progression of CKD based on GFR. and ii) is the renal function maintained after withdrawing ketoanalogue supplementation.

Methods: 40 CKD patients were randomized into two groups: Group 1 (Intervention) patients were supplemented with 6 tablets of ketoanalogue for 10 months. Patients were advised very low protein diet 0.4 g/kg/day. Group 2 (Control) patients were given conservative treatment with 0.6 g/kg/d protein restriction. Dietary assessment was done at visit 1 and at visit 2 (10 months), Nutritional Assessment was evaliated with SGA score. GFR and serum albumin were evaluated at baseline and at 10 months. After 10 months ketoanalogue supplementation was stopped. and patients were followed up for two years.

Results: At baseline, the GFR was higher in controls (51.14±15.1 ml/minute). compared to intervention group (47.79±13.2 ml/minute). GFR declined in the control group from 51.14 ml/min at baseline to 35.5±7.94 ml/minute after 10 months. In intervention group the GFR remained stable at 47.79±13.2 ml/minute. The serum albumin level decreased from 3.8±0.90 g/dL to 3.09±0.38 g d/l in control group, while the levels were maintained at 4.11±0.43 in intervention group. In ketoanalogue group decline in GFR was 3.5 ml/min in 10 months while in the control group decline in GFR was 16 ml/minute in 10 months. In ketoanalogue group patients did not comply to low protein diet, in stead they consumed normal protein diet 0.62±0.24 g/kg/d. After 10 months ketoanalogue supplementation was stopped and patients were followed up for two years. Gradual decline in GFR from 47.79±13.2 ml/minute to 28.0 ml/minute and in serum albumin (declined) from 4.11±0.43 to 3.6 g/dL was observed. Serum creatinine decreased from 1.61±0.52 to 1.40±0.52 during ketoanalogue supplementation and increased to 2.2 mg% after stopping ketoanalgue within 2 years. There was no change in the dietary pattern.

Conclusions: Ketoanalogue supplementation is an effective way of preserving renal function and nutritional status. without adherence to vLPD.

PUB107

The Approach of Non-Nephrologist Medical Practitioners to Abnormal Urinalysis and Kidney Function Test

Faheem M. Ahmed,[1] Mahdi Y. Alzamanan,[2] Abdullah S. Alyami,[2] Mesale A. Algshanen,[2] Ali A. Alnajrani,[3] Mohammed D. Alzamanan.[2] Kidney diseases research group, Najran *[1]Nephrology department, King Khalid Hospital Nanjran, Najran, Saudi Arabia; [2]Najran University, Najran, Saudi Arabia; [3]Najran university, Najran, Saudi Arabia.*

Background: Chronic kidney disease (CKD) is a devastating medical condition with a negative impact on the individual patient and the whole community. Primary screening for the high-risk group of patients is a crucial issue for early intervention and mitigation the progression of disease or at least minimization its complications. The aim of our study to evaluate the knowledge, attitude, and practice for non-nephrologist medical practitioners to abnormal renal function test.

Methods: A cross-sectional, KAP study conducted among the medical practitioners who are working in Najran city. A structured, self- administered questionnaire which consists of 20 items has been distributed to the targeted population.

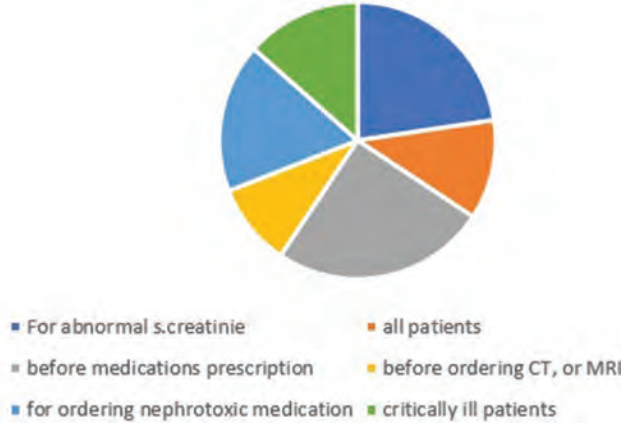
Results: The total number of responders is193. Around 80% of them routinely screen the high-risk patients for CKD. Regarding the approach to abnormal active urine sediments, a 25% of responders are preferred to consult the nephrologist, while the remaining are either prefer to repeat the test or to do further investigations. Regarding high serum creatinine, a 38% of them used to directly referred such patient to nephrologist while the others either they used to repeat the test or doing further investigations including imaging. Surprisingly, only 26% of the responder only used to calculate glomerular filtration rate (GFR) and most of them are not aware of the new equations for eGFR.

Conclusions: Most of the non-nephrologist medical practitioners are aware of CKD diagnosis, most of them they are aware when and whom to refer to a nephrologist. They need more orientation for interpretation of abnormal urinalysis and the proper way for calculation of eGFR.

Approach to abnormal urinalysis

	Repeat urinalysis immediately	Repeat with proper collection	Check Renal function	Check urine protein	Consult nephrologist	Take others opinion (non-nephrologist)	No action	urine culture	start treatment
Urine RBCs	9.1%	20%	28%	8.6%	25.7%	8.6%			
Urine WBCs	7.7%	23%	23%	6.6%	23.5%	11.5	1.1%	2.2%	1.6%
Urine casts	8.2%	10.3%	29.3%	2.7%	40.8	8.2%			0.5%
Proteinuria	8.2%	13.2%	30.8	7.1%	34.6%	5.5%			0.5%

RBCs = red blood cells, WBCs = white blood cells



PUB108

The Importance of a Multifaceted Care Approach for CKD

Takahiro Kuragano, Takeshi Nakanishi. *Hyogo College of Mediicne, Nishinomiya, Japan.*

Background: It is well known that chronic kidney disease (CKD) patients have several comorbidities such as anemia, hypertension, hyperuricemia, and CKD-MBD. To prevent the progression of CKD or adverse events in these patients, multifaceted care approaches by nephrologists are needed. In this study, we evaluated the effect of a multifaceted care approach by nephrologists on the progression of CKD.

Methods: The study was an observational study in a single center for a period of 3 years. In 88 patients with various stages of CKD (not HD) who were treated by nephrologists, blood levels of Hb, ferritin, iron, total iron-binding capacity (TIBC), and albumin were measured every 3 months, and high sensitive C reactive protein (hsCRP), β2microglbulin (MG), and intact-parathyroid hormone (iPTH), in addition to urinary sodium, potassium, calcium, phosphorus protein, and β2MG levels, were measured every 6 months. All patients were treated according to the clinical practice guideline for CKD (Japanese Society of Nephrology 2013).

Results: (Progression of renal dysfunction) In multiple regression analysis, baseline blood level of Hb (β=0.5, P<0.001), int-PTH (β=-0.33, P=0.001), vitamin D 125 (β=0.26, P=0.006), urinary phosphorus (β=0.33, P=0.001), urinary β2MG (β=-0.23, P=0.03) and urinary protein (β=0.28, P=0.02) were selected as predictors of estimated glomerular filtration rate (eGFR) or 1/ creatinine(Cr) at the end of the study. (Progression of renal anemia) Although there was no significant correlation among Hb level, serum ferritin and TSAT, serum phosphorus level (β=-0.24, P=0.03) and urinary logβ2MG (β=0.25, P=0.02) were selected as predictors of future Hb levels. (Risk factors for the initiation of RRT and adverse events) In the Cox hazard model, low calcium (HR: 0.37, P=0.03), high phosphate (HR:5.90, P<0.001), low 125 vitamin D (HR: 0.94, P=0.01), high int-PTH (HR:1.02, P<0.001) level, use of a phosphate binder (HR: 4.95, P=0.01), and use of vitamin D (HR:3.75, P=0.01) are selected as risks for initiation of RRT.

Conclusions: In this study, we found that although phosphate binder or vitamin D was administered appropriately, CKD-MBD factors (phosphate, calcium, vitamin D, int-PTH) were related with anemia progression, renal dysfunction and RRT initiation. With the multifaceted care approach for CKD, the focus on CKD-MBD related factors appeared to reduce the risk of CKD progression or RRT initiation.

PUB109

Relationship Between Sleep Duration and Kidney Function in General Adults: A Systematic Review and Meta-Analysis

Lin Jinwen. *Kidney disease center, the first affiliated hospital, Zhejiang University, Hangzhou, China.*

Background: The possible relationship between the duration of sleep and chronic kidney disease related disease are not clear. This study aimed to determine the relationship in general adult populatiion.

Methods: We searched MEDLINE, EMBASE, Cochrane Library from database inception to November 20, 2017. The studies related to sleep duration and chronic kidney disease in general adult population were included. Sleep duration was grouped into 3 categories, short sleep (< 6h), reference (≥ 6h %<8h), long sleep (≥ 8h). We included studies which reported odds ratio (OR) comparing the risks of chronic kidney disease, proteinuria and renal hyperfiltration. Pooled OR and 95% confidence intervals (CI) were calculated using the random-effect model with Stata 12.0 software.

Results: A total of 12 studies divided into 17 substudies were analyzed in this meta-analysis, covering 682,449 patients. Sleep duration had no significant risk of chronic kidney disease. There was a higher risk of proteinuria (OR = 1.38, 95% CI = 1.13 – 1.67) in short sleep group, while renal hyperfiltration (OR = 1.04,95% CI = 0.93 – 1.18) not. Long duration sleep had a higher risk of proteinuria (OR = 1.35, 95% CI = 1.17 – 1.54) and renal hyperfiltration (OR = 1.08, 95% CI = 1.01 – 1.15).

Conclusions: Though there was no significant association between sleep duration and chronic kidney disease, we suggested a potential association of proteinuria in both long and short sleep duration group, while not being with renal hyperfiltration. Objective sleep measurements and more cohort studies should be considered in future epidemiological studies.

PUB110

Validation of Self-Reported Race in a Provincial Renal Administrative Database

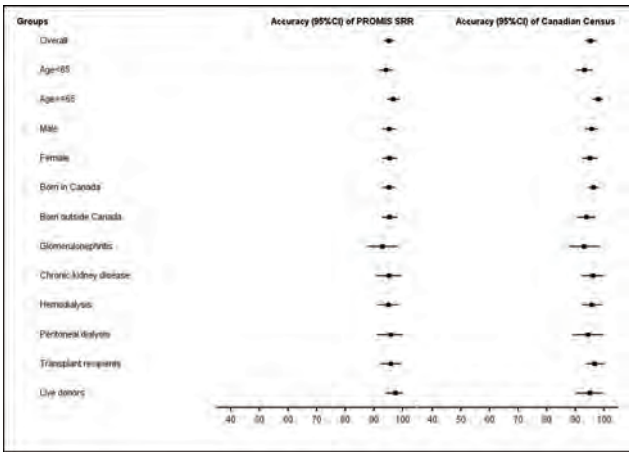
Aiza Waheed,[1] Ognjenka Djurdjev,[2] James Dong,[2] Jagbir Gill,[1,2] Sean Barbour.[1,2] *[1]University of British Columbia, Vancouver, BC, Canada; [2]BC Renal Agency, Vancouver, BC, Canada.*

Background: Administrative data is commonly used to study clinical outcomes in renal disease. Race is an important determinant of renal outcomes but is not validated in most administrative data, and the correlation with census-based definitions of race is unknown. We validated self-reported race (SRR) in a Canadian provincial renal administrative database (PROMIS) from British Columbia using a prospective patient survey and compared it to the Canadian census categories of race.

Methods: This is a cross sectional telephone survey of a random sample of all adults in PROMIS conducted from 02/2016 to 11/2016. Responders selected a race category from PROMIS and from the Canadian census. Sensitivity (Sn) and specificity (Sp) were calculated with 95% confidence intervals (CI).

Results: 21,039 patients met inclusion criteria, 1,677 were selected for the survey and 637 participated (38% response rate). There were no differences between the PROMIS, sampled and responder populations. PROMIS SRR had an accuracy of 95.3% (CI 94.2-97.0%) when validated against the survey SRR with Sn and Sp ≥90% in all race groups except in Aboriginals (Sn 87.5%). The positive and negative predictive values were ≥95%, except in very low and high prevalence groups, respectively. The Canadian census had an accuracy of 95.7% (CI 94.4-97.6%) when validated against PROMIS SRR with Sn and Sp ≥90%. The results did not differ in subgroups based on age, sex, birth outside Canada, or renal group (glomerulonephritis, chronic kidney disease, hemodialysis, peritoneal dialysis, transplant recipients or live donors).

Conclusions: We have shown high accuracy of PROMIS SRR that validates its use in the secondary analysis of administrative data for research. There is high correlation between PROMIS and census race categories which allows linkage with other data sources that use census-based definitions of race.



Accuracy of PROMIS SRR and census race categories with 95%CI, overall and for individual subgroups

PUB111

CKD Monitoring in Routine Clinical Practice: An Analysis of a National Laboratory Database

Jennifer L. Ennis,[1] Dajie Luo,[2] Barbara S. Gillespie.[3] *[1]Laboratory Corporation of America Holdings, Chicago, IL; [2]Laboratory Corporation of America® Holdings, Durham, NC; [3]Covance CRO; University of North Carolina, Cary, NC.*

Background: Published guidelines for chronic kidney disease (CKD) have existed for many years, but guideline implementation remains inconsistent in clinical practice. We evaluated the frequency of guideline-based CKD monitoring for patients with laboratory evidence of CKD in a data set from a national laboratory.

Methods: We identified all patients who had at least 2 eGFR results below 60 ml/min/1.73m2 at least 3 months apart based on serum creatinine testing performed at a LabCorp facility between November 2011 and April 2018. We then analyzed whether certain guideline-recommended tests (urine albumin/creatinine ratio (UACR), serum phosphorus (P), plasma parathyroid hormone (PTH), and LDL cholesterol (LDL-C)) were performed a) within 1 year of or b) at any time after the first qualifying eGFR result.

Results: Among the 4,909,840 patients who met criteria for the study, 58.2% were women. Mean age was 71.2 ± 12.0 years. Median follow-up was 25.7 (IQR=12.2 – 45.8) months. The percentage of patients in stage 3a, 3b, 4, and 5 based on the initial eGFR result were 70.3%, 21.9%, 6.3%, and 1.5%, respectively. At 1 year, rates of testing for UACR, PTH, and P were 24.4%, 11.8%, and 16.9%, respectively. Any time testing rates were only slightly higher: 35.4% (UACR), 20.5% (PTH), and 25.3% (P). However, rates of LDL-C testing at 1 year (75.5%) and any time (84.4%) were much higher, indicating that other routine testing was being performed on these patients.

Conclusions: Despite guideline recommendations, routine laboratory testing for CKD and its comorbidities remains low in US clinical practices. This data highlights the need for further strategies to improve CKD evaluation and management.

PUB112

Predicting the Progression of CKD to Kidney Failure in a Southeastern US Population

Jennifer C. Gander,[2] Lee Cromwell,[2] Musu M. Sesay,[2] Adam S. Wilk,[4] Teaniese L. Davis,[5] Joseph P. Austin,[1] Rachel E. Patzer,[6] Nirvan Mukerji.[3] *[1]Kaiser Permanente, Atlanta, GA; [2]Kaiser Permanente of Georgia Center for Research and Evaluation, Atlanta, GA; [3]Kaiser Permanente Georgia, Atlanta, GA; [4]Rollins School of Public Health, Emory University, Atlanta, GA; [5]Kaiser Permanente Georgia, Center for Research and Evaluation, Atlanta, GA; [6]Emory Transplant Center, Atlanta, GA.*

Background: There are >100,000 adults transitioning from chronic kidney disease (CKD) and end stage renal disease (ESRD) with a geographic disparity of ESRD incidence in the Southeastern U.S. We aimed to determine the risk factors associated with progressing from CKD to ESRD in a Southeastern population.

Methods: Adult (18<age<100) CKD Stage 3-5 patients of a large, Southeastern integrated healthcare system (2010-2017) were included in the cohort. CKD and ESRD were defined using diagnosis codes. Risk factors were collected at the time of CKD diagnosis. Descriptive statistics and Cox proportional hazard models were completed to determine the association and predictive power of the risk factors.

Results: Among 3,399 patients, 442 (13%) started dialysis with average age was 58, 60.4% were male, 71% Black, and the average estimated glomerular filtration rate was 31.0 per 5 mL/min/1.73m². Among those with ESRD, the average time between CKD and ESRD was 1.6 years, with Blacks having a significantly longer time (2.4±2.1) vs Whites (1.8±1.5) (p=0.01). In the fully adjusted model 4, Blacks (vs White), and patients with hypertension were 2.3 (HR=2.3; 95% CI 1.8, 3.0), and 2.5 (HR=2.5; 95% CI 1.2, 5.3) times more likely to transition to ESRD, respectively. Model adjustment improved predictive power and Goodness of Fit, with model 4 (c-statistic=0.8515). The area under the curve for the fully adjusted model remained stable around c=0.85 during follow-up time 0-6 years.

Conclusions: A predictive model using clinically routine variables can predict CKD progression to ESRD. Healthcare systems should consider integrating predictive analytics in their routine clinical visits to help alert them to a patient's increased risk for ESRD to enable timely intervention.

Retrospective Observation of the Prevalence of Proteinuria in a Newly-Diagnosed HCV Population

Emily Levine,[1] Chelsey Fix,[3] Crystal A. Gadegbeku.[2] *[1]Temple University Hospital, Philadelphia, PA; [2]Temple University, Philadelphia, PA; [3]NephCure Kidney International, King of Prussia, PA.*

Background: In response to a growing Hepatitis C (HCV) epidemic, many states are mandating screening programs for high risk populations to facilitate HCV treatment. Despite the well-recognized risk of chronic kidney disease (CKD) in patients with HCV, currently there are no guidelines for CKD screening. Given Pennsylvania's new mandate for HCV screening and CKD risk, we assessed the prevalence of dipstick positive proteinuria in newly-diagnosed HCV positive patients without history of CKD. The goal of this study was to explore the potential for early-detection of CKD in this high risk population.

Methods: A cross-sectional retrospective analysis was performed using data collected from electronic medical records of patients who were screened, diagnosed, and/or treated for HCV at Temple University Hospital, an urban tertiary care center in North Philadelphia in 2017. For identification of possible early-stage CKD, this analysis reviewed the availability and results of urine protein assessment after HCV diagnosis in patients with eGFR>60 ml/min. Data collection included demographics, comorbidities, eGFR, and urinalysis. Overt proteinuria was defined as urine dipstick with protein >1+. Positive proteinuria findings were excluded in samples with diagnosis of UTI, hematuria, or glycosuria.

Results: Of the 637 patients identified as HCV-positive, 498 had eGFR > 60 ml/min. The mean age was 52.4 ± 13.1 and 67.7% were male. Urinalysis was obtained in 199 patients (39.9%). Eighteen urine samples were excluded from qualitative analysis. Overall, 34 of 181 patients (18.8%) had overt proteinuria. Of these 34 patients, one was evaluated for proteinuria by a nephrologist within the Temple Health System.

Conclusions: Proteinuria is an early marker of CKD and its detection within high-risk populations may be beneficial. Our findings indicate a minority of HCV positive patients had urine evaluation after HCV diagnosis. The prevalence of overt proteinuria in our study was higher than reported in the general US population in NHANES (18.8% vs 1.3% respectively). Nephrology referral was infrequent. Although there are some limitations, these preliminary findings highlight the need for further investigation of CKD screening

in various high risk populations. Further prospective studies are needed to validate these results and outcomes of early detection.

PUB114

The Effect of CKD Risk Factor Scorecard Intervention Among Patients with Non-Dialysis CKD

Suyuan Peng,[1,2] Liwei Wang,[1] Yue Yu,[1] Xusheng Liu,[3] Hongfang Liu.[1] Accelerating Digital Medicine Empowered by Value-added NLP for Clinical Excellence(ADVANCE) *[1]Health Science Research, Mayo Clinic, Rochester, MN; [2]The second Clinical College, Guangzhou University of Chinese Medicine, Guangzhou, China; [3]The Second Affiliated Hospital, Guangzhou University of Chinese Medicine, Guanghzou, China*.

Background: Long-term management of chronic kidney disease (CKD) requires high-level patient involvement. Mayo Clinic developed a scorecard that contains 12 items of CKD risk factors to improve self-management skills for the purpose of reducing risk factors and slowing the progression of CKD. In this study we aim to compare the prognosis of patients of CKD3 with and without CKD Risk Factor intervention.

Methods: A single-center retrospective cohort study was performed using electronic medical records (EMR). Cases were included when patients (≥18 years) were followed up for at least 1 year or progressed to end-stage renal disease (ESRD) within 1 year from January 2009 to December 2017. Time-to-event analyses were performed with Kaplan–Meier method, and the time progressing to the ESRD in two groups was compared using log-rank test.

Results: We analyzed data of 19,973 patients (553 in scorecard group). The mean age was 73.03±12.71 years, 54.2% were male and 2.9% were African American. Kaplan-Meier analysis showed that renal survival was significantly lower in scorecard group compared with non-scorecard group (Log-rank test, p= .000).

Conclusions: The CKD Scorecard intervention isn't associated with progression reduction of kidney disease. Further studies are needed to explore the method of evaluating self-efficacy and the potential role of risk factors in the progression of CKD.

Affective Status, Disease Knowledge, and Treatment Adherence in CKD Mexican Patients

Aurora Calderon,[1] Rosa M. Meda,[1] Pablo Maggiani,[1] Jonathan Chavez,[1,2] Guillermo Garcia-Garcia.[2,1] *[1]University of Guadalajara Health Sciences Center, Guadalajara, Mexico; [2]Hospital Civil de Guadalajara FAA, Guadalajara, Mexico*.

Background: CKD is a public health concern and low adherence to treatment has been associated with poor health outcomes. Low adherence to treatment varies between 20%-70%. Multidisciplinary care (MDC) could improve management and outcomes of patients with CKD. We evaluated the prevalence of the affective status, depression, disease knowledge, and treatment adherence in CKD patients attending our MDC clinic.

Methods: A cross-sectional study in a convenience, non-probabilistic sample of pre-dialysis CKD patients, stage 3-5. Individuals were interviewed by psychologist with no time limitation. Measures: KiKS and PSS, Spanish versions; Adherence Scale for Chronic Patient Based on Explicit Behaviors; PANAS; Personality Inventory for DSM-5 (PID-5)-Adult, Depression and Anxiety Subscales.

Results: Table 1, Fig 1

Conclusions: Our results showed that a coordinated MDC can improve management and quality of care in patients with CKD, as demonstrated by the high levels of positive affect, disease knowledge, self-efficacy, and treatment adherence found in our study. Further research is needed to evaluate the program component effectiveness in CKD progression and management.

Risk Factors for CKD Progression to ESRD: Experience on 15 Years Follow-up in the Multidisciplinary CKD Clinic

Pantipa Tonsawan, Kittrawee Kritmetapak, Chitranon Chan-on, Eakalak Lukkanalikitkul, Cholatip Pongsakul, Dhavee Sirivongs, Sirirat Anutrakulchai. *Khon Kaen University, Khon Kaen, Thailand*.

Background: Chronic kidney disease (CKD) is a significantly worldwide health problem. Risk of CKD progression under holistic approach in developing countries are scarcely studies. Our aim was to investigate risk factors for chronic kidney disease progression to end-stage renal disease (ESRD) with dialysis in the multidisciplinary CKD clinic.

Methods: The retrospective cohort study was conducted in the CKD clinic at Srinagarind, A University Hospital in Thailand during January 1, 2000, to December 31, 2015. Our CKD clinic has been established for 15 years with multidisciplinary and holistic cares that include a nephrologist, nurse educator, dietician, pharmacist and physical therapist. The adult CKD patients who followed up at least 6 months were recruited. The medical and laboratories data every 6 months were recorded.

Results: Of 506 CKD patients were recruited, the mean age was 65.2 ± 13.5 years and mean follow up time was 41.5 ± 34.8 months. The majority CKD stage that physician refer to the specialist was CKD stage 4. The incidence rate of dialysis was 5/1000 patient-months. The overall renal survival rate in CKD clinic at 50 and 100 months were 75, 50 %, respectively. The overall mean slope of the estimated glomerular filtration rate decline

was -2.67 mL/min/1.73m² in the first year of follow-up. The results of multivariate Cox regression model showed that age > 55 year (hazard ratio[HR] 0.46, 95% confidence interval[CI] 0.30-0.72), diabetes (HR 1.56, 95%CI 1.04-2.33), hypertension (HR, 4.00, 95%CI 1.44-11.0), renal cancer (HR 2.67, 95%CI 1.13-6.30), CKD stage 4 (HR 15.95, 95% CI 2.17-117.2), and CKD stage 5 (HR 93.67, 95%CI 12.5-700.1) were independent association risk factors for ESRD with dialysis.

Conclusions: This study demonstrated that diabetes, hypertension, and referral to nephrologist with advanced CKD stage are independent predictors of dialysis-dependent ESRD.

PUB117

Culinary Techniques to Improve Education in Legume and Vegetable Consumption in CKD Patients

Secundino Cigarran,[1] Iria Acal,[2] Ana maria Sanjurjo amado,[1] Juan Latorre,[4] Nicolas Menendez,[1] Belen Rodriguez delgado,[1] Lourdes Vázquez-Odériz,[3] M? Angeles Romero-Rodríguez.[2] *[1]Nephrology Service. Hospital Da Costa, Burela, Spain; [2]University of Santiago de Compostela, Lugo, Spain; [3]University, Lugo, Spain; [4]Hospital Da Costa, Burela, Spain.*

Background: Good nutrition is relevant in for CKD pts. Legumes and vegetables by P & K content are restricted in CKD pts. Guidelines on Nutrition do not include recommendations on culinary techniques. The aim was to assess the influence of culinary techniques on removal P and K in legumes and vegetables and to assess the nutrients in manufactured as well.

Methods: Legumes (lentils, beans, chickpeas) obtained at supermarket and dried packaged in 1000 g packs. Likewise, legumes are obtained in glass jars that are cooked and conservate with water enriched with salt. Collard greens and chards (rawl and frozen) were obtained as well. Determination of humidity and ashes were performed accordance to method 934.01 AOAC (2012) (George and Latimer, 2012). Mineral assessments were performed by Optical Emission Spectrometer with Coupled Plasma (ICP-OES Optima 4000 DV by Perkin Elmer. The ashes of each samples were dissolved in 4 mL of a solution of 3 M HCl + 21 mL distilled water for the analysis of Zn, Fe, Ca, P, Mg, Na and K. Legumes were analized in raw, after soaking (12 hrs) and after soaking followed by boiling. Vegetables were included in 4 groups to analyze: the fresh product, after to be subjected to direct cooking, after being subjected to boil previous blanch and after being frozen with a prevoius blanching and then applying a boiled. Elements Na, K, Ca, Mg, Fe, Zn were measured after each and compared with fresh.

Results: Legumes: all techniques reduced P & K content respect to raw, being 12 hrs soaking plus boiling more efficient reducing up to 76.2%, keeping levels < 100 mg/100 mg fresh sample, and manufactured as well. Vegetables: all techniques reduced K content respect to raw. The more favourable techniques were blanching+boiling (82%), frozen (81%) and frozen manufactured (82%). All of them showed a K level <10 mg/ 100 mg fresh sample.

Conclusions: Industrial legumes; combining 12-hours-soaking and boiling reduced up to 70% of P & K content. Vegetables reduced K content in both in industrial frozen and fresh managed with all culinary techniques. Healthy culinary techniques should be included in the nutritional education programs for CKD pts. Legumes & vegetables provide fiber, vitamins of group B and are a good source of protein of vegetable origin.

CKD of Non-Traditional Etiology in the United States, 2000-2015: Incidence Rates Using Administrative and Electronic Health Records

Madeleine K. Scammell,[1,2] Omid Ameli,[3] Caryn M. Sennett,[1] David J. Friedman,[6] Michael Mcclean,[1] Daniel R. Brooks,[1] Marc Weisskopf,[5] Veronica M. Vieira.[4] *[1]Boston University School of Public Health, Boston, MA; [2]Visiting Scholar, OptumLabs, Boston, MA; [3]Boston University School of Public Health, Boston, MA; [4]University of California, Irvine, Irvine, CA; [5]Harvard TH Chan School of Public Health, Boston, MA; [6]Beth Israel Deaconess Medical Center, Brookline, MA.*

Background: Chronic kidney disease of non-traditional etiology (CKDnt) affects populations without traditional risk factors for chronic kidney disease (CKD). In Central America CKDnt affects primarily young working men, reaching epidemic proportions. Incidence in the United States has not been characterized.

Methods: We conducted a retrospective analysis of claims and electronic health record (EHR) data from the OptumLabs® Data Warehouse which includes de-identified claims data for privately insured and Medicare Advantage enrollees in a large, private, U.S. health plan, and de-identified EHR data from a nationwide network of provider groups. Our case definition of CKDnt was CKD with no prior documented diagnosis of 22 conditions known to cause CKD (e.g., nephropathies, diabetes, heart disease, autoimmune disease and malignancies). By definition, traditional CKD cases had prior diagnoses of these conditions. CKD cases with prior diagnosis of hypertension (a cause and consequence of kidney disease) were excluded from analyses. We used nonparametric regression to estimate annual incidence of CKD and CKDnt in claims data, examining differences by sex, age, race/ethnicity and geographic region. We examined new cases in EHR data, and differences by the same risk factors and insurance type.

Results: Seven percent of CKD cases with a year of continuous enrollment in claims were CKDnt. Incidence rates of CKD and CKDnt in claims data increased from 2000-2015 in all age groups with the exception of <18 years. CKD rates increased with age category, although were equal among the age 18-39 and 40-59 groups. In contrast, CKDnt rates were significantly higher in the 40-59 age group compared with all other age groups. This difference was driven by male cases. Compared to traditional CKD, CKDnt cases <60 years were 29% more likely to have advanced disease at initial diagnosis (RR=1.29; 95% CI 1.23-1.35). New CKD and CKDnt cases in EHR were more likely to be male and have Medicare compared to all other types of insurance.

Conclusions: Our results are the first to characterize increasing CKD incidence rates by age in the US, highlighting that CKD with no known risk factors may disproportionately affect men of younger ages.

Racial Disparities in the Effect of Inflammation on the Prediction of Albuminuria in Patients with the Metabolic Syndrome Using Machine Learning

Vikash R. Singh,[1,3] Satyesh K. Sinha,[2,4] Keith C. Norris,[4] Susanne B. Nicholas.[4] *[1]DataREACH, Los Angeles, CA; [2]Charles R Drew University of Medicine and Science, Los Angeles, CA; [3]Computational and Systems Biology, UCLA, Los Angeles, CA; [4]Medicine, David Geffen School of Medicine at UCLA, Los Angeles, CA.*

Background: C-reactive protein (CRP), an inflammatory marker, is associated with the metabolic syndrome (MetS) and chronic kidney disease. We previously showed that CRP mediated the association between microalbuminuria (MA) and MetS components by race/ethnicity. However, little is known about the effect of CRP on the predictive value of albuminuria in MetS patients, by race. In this study, we used a machine learning (ML) strategy to determine the extent to which the addition of CRP impacts the performance of predictive models among racial/ethnic groups.

Methods: We analyzed National Health and Nutrition Examination Surveys data (1999-2010) for adults (aged ≥20 years) with the MetS (N=5700). We created ML models using a comprehensive cloud-based platform (Microsoft Azure), which allowed us to build a variety of ML applications for testing and prototyping different models as well as integrating R, a programming language for statistical computing for data preprocessing and feature engineering. We created a boosted tree regression and performed random sweep parameter optimization. Regression models were created for each of the racial/ethnic subgroups both including and excluding CRP as a parameter, and the change in coefficient of determination (R^2) was calculated, which represents the total proportion of variance accounted for by the predictive model.

Results: The coefficient of determination (R^2) was 0.081, 0.154 and 0.113 in African Americans (AAs) Hispanics and Whites, respectively. The R^2 was most highly increased in AAs (0.119, 47%) followed by Hispanics (0.163, 5%) and Whites (0.119, 5%) with the addition of CRP to the models.

Conclusions: The data shows that the effectiveness of CRP to predict albumin concentration is greatest for AAs compared to Hispanics and or whites. This suggests that targeting CRP may be a feasible strategy to manage albuminuria in AAs. ML is a useful tool to support epidemiologic research and clinical management decisions.

Exercise Counseling for People with CKD: An International Survey of Nephrologists' Practice Patterns and Research Perspectives

Airis A. Taryana,[1] Rathika Krishnasamy,[2] Clara Bohm,[3] Suetonia Palmer,[4] Neil Boudville,[5] Jennifer M. MacRae,[6] Jeff S. Coombes,[1] Carmel M. Hawley,[7] Nicole Isbel,[7] Stephanie E. Thompson.[8] *[1]University of Queensland, Herston, QLD, Australia; [2]Nambour General Hospital, Nambour, QLD, Australia; [3]University of Manitoba, Winnipeg, MB, Canada; [4]University of Otago, Christchurch, New Zealand; [5]University of Western Australia, Nedlands, WA, Australia; [6]University of Calgary, Calgary, AB, Canada; [7]Princess Alexandra Hospital, Brisbane, QLD, Australia; [8]University of Alberta, Edmonton, AB, Canada.*

Background: People with chronic kidney disease (CKD) have identified the impact of lifestyle interventions such as exercise as a research priority. We investigated nephrologists' practice patterns and research perspectives with respect to exercise in CKD patients.

Methods: A 19-item electronic survey regarding exercise-related practice patterns and resources was administered to practicing nephrologists with publicly available email addresses in Canada (n=354), practicing nephrologists in Australia and New Zealand and to the members of the Australian and New Zealand Society of Nephrology (n=598).

Results: 198 nephrologists (21% response) completed the survey; 63% were 35 to 50 years old, 57% practiced in Canada, and 67% were men. Overall, 60% thought that exercise counseling was within a nephrologist's role. The most frequently reported barrier for exercise programs was lack of funding. On average, 96% agreed that regular exercise provides "health benefits" for all CKD stages and 71% reported "frequently" or "always" counseling patients on exercise. 38% respondents agreed that sufficient evidence exists to support regular exercise prescription for CKD patients. In a multivariate model, agreement with a sufficient evidence base for exercise in CKD and personal physical activity were not associated with exercise counseling practices. Female respondents (OR 2.31; 95% CI 1.16-4.58) and older respondents (OR 1.94; 95% CI 1.15-3.26) were more likely to offer exercise counseling. Exercise impact on patient-reported outcomes (quality of life [QoL] [28%],

symptoms [26%], and mental health [25%]) followed by cardiovascular parameters (18%) and CKD progression (16%) were identified as important outcomes for future research.

Conclusions: Most nephrologists consider exercise counseling as a component of their practice and consider that exercise offers patients improved health. Lack of funding for exercise programs is perceived as the principal barrier to implementation. Nephrologists identify core patient-centred outcomes as central to the future research agenda.

Socioeconomic Status and Geographic Factors May Be Related to Lower Renal Biopsy Rate and Higher ESKD Events: A Retrospective Study in Chiba Prefecture, Japan

Masaki Uehara, Takehiko Kawaguchi, Toshiyuki Imasawa. *National Hospital Organization Chiba-East Hospital, Chiba, Japan.*

Background: It is important to grasp the prevalence of kidney disease when we discuss about health policies in living area. Previous studies have reported that there are regional variations in the incidence of biopsy-proven kidney disease and end stage kidney disease even in small region. However, it is unclear whether those variations are associated with socioeconomic status or geographic factors. The aim of this study is to examine the relationships between regional backgrounds and incidence of kidney diseases at Chiba prefecture in Japan, with a population of six million.

Methods: We collected clinical data on renal biopsies performed between Apr.2014 and Mar.2016 at seven main hospitals in Chiba prefecture. We divided the prefecture into nine medical areas, and calculated biopsy rates in each area using regional statistical data from government's open data site. The biopsy rates were age-adjusted by using data from Japan Renal Biopsy Registry. Spearman's rank correlation coefficient was used to estimate associations between biopsy rate and regional backgrounds.

Results: A total of 910 cases were enrolled. The patients were mean age of 57 years and 56% of patients were male. There were different renal biopsy rates (19.9 ± 10.6 /100000 population) and disease variations in nine different area. No association was found between the number of nephrologist or health check-up participation rates and renal biopsy rates. But average incomes and numbers of hospitals in districts have correlations. (ρ=-0.87; p= 0.005, ρ=0.92; p=0.001)

Conclusions: Low-income regions had more renal biopsy than high income-regions, and the number of hospitals in areas was related to renal biopsy rates. It suggests that there may be some relationships between standard of living and onset of diseases, and that medical environment may affect chance to receive accurate diagnosis. Further studies are needed to verify those actual associations with regional backgrounds and incidence of kidney diseases.

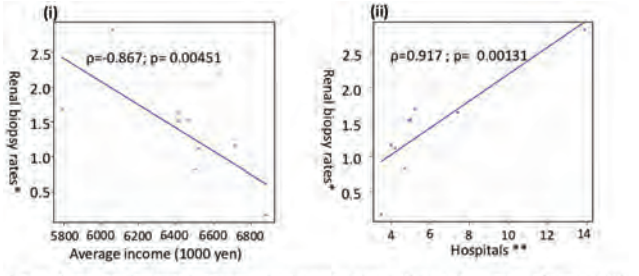

Figure: Association between biopsy rates and average income (i), and the number of hospitals (ii). Each dots indicates the medical areas.

PUB122

Individuals with Unrecognized CKD Can Be Identified and Referred into Care by a Workplace Wellness Program

Olga A. Iakoubova, Andre Arellano, Carmen H. Tong, Lance A. Bare, James J. Devlin, Charles E. Birse. *Quest Diagnostics, San Juan Capistrano, CA.*

Background: Of the 30 million Americans who have chronic kidney disease (CKD), 85 percent are unaware of their disease. Once recognized, lifestyle changes and medical therapy can slow CKD progression. A workplace wellness program was modified with the aim of improving the recognition of CKD and referral into physician care. We asked whether this modified program improved management of individuals with previously unrecognized CKD.

Methods: An ongoing workplace wellness screening program provides annual estimated glomerular filtration rate (eGFR) results. Those individuals (n=402) who had an eGFR <60 mL/min/1.73 m^2 in 2016 were invited to participate in the CKD program. All 402 received a confirmatory eGFR test during the 2017 wellness screening program. Those who agreed to participate in the CKD program also received a urine albumin test and were offered a telephone consultation with a program physician to discuss their test results and referral into physician care. Using a limited data set of health plan claims, we compared the proportion of physician visits between participants and non-participants using a logistic regression model that adjusted for age, sex and education level.

Results: Of the individuals eligible for the CKD program, 51 percent (205/402) agreed to participate. CKD was confirmed in 51 percent (105/205) of the participants, either by repeat eGFR <60 mL/min/1.73 m^2 or by urine albumin to creatinine ratio (ACR) ≥30 mg/g. The comparison group consisted of the 88 of the 402 individuals who had not accepted the invitation to participate and who had an eGFR result <60 mL/min/1.73 m^2 in the 2017 screening program. In the 3 months following confirmatory CKD testing, 2 participants visited a nephrologist, but no non-participants did. Because of the program, one participant with low eGFR levels (eGFR=10 mL/min/1.73 m^2 in 2016; eGFR=3 mL/min/1.73 m^2 in 2017) initiated kidney dialysis. The proportion of participants who visited a physician was about 2-fold greater than non-participants (21% vs. 10%): OR 2.3, 95% CI 1.0-5.4, p=0.047; this difference was not appreciably changed after adjustment for age, sex, and education level.

Conclusions: A workplace CKD outreach program can identify individuals who will benefit from a timely referral into physician care.

Funding: Commercial Support - Quest diagnostics: the CKD program was a part of the work-place wellness screening offered by Quest Diagnostics to it's employees at no cost

PUB123

Evaluation and Intervention of Barriers to Behavioral Modification in Avoiding NSAID Use for Pain Among Underserved Patients with CKD

Romela Petrosyan. *Greenville Health System, Greenville, SC.*

Background: The negative consequences of non-steroidal anti-inflammatory drugs (NSAIDs) use in patients with Chronic Kidney Disease have been long established in medicine and the American Society of Nephrology urges providers to encourage patients with kidney disease to avoid NSAIDs. Multiple studies have shown that use of NSAIDs progressively worsens renal function in patients with CKD. A large cohort study has demonstrated that this is still an aspect that requires further intervention and that disease awareness has not been associated directly with the proportion of patients using NSAIDs. Even recovery from acute kidney injury seems to be insignificant in affecting decision to avoid NSAIDs in patients who are vulnerable to developing CKD and patient-physician rapport plays an important role in reducing use of NSAIDs. The patient-physician relationship appears to have an important role in facilitating replacement of NSAIDs with other renally-friendly medications. It is not solely recognition and awareness of CKD that drives healthy behaviors and a better understanding of barriers to adaptation of healthy actions is necessary to identify the significant targets for intervention.

Methods: We select underserved patients who receive their care at the resident-led Internal Medicine Clinic in Greenville, SC with various stages of CKD and survey patient knowledge regarding pain as well as their perceptions and attitudes toward selecting medications, specifically NSAIDs to address pain. Patients are then provided with individualized interventional counseling targeting their original motifs for NSAID use and barriers to avoiding NSAIDs. Following intervention, patients are given a post-survey with the same attitude and perception questions to evaluate for change in understanding and behavior in use of NSAIDs.

Results: Per preliminary and observational evaluation, NSAID use among underserved patients with CKD appears to be driven by ease of access of these medications and a symptom-centered rather than co-morbidity vigilant approach to addressing pain. This study is currently accumulating further data and post-survey results following interventional interviewing is not yet available.

Conclusions: Identifying factors that drive individual behavior of using NSAIDs is significant in developing appropriate intervention to affect patient behavior.

PUB124

Annual Estimated GFR Decline in Japanese Patients with CKD G3b-5: A Result from a Japanese Nationwide Cohort Study for Patients with Advanced CKD: The Reach-J Study

Junichi Hoshino,[1] Kei Nagai,[2] Ryouya Tsunoda,[2] Hirayasu Kai,[2] Reiko Okubo,[2] Chie Saito,[2] Masahide Kondo,[2] Hirokazu Okada,[3] Ichiei Narita,[7] Takashi Wada,[4] Naoki Kashihara,[5] Bruce M. Robinson,[6] Kunihiro Yamagata.[2] The Reach-J *[1]Toranomon Hospital, Tokyo, Japan; [2]University of Tsukuba, Tsukuba-city, Japan; [3]Saitama Medical University, Saitama, Japan; [4]Kanazawa University, Ishikawa, Japan; [5]Kawasaki Medical School, Kurashiki City, Japan; [6]Arbor Research Collaborative for Health, Ann Arbor, MI; [7]Niigata University, Niigata, Japan.*

Background: CKD progression in Japanese patients with advanced chronic kidney disease (CKD)—an estimated glomerular filtration rate (eGFR) <45 ml/min/1.73m^2—has remained largely unexamined.

Methods: We conducted a nationwide cohort study of Japanese patients with advanced CKD. We recruited 2,249 advanced CKD patients (eGFR<45/ml/min/1.73m^2) receiving nephrologist care from a national sample of 31 facilities throughout Japan, randomly selected with stratification by region and facility size, aligned with the international CKD Outcomes and Practice Patterns Study (CKDopps). From baseline data, we calculated annual eGFR declines by CKD stage and causes of CKD over 4 years before enrollment.

Results: Of 1903 eligible patients with eGFR data before enrollment, their mean(±SD) median (IQR) annual eGFR declines were -2.49±4.20 and -2.00 (-3.96, -0.40) ml/min/1.73m^2. The reported causes of CKD were 474 had diabetic nephropathy(DN), 269 had CGN, 507 had nephrosclerosis, 110 had PKD, and 543 had other renal diseases. Their median (IQR) annual eGFR decline were: DN, -2.73(-5.46, -0.68); CGN, -2.07(-3.75, -0.53); nephrosclerosis, -1.57(-3.23, -0.12); PKD, -2.75(-4.35, -1.70); and others, -1.62 (-3.65, -0.24) ml/min/1.73m^2, respectively. For all causes of CKD, eGFR decline was faster with more advanced CKD. In addition, in CKDG5, eGFR declines of DM (-4.11 (-6.82, -2.02)) and PKD (-3.90 (-5.60, -2.19) ml/min/1.73m^2) were significantly faster than those of other groups (CGN, -2.84 (-4.85, -1.33); nephrosclerosis, -2.51 (-3.83, -1.56); others -2.08 (-4.20, -0.84) ml/min/1.73m^2).

Conclusions: Our study clarifies annual rates of eGFR decline by CKD stage and cause of CKD in a national sample of advanced CKD patients receiving nephrologist care.

Prospective data collection is ongoing to facilitate study of international practice variation in advanced CKD and with focus on the transition to ESKD.

Clinical Features of Patients with Multiple Myeloma with Renal Injury

Cheng Jun. *KidneyDisease Center, The First Affiliated Hospital, MedicalSchoolofZhejiangUniversity, HangZhou, China.*

Background: To understand the clinical features of patients with multiple myeloma (MM) patients **with renal injury (**defined as proteinuria or/and eGFR is less than 60ml/min**) for** reduceing missed diagnosis and misdiagnosis.

Methods: A retrospective analysis of patients with multiple myeloma diagnosed in this hospital for the past 5 years in the database was performed. According to the presence or absence of renal injury **(**defined as proteinuria or/and eGFR is less than 60ml/min**),** divided into no kidney injury group and kidney injury group, comparing the two groups in gender, age, serum calcium, hematuria light chain and hypercalcemia. At the same time, compared with patients with IgA nephropathy and SLE from the database in the recent 5 years. Use spss software analysis.

Results: A total of 559 patients with multiple myeloma were enrolled, including 290 males and 269 females. Of these, 343 were associated with renal impairment (defined as proteinuria or/and eGFR is less than 60ml/min). There was no significant difference in age and gender between the two groups with renal injury and no kidney injury. There were no significant differences in the blood globulin. The expression of M-band in renal damage was lower than that in the group without renal damage, but the incidence of hypercalcemia was higher in renal damage than that in the group without renal damage. The hemoglobin in the renal damage group was significantly lower than that in the no kidney damage group. There was no significant difference in the total blood kappa, lamda and kappa/lamda ratio between the two groups, but there were significant differences in the urinary kappa, lamda and kappa/lamda ratio between the two groups. Compared with SLE and IgA non-plasma cell nephropathy, the albumin ratio of urinary protein electrophoresis was less than 30% in MM patients with renal injury.

Conclusions: 1 There were significant differences in the urinary kappa, lamda and kappa/lamda ratio between renal damage and without renal damage group; Compared with MM without renal injury, Kidney injury group has higher incidence of high calcium and lower hemoglobin. The electrophoresis M band rate was lower in Kidney injury group. 2 Compared with patients with SLE and IgA, less than 30% of the albumin ratio in urine protein electrophoresis, and abnormal blood kappa/lamda ratio greater than 4:1 or less than 1:4 is an important feature of MM associated with kidney damage.

PUB126

Assessing Hyperkalemia Risk and Its Associated Clinical Sequelae: A Novel Risk Tool

Marc L. Evans,[4] Philip McEwan,[5] Oliver T. Darlington,[5] Susan Grandy,[2] Eirini Palaka,[3] Lei Qin.[2] *[2]Astrazeneca, Gaithersburg, MD; [3]AstraZeneca, Cambridge, United Kingdom; [4]University Hospital Llandough, Cardiff, United Kingdom; [5]Health Economics and Outcomes Research Ltd, Cardiff, United Kingdom.*

Background: Patients with chronic kidney disease (CKD) and heart failure (HF) are at greater risk of hyperkalaemia (HK). HK is associated with increased risk of death, major adverse cardiovascular events (MACE), hospitalisation, and discontinuation of renin-angiotensin-aldosterone system inhibitors (RAASi). This study aimed to develop an interactive tool to synthesise current evidence relating patient characteristics and serum potassium (K^+) concentrations to clinical outcomes.

Methods: A review of studies published 1/11/2002–1/11/2017 was conducted to identify risk equations quantifying risk of HK and related clinical outcomes in patients with CKD or HF, and with or without diabetes or RAASi usage. Patient population, clinical outcomes and risk prediction methods were extracted from all eligible studies. The HK Risk Awareness and Impact Tool (RAIT) was developed in Microsoft Excel to characterise associations between patient characteristics and the incidence of HK and related clinical outcomes in CKD or HF patients.

Results: A total of 91 studies were identified, allowing for risk of HK, death, MACE, hospitalization and RAASi discontinuation to be characterized within the RAIT. For example, the RAIT shows how risk of HK increases in CKD patients with age, severity of renal impairment, diabetes or cardiovascular comorbidity, and RAASi use. For a 75-year old male CKD patient, not on RAASi and with eGFR 45mL/min/1.73m^2, a 15mL/min/1.73m^2 decrease in eGFR is associated with a 65.1% increase in 1-year HK risk; RAASi use is associated with a further 37.5% increase in risk. Additionally, the RAIT quantifies elevated risk of adverse outcomes associated with HK. For the same CKD patient receiving RAASi, estimated 1-year risks of death, MACE, hospitalization, and RAASi discontinuation were 3.3%, 7.5%, 13.6% and 10.4%, respectively, with HK (K^+=5.5mmol/L) versus 2.1%, 6.9%, 11.2% and 6.8% with normokalaemia (K^+=4.5mmol/L); relative increases of 57.1%, 8.7%, 21.4% and 52.9%, respectively.

Conclusions: HK imposes a significant burden to patients and healthcare providers/payers; particularly in CKD and HF populations. The RAIT provides a basis for synthesising contemporary evidence to quantify the association between patient characteristics, HK and its clinical sequelae. Further validation of the risk scores in a RCT setting is warranted.

An New Glomerular Filtration Rate Estimating Model Using Mini-Deep Neural Network

Xun Liu,[1] Ningshan Li,[2] Linsheng Lv,[3] Yuqiu Ye,[4] Wentao Hu.[4] *[1]The Third Affiliated Hospital of Sun-Yat-Sen University, Guangzhou, China; [2]South China University of Technology, Guangzhou, China; [3]The Third Affiliated Hospital of Sun Yet-sun University, Guangzhou, China; [4]Department of Nephrology, The Third Affiliated Hospital of Sun Yat-sen University, Guangdong, China, Guangzhou, China.*

Background: Accurate estimating glomerular flirtation rate (GFR) is crucial in clinical practice. The performance of GFR estimating equations has remained unimproved since the famous Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation was presented on NEJM in 2012.

Methods: We hypothesized that a deep neural network (DNN) may achieve better GFR estimating performance for its capacity in modeling complicated non-linear correlation.

Results: Here a cohort of 937 chronic kidney disease patients were assigned as the development dataset and additional 377 patients were enrolled as the external validation data set. GFR was measured by ^{99m}Tc-DTPA renal dynamic imaging and then recalibrated to a dual plasma sample ^{99m}Tc-DTPA GFR. New models of mini-deep fully connected forward neural network (mini-DNN) and revised CKD-EPI-like equations with 4 variables (age, sex, serum creatinine and Cystatin C) and 3 variables (sex, age and serum creatinine) were developed in the same time. In the external validation dataset, bias and accuracy of the proposed mini-DNNs were better than revised equations, especially in the case of 4 variables mini-DNN achieved superior bias, precision, and accuracy than the 4 variables revised equation. This work provides insights into the advantage of representative machine learning strategy DNN in GFR estimating, and finally the 4-variable mini-DNN was deployed through a exe file. We also discussed the challenges of accurately estimating individuals' GFR and potential solutions were suggested.

Conclusions: The DNN was expected to perform further better when derived from a larger development data set.

Funding: Government Support - Non-U.S.

Association Between Malnutrition Risk and Drug-Related Adverse Reactions in Patients with CKD from the Hospital Civil De Guadalajara "Dr. Juan I. Menchaca" and Clinica 46 del IMSS

Jorge Andrade-Sierra,[1,2] Diana M. Hernandez corona,[5] Erika Cardona reynozo,[5] Leonardo Pazarin-Villaseñor,[3,2] Tonatiuh Gonzalez-Heredia,[4] Lydia A. Mercado,[4] Jorge fernando Topete reyes,[4] Francisco G. Yanowsky-Escatell.[6] *[1]Universidad de Guadalajara, Cucs, Guadalajara, Jalisco Mexico, Mexico; [2]Internal Medicine, Opd-Civil Hospital "Dr Juan I Menchaca", Guadalajara, Mexico; [3]I.M.S.S., Guadalajara, Mexico; [4]Universidad de Guadalajara, Guadalajara, Mexico; [5]Universidad de Guadalajara, Tonalá, Mexico; [6]Hospital Civil de Guadalajara Dr. Juan I. Menchaca, Guadalajara, Mexico.*

Background: Patients with chronic kidney disease (CKD) manifest a high prevalence of malnutrition risk and constitute a high-risk population to drug related adverse reactions. The selection and appropriate dosage of the drug are vital to avoid adverse effects in this population. **OBJECTIVE:** To associate malnutrition risk and the presence of drug related adverse reactions in patients with CKD.

Methods: Descriptive cross-sectional study in which 89 patients with CKD were evaluated as outpatients in the Nephrology service of two hospitals from September-December 2017. Malnutrition risk was measured using the Subjective Global Assessment (SGA) form and the adverse reactions were identified through a survey. The association between malnutrition risk and adverse events was analyzed by bivariate correlation and was considered significant at $p < 0.05$.

Results: Sixty-five (73%) of the patients were men and twenty-four (27%) were women, with an average age of 47.3 ± 18.4 years, BMI of 25.3 ± 5.8. According to the CKD stages it was found that: 7 patients (7.9%) were stage 3, 14 (15.7%) stage 4, and 64 (71.9%) were stage 5. According to the SGA, 54 (60.1%) patients had malnutrition risk. It was found that 43 (67.2%) patients had stage 5 and malnutrition risk. The reported adverse reactions corresponded to anorexia 13 (14.6%), nausea 8 (9%), vomit 6 (6.7%), diarrhea 9 (11.1%), constipation 20 (22.5%), dizziness 17 (19.1%) and 28 (31.5%) with reduced muscle strength. An association between the malnutrition risk and anorexia was found: 3 (3.4%); $p<0.001$, likewise malnutrition risk and reduced muscle strength 10 (11.2%); $p<0.05$.

Conclusions: The adverse events related to mild-moderate malnutrition, by SGA, are anorexia and reduced muscle strength, and the more advanced the renal disease stage is, the greater the malnutrition.

PUB129

Recurrence of Hyperkalemia in the United States

J. Michael Woolley,[1] Keith Betts,[2] Deborah Goldschmidt,[3] Fan Mu,[3] Xinyue Liu,[3] Lei Yin,[3] Eric Wu.[3] *[1]AstraZeneca, Wilmington, DE; [2]Analysis Group, Inc., Los Angeles, CA; [3]Analysis Group, New York, NY.*

Background: The objective of this study was to describe the frequency of recurrent hyperkalemia (HK) in patients with a documented case of HK in the United States (US) adult population

Methods: Adult patients with HK, defined as having at least two lab results with serum potassium>5.0 mEq/L (positive potassium lab), or one diagnosis code of HK (ICD-9: 276.7), or one prescription for sodium polystyrene sulfonate (SPS), were identified from a large US commercial claims database (1/1/2010-12/31/2014). Patients were required to have continuous enrollment for at least 6 months before (baseline period) and 12 months after (study period, 1-year cohort) the date HK was first identified (index date), and to have at least two potassium lab tests during the study period. HK events, defined as a positive potassium lab or diagnosis code for HK or SPS prescription, during the study period were analyzed. Time from the index date to the next HK event was analyzed using Kaplan-Meier analysis. Additional analyses were conducted on patients during a 36-month study period (3-year cohort) and for the subgroup of patients with chronic kidney disease and/or heart failure (CKD/HF) at baseline. Sensitivity analyses were conducted using a cutoff of 5.5 mEq/L to define a positive potassium lab result.

Results: A total of 11,990 patients with an HK event were included in the 1-year cohort. Mean age was 60.8 years and 53.4% were men. Most patients (58.9%) had a subsequent HK event during the 1-year study period, and 44.0% had a subsequent HK event within the first 6 months following the index date. The median time from the index date to the subsequent HK event was 7.9 months. Among the CKD/HF subgroup (N=4,798), 67.1% had an HK event during the study period and the median time to subsequent HK event was 5.3 months. In the 3-year cohort of CKD/HF patients (N=1,198), 78.4% had a subsequent HK event. In a sensitivity analysis, 46.7% of patients overall - and 53.7% of CKD/HF patients - had at least one subsequent HK event during the 1-year study period using the alternate 5.5 mEq/L cutoff for positive potassium lab results.

Conclusions: The majority of patients with documented hyperkalemia went on to have another hyperkalemia event within 12 months, indicating that hyperkalemia is often a recurrent condition, and the rate of recurrence is even higher in patients with chronic kidney disease and/or heart failure.

PUB130

A Cross Sectional Analysis of Retinal Layer Thinning and Renal Function in a Clinical Population

Euan N. Paterson,[2] Meera Ravindran,[2] Kayleigh Griffiths,[2] Claire A. Le velly,[2] Rachel V. Mccarter,[2] Thomas J. Macgillivray,[3] Ruth E. Hogg,[2] Mark Harbinson,[1] Chris Cardwell,[1] Alexander P. Maxwell,[2] Gareth J. McKay.[4] *[1]Queen's University Belfast, Belfast, United Kingdom; [2]Queens University Belfast, Belfast, United Kingdom; [3]University of Edinburgh, Edinburgh, United Kingdom; [4]Queen's University Belfast, Belfast, United Kingdom.*

Background: Reduced thickness of the neuronal tissue of the retina and the vascular choroid have been linked to vascular damage and diabetes. Retinal thinning may offer utility as a biomarker of accumulated damage in chronic kidney disease (CKD). We aimed to assess associations between retinal and choroidal thickness and reduced renal function in a population with a high burden of comorbidity.

Methods: A cross-sectional analysis of participants attending nuclear cardiology or renal medicine clinics was carried out. Retinal thickness and choroidal measures were obtained using spectral domain optical coherence tomography. Estimated glomerular filtration rate (eGFR) was calculated using the CKD Epidemiology Collaboration creatinine equation (CKD-EPI). CKD stage 3-5 status was based upon a single measure of eGFR <60 ml/min/1.73m^2.

Results: 241 participants with a mean age of 65 years (standard deviation [SD] 9.48) had a mean eGFR of 66.91 ml/min/1.73m^2 (SD 24.75) with 27% of the population using diuretics. In the present sample, 39% had diabetes. In unadjusted analyses, lower inner retinal thickness was associated with lower eGFR and CKD stage 3-5, a pattern similar to that reported in diabetes. In adjusted analyses, significant associations were found bilaterally (i.e. in both eyes) between lower thickness of the temporal and superior segments of the inner nuclear layer (INL) and the foveal area of the outer nuclear area (ONL) of the retina with lower eGFR. In the outer temporal segment of the nerve fibre layer (NFL), greater thickness was significantly associated with lower eGFR. There were no significant associations between choroidal measures and eGFR or CKD stages 3-5 after adjustment.

Conclusions: INL and NFL thickness were associated with renal function in a minority of retinal segments. Given the large number of associations tested, these findings do not indicate reliable independent associations between retinal thickness and renal function. INL and NFL thickness were associated with renal function in a minority of retinal segments. Given the large number of associations tested, these findings do not indicate reliable independent associations between retinal thickness and renal function.

Factors Associated with the Non-Inclusion of a Kidney Transplant Protocol: Results of a Mexican Cross-Sectional Study

Petra Martínez,[1] José F. Lucas,[5] Norma C. Ruiz Cruz,[3] Benjamin Gomez-Navarro,[2] Basilio Jalomo martínez,[4] Alfonso M. Cueto-Manzano,[1] Enrique Rojas-Campos,[3] Miguel Medina Pérez.[6] *[1]Medical Research Unit in Kidney Disease, Specialty Hospital,CMNO, Guadaljara, Mexico; [2]IMSS, HECMNO, Zapopan, Jalisco, Mexico; [3]Instituto Mexicano Del Seguro Social, Guadalajara, Mexico; [4]IMSS, Guadalajara, Mexico; [5]Hospital, Guadalajara, Mexico; [6]Instituto Mexicano del Seguro Social, Tonala, Mexico.*

Background: Kidney transplantation is the best option for patients with ESRD. Some clinical situations could contraindicate a kidney transplant. In our setting there is scarce information regarding that factors. ***Objetive:*** To determine the factors that are associated with non-inclusion to kidney transplant protocol (KTP).

Methods: Cross-sectional Study, performed in Hospital General Regional 110. A survey was applied to patients with chronic kidney disease stage 5 *K-DOQI*, with age ≥16 years old, any gender were included. Further Clinical/biochemical data were obtained from medical chart: age, gender, body mass index, systolic and diastolic blood pressure, The comorbidity index was calculated (Charlson) **Statistical Analysis:** Comparisons were done with t-student, Mann-Whitney-U, Wilcoxon of test. Logistic regression analysis was used to evaluate associated factors with not including to KTP

Results: 355 patients were included, age 48±17 years, 57 % men, 106 (30%) patients were included to KTP; of them 65% were on the waiting list. Clinical and biochemical comparisons between patients included and not including in a KTP are shown in table. The factors associated with not including to KTP were: Charlson index (*OR,1.25;IC:0.97-1.6 p=0.84),* evolution time of CKD (*OR,0.98; IC:0.97-0.99 p=0.008,* dialysis time *(OR,1.01;IC:1.0-1.03 p=0.05),*cholesterol *(OR, 1.01;IC:1.01-1.03 p=0.02),* serum albumin *(OR,0.47; IC:0.23-0.95 p=0.03)* and Diabetes *(OR,4.87; IC:1.82-13.02 p=0.002)*.

Conclusions: It is necessary to shorten the waiting list and replacement therapy times to avoid more comorbidities.

Variable	KTP	Non KTP	p-value
Age (years)	37±14	53±16	<.001
Diabetes, N (%)	17 (10)	145 (90)	<.001

Psychosocial Stress Is Associated with Incident CKD Development in Subjects with Normal Renal Function

Joohwan Kim, Yooju Nam, Seon yeong Lee, Ki Heon Nam, Dae-Suk Han, Jung Tak Park. *Yonsei University College of Medicine, Seoul, Republic of Korea.*

Background: Recent investigations have shown that psychosocial stress could be related with the development of several diseases including metabolic syndrome and cardiovascular diseases. Nonetheless, the impact of psychosocial stress on renal function has not been fully elucidated yet. Therefore, this study was conducted to examine the association between psychosocial stress and the development of incident chronic kidney disease (CKD).

Methods: Data from the Korean Genome and Epidemiology Study (KoGES), a prospective observational cohort, were used for the analysis. A total of 7,625 subjects with normal renal function were included in the final analysis. Psychosocial stress was measured by psychosocial wellbeing index-short form (PWI-SF) through self-administered questionnaires. The mean PWI-SF score during the study duration for each individual was considered as the amount of psychosocial stress inflicted. The subjects were classified into low stressed and high stressed groups based on the mean amount of psychosocial stress. Incident CKD was defined as estimated glomerular filtration rate (eGFR) < 60mL/min/1.73 m^2.

Results: The mean age of the subjects was 51.9 ± 8.7 years and 47.8% were male. Low stressed and high stressed groups were composed of 6,411 (84.1%) and 1,214 (15.9%) subjects, respectively. The baseline eGFR (94.1 ± 14.1 vs 94.2 ± 13.8 ml/min/1.73m^2, P =0.946) was comparable between the groups. Subjects with hypertension (14.0% vs 18.2%, P<0.001) and diabetes mellitus (5.8% vs 9.5%, P<0.001) was more prevalent in the high stressed group compared to the low stressed group. During a mean follow-up duration of 118.9 ± 36.7 months, incident CKD development was observed in 1,361 (21.2%) and 331 (27.3%) subjects in the low stressed and high stressed group, respectively. Multivariate Cox proportional hazard analysis revealed that subjects in the high stressed group were at a higher risk of developing CKD [hazard ratio (HR), 1.187; 95% CI, 1.051 – 1.342; $P = 0.006$] even after adjustments were made for confounding factors including hypertension and diabetes status.

Conclusions: Exposure to higher amounts of psychosocial stress was significantly associated with incident CKD development in normal renal function subjects. Managing psychosocial stress issues may have a role in preventing CKD development.

PUB133

Changes in Estimated Glomerular Filtration Rate (eGFR) Are Significantly Associated with Serum Uric Acid Levels in a Population-Based Screening: The Aragon Workers' Health Study (AWHS)

Hilda M. Villafuerte Ledesma,[1,2] Abdul Rashid T. Qureshi,[3] Juan J. Carrero,[3] Bengt Lindholm,[3] Peter Stenvinkel,[4] Rafael Alvarez lipe,[1,2] Pablo J. Inigo Gil,[1] José A. Casasnovas.[5] *[1]Hospital Clínico Universitario Lozano Blesa, Zaragoza, Spain; [2]The Health Sciences Institute in Aragon, Zaragoza, Spain; [3]Karolinska Institutet, Stockholm, Sweden; [4]Karolinska University Hospital Huddinge, Stockholm, Sweden; [5]University of Zaragoza, Zaragoza, Spain.*

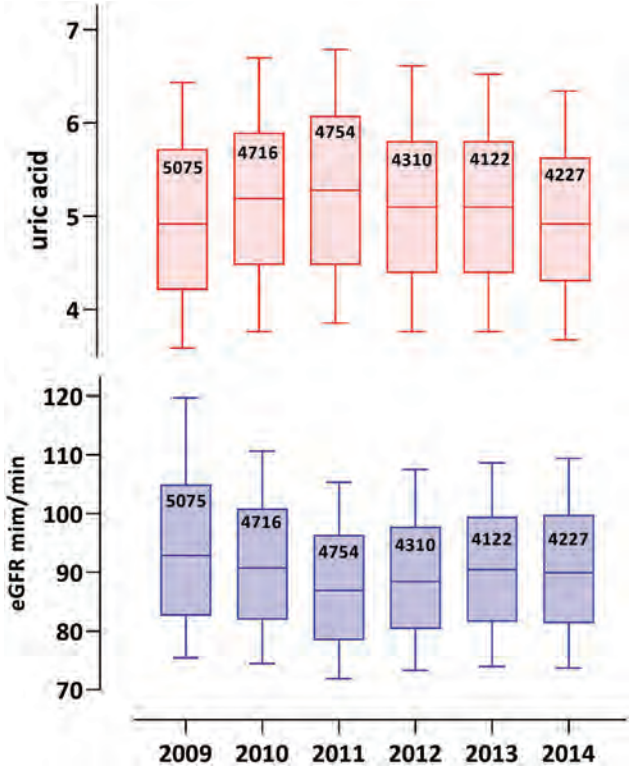
Background: Serum uric acid (SUA) is associated with hypertension, metabolic syndrome, diabetes and heart failure in the general population. There is mixed evidence suggesting that SUA levels may play a role in the development and progression of CKD. The aim of present study was to determine the association between SUA and eGFR in a population-based screening of Spanish middle-aged adults.

Methods: This longitudinal follow-up study of Aragon Workers' Health Study(AWHS) included 5075 subjects (median age 50 years, 94%male, 7%diabetes, 38%dyslipidaemia, 30%hypertension) with anthropometric and biochemical data. The recruitment started in 2009 and participants were followed annually for 6 years. Blood pressure, BMI, HDL, triglycerides, and SUA were available at each visit. The longitudinal association between uric acid and eGFR was evaluated by logistic regression mixed models.

Results: At baseline, there were associations between eGFR and SUA (rho= -0.22 p<0.001), total cholesterol(rho= -0.14 p<0.001), glucose(rho= -0.13 p<0.001), ASAT(rho= -0.21 p<0.001), ALAT(rho= -0.13 p<0.001), hsCRP(rho= -0.01 p=0.55) and BMI (rho= -0.15 p<0.001). In a multivariable-adjusted linear mixed model, changes in eGFR were significantly associated with diabetes 1.31(0.26), hypertension -0.23(0.22), dyslipidaemia -0.92(0.21), and longitudinal changes BMI -0.18(0.03) and SUA -2.87(0.08).

Conclusions: SUA was negatively associated with variation of eGFR in a cohort of community-dwelling middle-aged men, supporting the notion that SUA may be a risk factor or marker of CKD progression.

Funding: Government Support - Non-U.S.



Box plot of SUA (mg/dl) and eGFR (ml/min), median (10-90 percentiles).

PUB134

The Association Between Serum Uric Acid with Inflammation, Body Fat, and Renal Function

Sewon Oh,[1] Young-Bin Son,[1] Junyong Lee,[2] Jihyun Yang,[3] Myung-Gyu Kim,[1] Sang-Kyung Jo.[1] *[1]Korea University Anam Hospital, Korea University College of Medicine, Seoul, Republic of Korea; [2]Korea University Anam Hospital, Seongbuk-Gu, SEOUL, Republic of Korea; [3]Korea universtiy Anam hospital, Seoul, Republic of Korea.*

Background: Hyperuricemia has been related to metabolic syndrome, cardiovascular disease, and renal disease. Uric acid is associates with the presence of atherosclerosis in recent studies and adiposity and inflammation lead to atherosclerosis. It is unclear whether serum uric acid could be a predictive marker to determine adiposity, inflammation, and renal progression in longitudinal study.

Methods: Among the 56,367 adult participants who underwent health check-ups during 2004-2017, we included 16,695 participants with estimated glomerular filtration rate (eGFR) ≥60 ml/min/1.73m^2 and repeated measurements of uric acid and eGFR. We divided participants into sex-specific quartile groups according to the baseline serum uric acid level. The decline of renal function aggravation was defined by the decrease in eGFR by more than 30%. Body fat and muscle were evaluated by bioimpedance analysis.

Results: The average age of the participants was 46.7±12.5 years and 52.5% were male. Baseline serum uric acid is positively associated with body mass index, serum C-reactive protein (CRP), monocyte count, and body fat at baseline and follow up examination (P<0.05) after the adjustment of multiple factors. In addition, serum uric acid is negatively related to body muscle (P<0.05). The highest quartile of uric acid was associated with the development of metabolic syndrome (RR, 1.608; 95% CI, 1.068-2.423) during 54.3± 37.5 months of follow up period. The risks of decline in renal function were significantly higher in the third (RR, 3.015; 95% CI 1.455-6.247) and highest quartile (RR, 4.848; 95% CI 2.379-9.878) compared than the lowest quartile. The participants with highest quartile showed 2.329-fold risk elevation of CKD development (95% CI 1.482-3.659).

Conclusions: Serum uric acid is associated with adiposity and inflammation at baseline and follow-up study. Hyperuricemia is associated with development of metabolic syndrome, renal function decline, and chronic kidney disease.

PUB135

Correlation Between Home, Clinic, and Ambulatory Blood Pressure Monitoring Among CKD Patients

Prof Narinder P. Singh, Sanket Mathukiya, Neeru Aggarwal, Anish Gupta. *Max Super Speciality Hospital, Ghaziabad, India.*

Background: There are various options for BP monitoring like home blood pressure (HBP), office(clinic) (CBPM) and twenty four hour Ambulatory BP monitoring (ABPM). HBP could provide an appropriate alternative to ABPM in terms of diagnosis, particularly in primary care where it might not be immediately available or deemed too costly or when patients find it inconvenient or uncomfortable. By early detection of hypertension (HTN) in CKD patients, life threatening adverse outcomes can be prevented and management can be modified accordingly. Hence, the study was conducted to detect masked hypertension in CKD patients and to investigate whether home HBP monitoring provides feasible and reliable alternative to ABPM and repeated CBPM in detection of HTN and differentiating true from white-coat HTN.

Methods: Total 75 patients, >18 yrs of age and having CKD stage1-4 (pre-dialysis) were enrolled and those having heart disease, acute infection and pregnancy were excluded. HTN was defined as per JNC-7 and British hypertension society as CBP:≥140/90mmHg, mean HBP:>135/85mmHg, mean ABPM daytime:>135/85mmHg, mean ABPM nighttime:>120/70 mmHg. Patient details were incorporated in proforma along with CBP measurement on two different occasions and ABPM once during time period of 7 days of HBP measurement.

Results: Majority of patients were males (61%) with age of 58.3±6.31 years. More than half were CKD stage 3. Around 69%, 61% and 40% were hypertensive when detected by ABPM, HBP and CBP respectively. Among hypertensive, 38.7% were masked HTN, 9.33% observed with white coat HTN, 30% were sustained HTN and 21% were normotensive. Prevalence of normotension showed concordance between ABPM and HBP when it compared by all three methods. Similarly ABPM and HBP showed concordance in 88.46% hypertensive. HBP achieved a specificity of 100% and a sensitivity of 88.45% for the detection of hypertension when using ABPM as gold standard. For accuracy and precision of HBP and CBP in predicting ABPM, HBP was superior to CBP.

Conclusions: ABPM was the gold standard for detecting of hypertension. HBP was no more far behind to ABPM in terms of detecting white coat and masked HTN. The present data may serve as a starting point for more elaborate cost-effectiveness studies and reimbursement of BP monitoring devices.

PUB136

Assessing the Rate of Progression of CKD of Unknown Etiology in Sri Lanka

Lali (Lalarukh) Haider,[1] Shuchi Anand,[2] Stephen L. Schensul,[3] Penny Vlahos,[4] Nishantha Nanayakkara.[5] *[1]Medicine, UConn Health, Farmington, CT; [2]Stanford University, Palo Alto, CA; [3]University of Connecticut School of Medicine, Farmington, CT; [4]University of Connecticut, Groton, CT; [5]Teaching Hospital, Kandy, Kandy, Sri Lanka.*

Background: Chronic kidney disease of unknown etiology (CKDu) is a global epidemic, identified in the lowland, arid agricultural regions of many countries including Sri Lanka. The primary research objective thus far has been to identify individual causal factors. The research presented in this paper shifts the focus to understand risk factors for kidney disease progression in established cases.

Methods: Working with a Ministry of Health screening operation in the Wilgamuwa Division of the CKDu endemic Central Province, 296 individuals with CKDu were identified using a clinical case definition. They were consented, and administered a detailed survey covering exposure, behavioral and clinical factors with micro-environmental assessment of water and soil agrochemical contamination at the household level. A follow-up clinical exam was conducted at the Wilgamuwa kidney clinic. Serum creatinine was repeated to confirm the diagnosis of CKDu. Thereafter participants undergo quarterly clinical exams and serum creatinine assessments.

Results: The recruited participants are between 30-65 (mean 54 [SD 8.2]) years. Consistent with the reported sex distribution of CKDu, 76.6% are men. The mean education is to the 6th standard; 75% live in nuclear families. Baseline CKD-EPI eGFR was 40.7 (SD=13.7) ml/min/1.73m^2, with a range from 17 to 80. eGFR mean change from baseline to first quarterly follow-up was 2.97 (SD=8.0) ml/min/1.73m^2, with a range of-32.3 to +54.6. 81 (41.5%) participants showed a decline in eGFR of more than 5 ml/min/1.73m^2; 114 (58.5%) showed no change or an increase in eGFR.

Conclusions: Our initial results indicate that there is a range of variation in progression of the disease, enabling us to explore the environmental, behavioral and clinical factors associated with progression. There is currently little available for primary and secondary prevention; it is our hope that by identifying the contributing factors this research can provide guidelines for slowing progression.

PUB137

Heat Stress as the Main Cause of CKD in Agricultural Communities - Seven Arguments Against the Hypothesis

Chulani A. Herath,[2] Channa Jayasumana,[3] Sisira Siribaddana,[4] Marc E. De Broe.[1] *[1]University of Antwerp, Lokeren, Belgium; [2]Sri Jayawardenepura General Hospital, Colombo 5, Sri Lanka; [3]Faculty of Medicine, Anuradhapura, Sri Lanka; [4]Faculty of Medicine, Rajarata University of Sri Lanka, Nugegoda, Sri Lanka.*

Background: There are two main hypotheses suggested as causative of the global epidemics of chronic interstitial nephritis of agricultural communities (CINAC). The toxic hypothesis implicates an environmental/occupational toxin while the heat stress/dehydration hypothesis (HSDH) attributes the disease to recurrent acute kidney injury (AKI) caused by heat stress. Our aim is to demonstrate that heat stress is unlikely to be the main cause for this epidemic.

Methods: The following data sets are used to refute the HSDH as the driving force of CINAC: 1.Geographil, 2. Climatologic, 3. Ecologic, 4. Epidemiologic, 5. Physiopathologic, 6. Biochemical and 7. Agrarian.

Results: Absence of CINAC in many hot agricultural regions of the world is a stronger anti-correlation than the correlation assumed by presence of CINAC in a few such regions. The mosaic pattern of case distribution in Sri Lanka contradicts the HSDH. It is doubtful that the small temperature increases in the latter twentieth century caused significant renal effects. CINAC is seen in people not exposed to hot working conditions, while it is not seen in many occupations with higher temperature exposure. Individuals who drink spring water are not affected in contrast to those who drink from shallow wells in nearby communities. It is doubtful that field studies in agricultural workers show significant AKI, and that this degree of community-acquired recurrent pre-renal injury is adequate to cause CINAC. Biochemical changes postulated to perpetuate CKD have not been proven. In Sri Lanka, mechanization of paddy farming has reduced farmers' heat exposure.

Conclusions: It is unlikely that heat stress is the main cause for the CINAC epidemic.

PUB138

To Assess the Association Between Obesity and CKD in New York City Population

Kay thwe Kyaw. *Nursing Home, Essen Health Care, Bronx, NY.*

Background: The increasing prevalence of obesity in the United States is a major public health concern. Obesity is known to be associated with several conditions that can compromise renal function, such as diabetes and hypertension. It is unclear, however, if obesity is an independent risk factor for chronic kidney disease. Currently, there is limited, conflicting research concerning obesity and chronic kidney diseases at the population level. This study was performed to better understand the association of obesity and chronic kidney disease in the population of New York City.

Methods: A cross sectional study was performed to identify the association between obesity and CKD using the 2013-2014 New York City Health and Nutrition Examination Survey. Obesity status, determined by BMI, was the exposure, and the outcome was chronic kidney disease defined using a survey question about the presence of kidney disease. Chi-Square and univariate tests were used to test for bivariate association between obesity and covariates of interests: age, gender, marital status, physical activity level, diabetes, and hypertension. Logistic regression was performed to find association between obesity and chronic kidney disease adjusted for age, gender, physical activity, diabetes, hypertension, and marital status.

Results: This study includes study population of 6,008,489. A statistically significant association was found between obesity and chronic kidney disease at p-value: 0.03 (Chi-square test). After adjusting for confounders, however, there was no statistically significant association between obesity (BMI > 30) and CKD (p-vale: 0.2811, OR: 1.90, 95% CI (0.589, 6.171).

Conclusions: In this population-based, cross sectional study, a statistically significant association was found between obesity and chronic kidney disease. However, after adjusting for known risk factors, this association was no longer significant, indicating that obesity may not be an independent risk factor for chronic kidney disease. This study was limited by the use of a survey question to determine the presence of renal disease, rather than objective laboratory data. However, this study adds to the currently available evidence and encourages further research regarding the association between obesity and chronic kidney disease.

PUB139

Gender Difference About Clinical Outcomes in CKD Patient over 55 Years of Age

Mariko Miyazaki,[5] Ayaka Minota,[2] Tae Yamamoto,[1] Gen Yamada,[2] Masaaki Nakayama,[3,1] Hiroshi Sato,[4,1] Sadayoshi Ito.[5] Gonryo CKD study group *[1]Tohoku University Hospital, Sendai, Japan; [2]Tohoku University, Sendai, Japan; [3]St Luke's International Hospital, Tokyo, Japan; [4]Clinical Pharmacology and Therapeutics, Graduate School of pharmaceutical Sciences, Tohoku University, Sendai, Japan; [5]Tohoku Graduate School of Medicine, Sendai Miyagi, Japan.*

Background: Gender differences in chronic kidney disease (CKD) are reported in previous researches. For example, graft survival time is reduced in recipients of kidneys from female donors as compared with recipients of male donor kidneys. However, few studies compared with male and female in CKD patients, because sex were previously treated as a kind of co-factor on outcomes.The aim of this study is to examine the characteristics of CKD patients over 55 years old and the factors contributing to death and cardiovascular disease (CVD) events.

Methods: Setting : Multicenter Prospective cohort study. The subject of this study was 1392 CKD patients over 55 years old. they were observed 5 years (till 2013). Male were 55.0% of them. We surveyed patient characteristics, laboratory findings (Hb, sCr, eGFR etc…), medication. Outcome:All-cause mortality, CVD events.

Results: In CKD patients of over 55 years old, there was gender difference in the risk of mortality and ESKD but not in that of CVD events. Lower systolic blood pressure, lower serum albumin, lower eGFR, past CVD, and lack of angiotensin receptor blocker were related with all cause mortality in male. On the controther hand, lower hemoglobin, proteinuria, needs of iron, diuretics, and vitamin D were significant with mortality in female. CVD risk was not shown statistically significant difference between gender. Past CVD was most important risk for both gender. Lack of RASI, positive proteinuria, and need of beta blocker were significant in male. Need of erythropoiesis stimulating agent was significant in female.

Conclusions: As a result, characteristics and risk factors differed even between male and female CKD patients of age after menopause. Blood pressure effected the prognosis in male and anemia controlled that in female. We should consider the different risk factors in CKD between gender even elderly.

Cardio-Renal Risk Factors Are Highly Prevalent in Rural Population - Findings from Multi-site Screening Programs in Bangladesh

Md M. Iqbal,[1,2] Md ayub ali Chowdhury,[3] Kazi S. Alam.[3] Kidney Disease Research Group (KDRG) *[1]Nephrology, SSMC, Dhaka, Bangladesh; [2]KDRG, Dhaka, Bangladesh; [3]National Institute of Kidney Disease & Urology, Dhaka, Bangladesh.*

Background: Population of urban and rural areas have difference in life style, environment and livelihood. Rural population are generally less investigated. The aim was to investigate the dirtribution pattern of diabetes (DM), hypertension (HTN), dyslipidemia and proteinuria as cardio-renal risk factors in rural and urban population.

Methods: Multiple screening programs in different urban and rural areas of Bangladesh were conducted by Kidney Disease Research Group (KDRG). An 'open to all' invitation was announced in selected areas for interested adult population to attend on a specified date in early morning preferably fasting. On screening day attending participants were interviewed by research physicians. Socio-demographic information, blood pressure (BP) recording and anthropometric measurements were done. Spot urine was collected and blood sample was drawn for blood sugar, lipid profile and serum creatinine (non-enzymatic) measurements. Estimated GFR (eGFR) was calculated by MDRD equation.

Results: In 2000 subjects 51% was male, age between 18-40 years in 61%; 69% had school level of education; 59% belonged to low income group and 18% were tobacco user. Parental DM was present in 16% and HTN in 23%. At screening pre-diagnosed HTN was present in 13%, DM 10% and nephropathy <1% subjects. After screening hypertension was detected in 23% (18% systolic and 19% diastolic). Blood sugar was >7.0 mmol/l in 22 % (of which 7% had > 11.1). The lipid profile showed raised TG (>150mg %) in 58%, low HDL (<40 mg %) in 58% and high LDL (>130 mg %) in 24%. Proteinuria was detected in 4.4 % subjects. The eGFR < 60ml/min was found in 18.6% subjects. Comparison of urban versus rural population showed diastolic HTN 16% vs. 23% (p<0.002); blood sugar <5.5 mmol/l in 64% vs. 53% (p<0.001); HDL <40mg% in 47% vs. 65% (p<0.001); TG> 150 mg % in 53% vs. 60% (p<0.01) and eGFR < 60ml/min in 16% vs. 19% (p<0.001).

Conclusions: The prevalence of hypertension, altered blood sugar, dyslipidemia and renal dysfunction is higher in rural population than the urban. This indicates a probable paradigm shift in diseases in an unaware underprivileged larger cardio-renal risk group needing urgent attention.

PUB141

Pre-Renal Biopsy (PRB) Bleeding Prophylaxis with Desmopressin (DDAVP)

Haridian Sosa Barrios, Victor Burguera, Melissa Cintra Cabrera, Sofia Ortego, Ester Casillas, Milagros Fernandez lucas, Maite Rivera. *Hospital Universitario Ramón y Cajal, MADRID, Spain.*

Background: DDAVP is a synthetic vasopressin analog. Its use to reduce bleeding risk pre PRB is arguable due to side effects, like reduced coronary flow and hyponatremia.

Methods: Analyze DDAVP complications when administered pre PRB from January 2013 until December 2017 in our centre.

Results: Of 482 PRB's, 65 (13,5%) received a single intravenous DDAVP dose (0,3 mcgr/kg) to enhance platelet function (table 1). DDAVP indications: altered PFA100 (72,5%), 15,5% uremia (GFR <25 ml/min), 9% antiplatelet drugs and 3% thrombocytopenia. 71% did not take any antiplatelet agents previously, 15% used anticoagulation that was either suspended 8-12 days pre PRB or replaced by low molecular weight heparin (not given one day pre procedure). PRB complications: 30,4% minor asymptomatic complications detected by routine ultrasound and 4,6% had major complications (surgical or radiological intervention and/or blood products requirement). Risk factors: pre PRB hemoglobin levels <10 g/dL and diastolic blood pressure >90 mmHg were significant risk factors. Abnormal PFA 100 wasn't statistically significant. DDAVP complications: Mean sodium decline was 0,9±3,4 mEq/L. 2 patients had hyponatremia without neurological symptoms: one dropped from 128 to 124 mEq/L and another one had a sodium decrease of 12 mEq in 24 hours. None of the patients had a cardiovascular event after dosage (up to one month).

Conclusions: Single dose DDAVP pre PRB is safe and can be used in patients with higher risk of hemorrhagic complications, such as uremia.

A Pilot Study of Wearable Devices to Detect Sepsis

Jennifer H. Yo,[1] Connie S. Karschimkus,[1] Frank Volpato,[2] Steve Christov,[1] Paul J. Champion de Crespigny,[1] Stephen G. Holt.[1] *[1]The Royal Melbourne Hospital, Melbourne, VIC, Australia; [2]Royal Melbourne Hospital, Parkville, NSW, Australia*.

Background: Infection is an important cause of morbidity and mortality among patients with kidney disease, and early identification and treatment reduces mortality. Diagnosis remains a challenge, but fever is a relatively reliable sign. Health monitoring devices are popular, accepted and purchased by many patients. We assessed the feasibility of a watch device to detect infection.

Methods: We conducted a single-center prospective cross-sectional pilot study of inpatients to demonstrate proof of concept. Patients admitted under the nephrology unit between August 2017 and April 2018 were consented to wear a monitoring device. Participants wore a clinical grade device that measured peripheral temperature at the wrist (Empatica E4) along with other physiological variables, and we report early analysis of temperature *(t)* alone. We classified patients as having sepsis, no sepsis and/or treated sepsis and examined how well *t* correlated with the presence of sepsis.

Results: 104 patients underwent data recording and 82 patients had complete data. 58 patients had no sepsis, 15 patients had sepsis and 9 patients had treated sepsis. None of the 41 patients who had at least 84% of readings <35°C had active sepsis. Of the 41 patients with greater than 16% of readings ≥35°C, 15 had sepsis (PPV=21%, NPV=100%). 9 out of 10 patients who had >0.5% of readings ≥37°C had sepsis (PPV=52%, NPV=92%). 1 false positive was admitted with limb ischaemia after occlusion of a vascular graft.

Conclusions: Peripheral temperature measurement may add value to sepsis detection. Further data analysis is underway to refine the detection algorithm. We hope to be able to incorporate such algorithms into a consumer device that can continuously monitor and signal the user of impending infection.

PUB143

Clinical Feature of Tuberculosis in Japanese CKD Patients

Tetsuharu Oku,[1] Kenichiro Kitamura,[2] Fumihiko Furuya.[1] *[1]University of Yamanashi, Chuo, Japan; [2]University of Yamanashi School of Medicine, Chuo, Japan*.

Background: The chronic kidney disease (CKD)-related immunodeficiency would suggest that early stage CKD could also be a risk factor for Tuberculosis (TB). Immunodeficiency associated with CKD appears to be multifactorial in etiology. Changes in immunity begin as early as stage 3b CKD (defined as a glomerular filtration rate <45ml/min per 1.73 m2) and worsen in later stages as kidney function deteriorates and waste products accumulate. Active TB is an infectious complication that may develop and result from progression of *Mycobacterium tuberculosis* infection after recent exposure or reactivation of latent tuberculosis infection (LTBI) from a distant exposure, often years before the disease develops.

Methods: Retrospective cohort study was performed in CKD patients who were diagnosed as TB during recent 11 years (from January, 2006 to December, 2017). The end point is all cause of death.

Results: Twenty hundred thirty-seven CKD patients who was diagnosed as TB were admitted to and followed up 11 years. Mean age of the patients was 76.0±11.8 years. One hundred sixty-three (68.8%) patients were male and 74 (31.2%) were female. Sixty-five patients were died (mortality rate: 27.4%). CKD was stratified by eGFR into 4 groups of G3b (eGFR 30-45 ml/min. per1.73m2 n=65;27.4%), G4 (eGFR 15-30 ml min. per1.73m2 n=48;20.3%), G5 (eGFR <15 ml/min. per1.73m2 n=33;13.9%), G5D (hemodialysis n=91;38.4%). Moreover, the mortality rate increased with progress of stage as G3b: 23.1, G4: 35.4, G5: 42.4, G5D: 20.9 (%), respectively, while the mortality rate tended to decrease with dialysis.

Conclusions: The mortality rate of TB patients with CKD was enhanced, compared without CKD patients. The mortality rate was gradually enhanced with CKD stage-depending. The mortality rate of TB in G5D was significantly decreased in that in G5 patients. Comparing G5 with G5D, the frequency of use of Levofloxacin among anti-tuberculous drugs is more common in G5 than G5D (24%: 8%). The treatment with anti-TB drugs were started in the patients with dialysis. From now on, it is considered that study of tuberculosis treatment for each CKD stage is necessary by further investigation. In the future study, we clarified the efficacies of TB treatment for each stages of CKD patients.

PUB144

Renal Embolization Therapy in Nephrological Patients: A Retrospective Analysis

Melissa Cintra Cabrera, Victor Burguera, María C. Chediak, Haridian Sosa Barrios, Milagros Fernandez lucas, Maite Rivera. *Nephrology, Ramón y Cajal Hospital, Madrid, Madrid, Spain*.

Background: Renal embolization (RE) is an invasive procedure used in Nephrology for the treatment of some pathologies such as renal bleeding (ReB), angiomiolypoma (AML), post renal biopsy vascular complications (arteriovenous fistulae (AVF) and pseudoaneurysm) complicated cysts or renal graft intolerance. There are few studies with small sample sizes. Our objective was to analyze the data and adverse events of ReB.

Methods: We retrospectively reviewed the RE performed in our unit for 22 years (1995-2017), including both complete and super selective RE. Data were obtained from hospital database and patient's clinical records.

Results: Thirty-eight embolization, 24 males/14 females (mean age 58.35+/-13 years). Seventeen patients were already on dialysis (45%). Super selective embolization was performed in 24 cases (63%) and complete kidney embolization in 14 cases (37%); 16 on native kidneys and 22 on kidney grafts. The main indication was ReB (32%), most spontaneous or after renal biopsy. Second indication was complicated AVF secondary to renal biopsy (37%) that caused hemodynamic instability or bleeding. Post-embolization syndrome occurred in 6 patients (16%), acute anemia requiring blood products in 10 (26%), hypotension in 3 and major hematuria in 1. Mild-moderate hyponatremia (126-135 mEq/l) appeared in 45% and mild hyperkalemia (5.5-5.9 mEq/l) in 2 cases who had it previously. In the non-dialysis group (n=21), there was a non-significant mean increase in creatinine of 0.6+/-1.89 mg/dl at 48 hours (p = 0.1); 0.3+/-1.6 mg/dl at 10 days (p = 0.63) and 0.4+/-1.9 mg / dl at 6 months (p = 0.9). Embolization triggered the onset of dialysis in 8 cases (21%). Two patients died during the first month (respiratory infection and hypovolemic shock). A second embolization was performed in 5 patients and nephrectomy in 3.

Conclusions: In our experience, post-biopsy complications are the most frequent cause of kidney embolization. Embolization can trigger the onset of dialysis in a significant percentage of patients mainly in patients with previous CKD. Mild-moderate asymptomatic and unexplained hyponatremia was frequent, that may be secondary to a transient syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

PUB145

Clinico-Pathological Characteristics and Outcome of Patients with Biopsy-Proven Oxalate Nephropathy

Shao-shan Liang, Dandan Liang, Feng Xu, Li-juan Li, Cai-hong Zeng. *National Clinical Research Center of Kidney Diseases, Jinling Hospital, Nanjing University School of Medicine, Nanjing, China*.

Background: To investigate the etiology, clinicopathological features, treatment and prognosis of oxalate nephropathy.

Methods: A retrospective analysis of patients diagnosed as oxalate nephropathy by renal biopsy from January 2013 to April 2018 in Jinling Hospital was performed. The etiology and clinicopathological characteristics of the patients were analyzed.

Results: A total of 52 cases of OxN were collected, including 39 males and 13 females with a mean age of 49yr. Two cases were primary hyperoxaluria and 50 cases were secondary OxN. The most common cause was medication, including infusion of Vitamin C (16 cases), glycine (5), tiopronin (1), xylitol (1). Ingestion of foods rich in oxalate was in 4 cases, and dimethyl oxalate poisoning was in 1 case. The most frequent chief complains were oliguria/anuria (50.0%), followed by, edema (30.8%), lumbodynia (30.8%). Thirty-nine cases were diagnosed as AKI, 10 cases were AKI on CKD (ACKD), and 3 cases were allograft kidney. The highest serum creatinine during hospitalization was 8.86(range 1.73-20.03) mg/dl. There were 38.5% cases with hypoalbuminemia, and 40.4% with anemia. Urine test showed that elevated of retinol-binding protein (RBP), NGAL, lysozyme in 92.3%, 77.5%, and 59.2% cases, respectively. Kidney biopsy showed extensive calcium

oxalate crystal deposition with acute tubulointerstitial nephritis. Ten of them were in the background of glomerulonephritis or hypertensive nephrosclerosis. Percentage of acute tubular injury, interstitial cells infiltration were 46(10-70)%, 39(5-90)%, respectively. Twenty-seven patients (51.9%) received continuous renal replacement therapy. At the end of follow-up of 12.1 (0.2-57.2) months, 2 patients reached ESRD. In 33 of 41 patients who followed up for >3 months, renal function returned to normal in 56 (14-165) days. Compared with those of renal function non-recovery, the renal function recovery patients had lower ACKD rate, higher serum albumin and hemoglobin, lower urinary RBP and lysozyme, and less renal interstitial cells infiltration.

Conclusions: The oxalate nephropathy is associated with a cluster of etiologies and manifestations as AKI or ACKD. Half of the patients required renal replacement therapy. Most of the patients had renal function recovery.

PUB146

Development and Validation of a Cognition Questionnaire for Patients with CKD

Jiawei He,[2,4] Suyuan Peng,[3,2] Min Zhang,[2] Jiasheng Huang,[1] Meifang Liu,[2] Xusheng Liu,[2] Yifan Wu.[2] *[1]Guangzhou University of Chinese Medicine, Guangzhou, China; [2]The Second Affiliated Hospital of Guangzhou University of Chinese Medicine, Guangzhou, China; [3]Mayo Clinic, Rochester, MN; [4]Peking University First Hospital, Department of Nephrology, Beijing, China.*

Background: To date, there is no a validated questionnaire which is used to know chronic kidney disease(CKD) patients' level of cognition for their disease. Being as the basis for Knowledge-Attitude-Practice Model, the level of cognition is essential if we need to conduct medical behaviors in a targeted manner. Therefore, the aim of the present study is to develop and validate a cognition questionnaire for CKD patients.

Methods: A cross-sectional study was conducted among CKD patients using the self-developing questionnaire in Guangdong Provincial Hospital of Traditional Chinese Medicine. Additionally, we conducted statistic analysis to know whether this questionnaire was appropriate.

Results: 110 questionnaires were distributed and 100 of which were qualified ones. After the item analysis, 2 items were excluded. Therefore, 18 items were retained to compose the final set of the questionnaire. For validity analysis, 4 components could explain cumulative 72.046% extraction sums of squared loadings; For reliability analysis, Guttman Split-Half coefficient was 0.918.

Conclusions: This cognition questionnaire reveals favorable validity and reliability. It seems to be an impactful method for the evaluation and measurement of levels of disease-related cognition among the CKD patients.

	Know nothing	Know a bit	Know the basis	Know most of it	Know clearly
1.Do you know what the symptoms will occur when your condition get worse?					
2.Do you know what will aggravate your kidney disease?					
3.Do you know the long-term prognosis of your disease?					
4.Do you know the most appropriate range of your blood pressure?					
5.Do you know the name and the usage of the medicine you are taking?					
6.Do you know the effectiveness of the medicine you are taking?					
7.Do you know which medicine may impair your kidney functions?					
8.Do you know what the unhealthy eating habits are?					
9.Do you know what foods contain high-quality protein?					
10.Do you know what foods should be avoided?					
11.Do you know the maximum of salt for each day?					
12.Do you know what exercise are recommended each day?					
13.Do you know what laboratory examination you should review regularly?					
14.Do you know how to leave the specimen of urine?					
15.Do you know how to read the laboratory examination reports?					
16.Do you know how to judge the curative effect?					
17.Do you know what health education activities are organized regularly in our clinic?					
18.Do you know how to contact our medical staffs when you have problems?

Strong Association Between Endothelial Dysfunction and Arterial Stiffness in Pre-Dialysis Patients with Stage 3-5 CKD

Yue Gu,[1] Lei Yan,[2] Lamei Zhao,[2] Lijiao Wang,[2] Fengmin Shao.[2] *[1]Division of Nephrology, Henan Provincial People?s Hospital, Zhengzhou City, China; [2]Henan Provincial People?s Hospital, Zhengzhou, China.*

Background: Cardiovascular disease (CVD) is the most common cause of mortality in chronic kidney disease (CKD) patients. Arterial stiffness is a major risk factor for cardiovascular and all-cause mortality in CKD patients. Endothelial function is impaired in CKD patients and contributes to a high risk of cardiovascular morbidity and mortality in this population. The aim of study was to investigate the association between endothelial function and arterial stiffness in pre-dialysis patients with stage 3-5 CKD.

Methods: In this cross-sectional study, hospitalized pre-dialysis patients who were diagnosed of stage 3-5 CKD in a single center from November 2016 to February 2018 were enrolled. On enrollment, demographic and clinical data collected included age, sex, height, weight, diabetic status and etiology of CKD. Ultrasound evaluation was conducted on brachial artery to estimate endothelial-dependent flow-mediated dilation (FMD). Automatice pulse wave velocity (PWV) measuring system was applied to examine the carotid-femoral PWV. Blood pressure and biochemical parameters were detected. Pearson's correlation and Stepwise multiple regression analysis were performed to explore relationship between FMD and PWV.

Results: We enrolled 206 patients in our center into this study. PWV was significantly higher in patients with diabetes as compared to those without diabetes (12.37 ± 2.15 m/s vs 10.50 ± 1.97 m/s; $P < 0.001$). PWV did not differ significantly between male and female patients. PWV was correlated with age ($r = 0.39$, $P < 0.01$), SBP ($r = 0.38$, $P < 0.001$), 24-hour proteinuria ($r = 0.18$, $P < 0.01$), uric acid ($r = 0.16$, $P < 0.05$), and CRP ($r = 0.15$, $P < 0.05$). Also, PWV correlated negatively with FMD ($r = -0.21$, $P < 0.01$) and estimated glomerular filtration rate ($r = -0.23$, $P < 0.01$). In multivariate regression analysis, FMD, age, SBP, DM, estimated glomerular filtration rate were each independently associated with PWV after adjustment.

Conclusions: Endothelial dysfunction is associated with greater arterial stiffness in pre-dialysis patients with Stage 3-5 CKD. This result suggests that increased CVD due to increased arterial stiffness is mediated by endothelium dysfunction in pre-dialysis patients with Stage 3-5 CKD.

PUB148

Validating Cardiac Troponin T in Predicting Cardiovascular and Mortality Risk in Kidney Transplant Candidates

Tripta Kaur,[1] Harini Chakkera,[2] Nan Zhang,[1] Raymond L. Heilman,[1] Mira T. Keddis.[1] *[1]Mayo Clinic Arizona, Phoenix, AZ; [2]Mayo Clinic, Phoenix, AZ.*

Background: We evaluate cardiac troponin T (cTnT) as a predictor of cardiovascular (CV) and mortality risk in a racially diverse cohort with high morbidity presenting for KTx evaluation.

Methods: 484 patients presenting for KTx evaluation from 2011-2013 at Mayo Clinic Arizona were evaluated. CV event was defined as coronary artery disease (CAD) or heart failure, and/or vascular event (stroke or peripheral vascular disease (PVD)). Normal cTnT <0.01ng/ml. The outcome of interest was combined CV event and/or mortality after KTx evaluation.

Results: Mean age 53.7±14 years; 58.5% male; 70.9% white, 23% Hispanic, 11.0% African American (AA), and 8.3% Native American; 42.1% diabetic; 30.2% CV event; 41.4% on statins; 32.8% on antiplatelet therapy; 57.2% on dialysis and mean time on dialysis 20.1±25 months; mean body mass index (BMI) 29±5.9kg/m^2; mean follow-up after KTx evaluation 44±19 months; 53.8% had cTnT≥0.01ng/ml. 61% had a KTx. 23.6% had a composite event (3.7% cardiac, 3.1% vascular, 19% died) with 79.8% occurring prior to KTx. ROC analysis identified cTnT≥0.036ng/ml to be best predictive of composite outcome (sensitivity 60%, specificity 71.4%). cTnT differed racially; more AA (55.6% vs 44.4%) and fewer whites (32.4% vs 67.6%) had cTnT≥0.036ng/ml. Predictors of increased cTnT included: male sex, older age, higher BMI, hypertension, diabetes, dialysis, CV events, and use of statins and antiplatelet therapy. On multivariable analysis of predictors of composite events, cTnT≥0.036ng/ml, older age and cardiac disease were independent predictors of composite outcome [Table 1].

Conclusions: We confirm that cTnT≥0.036ng/ml was the most powerful predictor of the composite outcome independent of other clinical variables in a racially diverse cohort with significant CV burden at the time of KTx evaluation.

Table 1. Multivariable analysis of predictors of composite outcome.

Variable	HR (95% CI)	P value
cTnT≥0.036ng/ml	2.58 (1.68-3.97)	p < 0.001
Age (years)	1.02 (1.00-1.03)	0.035
BMI (kg/m2)	1.00 (0.97-1.03)	0.923
Sex (Female)	0.75 (0.50-1.13)	0.164
Dialysis	1.12 (0.73-1.73)	0.609
Hypertension	0.59 (0.30-1.14)	0.114
History of CAD	1.82 (1.19-2.78)	0.006
History of PVD	1.78 (0.98-3.26)	0.060

Training Peer Mentors for Patients with CKD and Their Caregivers: A Qualitative Study

Tara Liaghat, Nasrollah Ghahramani, Mo'Tasem Alkhasoneh, Said Al Zein, Eugene Lengerich, Jennifer Kraschnewski. *Penn State College of Medicine, Hershey, PA.*

Background: Peer mentoring may improve patient-centered outcomes such as quality of life and engagement in care among patients with chronic kidney disease (CKD). However, training programs for peer mentoring and the mentors' experiences are not well-studied. Our study consisted of a structured 16-hour program to train peer mentors (PMs) for face-to-face and online mentoring of patients with CKD and their caregivers. This qualitative analysis examines perceptions of PMs regarding their training and the overall mentoring experience.

Methods: PMs were recruited to participate in training. Six months following training and serving in this role, 17 PMs participated in 3 focus group discussions. Discussions followed a guide, which identified how PMs felt about their training, their experiences with mentees, and their perception of how the program changed mentees' attitudes. Discussions were audio-recorded and transcribed. Thematic analysis was performed by 2 researchers (MA; NG), assisted with use of NVivo11.0 software.

Results: Analysis revealed an overall positive perception of the training. PMs commented that training provided appropriate information, improved their understanding of the disease and clarified their role as mentor. Suggestions for improvement included incorporation of more interactive sessions such as role play. The PMs used strategies learned during training to foster mentees' engagement in their own care by encouraging them to ask questions of their care team and by empowering them to request lay language in discussions. PMs perceived that their mentoring improved mentees' adjustment to modality of treatment and to treatment failure. PMs felt valued and appreciated the relationship based on shared experience. They perceived the mentoring experience to have increased their knowledge of treatment modalities. The main perceived challenge was the mentees' inadequate understanding of purpose of the mentoring program and the PMs' role. PMs suggested educating mentees about the program and the PMs' role.

Conclusions: A structured training program for peer mentoring is associated with satisfaction and perception of effectiveness by PMs. Peer mentoring provides benefits to PMs, including emotional satisfaction and perceived improvement in knowledge about their disease. **Funding: PCORI**

Short-Term Prognosis of Emergently Hospitalized Dialysis-Independent CKD Patients: A Nationwide Retrospective Cohort Study in Japan

Hiroaki Kikuchi,[1] Eiichiro Kanda,[2] Takayasu Mori,[1] Soichiro Iimori,[3] Naohiro Nomura,[1] Shotaro Naito,[1] Eisei Sohara,[1] Tomokazu Okado,[4] Shinichi Uchida,[1] Kiyohide Fushimi,[1] Tatemitsu Rai.[5] *[1]Tokyo Medical and Dental University, Tokyo, Japan; [2]Kawasaki Medical School, Kurashiki, Japan; [3]Department of Nephrology, Tokyo Medical and Dental University, Tokyo, Japan; [4]Department of Nephrology, Tokyo medical and dental university, Tokyo, Japan; [5]Tokyo Medical & Dental Univ, Tokyo, Japan*.

Background: In patients with chronic kidney disease (CKD), low body mass index (BMI) is associated with high mortality. This relationship in emergently hospitalized CKD patients is unknown. We investigated short-term protective effects of obesity in emergently admitted dialysis-independent CKD (DI-CKD) patients with and without inflammation.

Methods: This retrospective cohort study examined Diagnosis Procedure Combination data of 19822 emergently hospitalized DI-CKD patients. Patients were divided into 8 groups according to their BMI and the presence of inflammation. The primary outcome was in-hospital death within 100 days.

Results: Cox proportional hazards models adjusted for baseline characteristics showed that low BMI was associated with the outcome both in inflamed and in noninflamed patients (referred to as noninflamed and medium BMI [24–26 kg/m^2] group): inflamed and the lowest BMI (≤20 kg/m^2) group, hazard ratio (HR) 3.46 (95% confidence interval 2.80, 4.26); noninflamed and the lowest BMI group, 1.86 (1.48, 2.33). When patients were stratified according to presence of diabetes mellitus (DM), patients with DM showed that low BMI was associated with the outcome both in inflamed and in noninflamed patients, whereas in non-DM patients, this relationship was not observed in the noninflamed group.

Conclusions: For emergently hospitalized CKD patients with inflammation, high BMI was associated with lower mortality irrespective of the DM status. For noninflamed patients, the protective effects of obesity for in-hospital mortality were modified by the DM status.

Model	BMI quartile	Inflammation Present			Inflammation Absent		
		HR (95% CI)		P	HR (95% CI)		P
I	Q1 (≤20 kg/m^2)	3.46	(2.80, 4.26)	<0.001	1.86	(1.48, 2.33)	<0.001
	Q2 (21–23 kg/m^2)	2.79	(2.23, 3.48)	<0.001	1.35	(1.07, 1.71)	0.011
	Q3 (24–26 kg/m^2)	2.33	(1.82, 2.97)	<0.001	1	Ref

Aging and Renal Arterio-Arteriosclerosis in Relatively Younger Patients with CKD

Nanako Ohshiro,[1] Tsuyoshi Miyagi,[2] Ryo Zamami,[3] Yusuke Ohya,[3] Kentaro Kohagura.[4] *[1]Graduate School of Medicine,University of the Ryukyus,Okinawa,Japan, Nishihara-cho, Japan; [2]Okinawa Daiichi Hospital, Okinawa, Japan; [3]University of the Ryukyus, Nishihara-cho, Japan; [4]University of the Ryukyus Hospital, Nishihara-cho, Japan.*

Background: Aging is well known risk factor for renal areterio-arteriolosclerosis. However, effect of relatively younger age on the renal areterio-arteriolosclerosis is unknown in patients with chronic kidney disease (CKD).

Methods: A total of 174 consecutive patients who underwent renal biopsy at our department between 2010 and 2013 were considered for the study. We excluded patients with vasculitis and those who were receiving calcineurin inhibitors leaving us with 139 patients. Arteriolar hyalinosis (Hy) and small arterial intimal thickening (IT) was semiquantitatively assessed via grading system. Arterial stiffness and endothelial function was assessed by brachial-ankle pulse wave velocity (ba-PWV) and % flow-mediated dilatation(%FMD) of brachial artery.

Results: The mean for age, BP, estimated glomerular filtration rate (eGFR), and urine protein were as follows: 46 years, 124/72 mmHg, and 72 ml/min/1.73 m^2, respectively. Even in the teens, Hy and IT were observed some patients, and their prevalence and the severity were linearly elevating as age group advancing. Similarly, the severity of ba-PWV was linearly elevating from the twenties. While, decreased %FMD was prevalent from the forties. Multivariate logistic analysis for the presence of Hy or IT were conducted adjusted with sex, systolic blood pressure, HbA1c, total cholesterol, uric acid and Brinkman index. The twenties was significantly associated with the presence of Hy (OR 9.8, 95% CI 1.2-76.7, p=0.03) and (OR 7.1, 95% CI 1.1-46.0, p=0.04), respectively compared with the teens. Additional adjustment with ba-PWV disappeared the significance of the twenties.

Conclusions: Aging may be associated with renal arterio-arteriolosclerosis even in relatively younger age group. Age-related arterial stiffness may be responsible for this association.

PUB152

Does Peripheral Vascular Disease Affect Loss of Glomerular Filtration Rate?

Nuri Baris Hasbal,[1] Melek Yalcin,[2] Mustafa Kemal Yeniay,[2] Deniz Akan,[3] Mutlu Cagan Sumerkan,[4] Mustafa Sevinc,[1] Fatih Borlu,[2] Abdulkadir Unsal,[1,5] Taner Basturk.[1,5] *[1]Nephrology, Sisli Hamidiye Etfal Training and Research Hospital, Istanbul, Turkey; [2]Internal Medicine, Sisli Hamidiye Etfal Training and Research Hospital, Istanbul, Turkey; [3]Radiology, Sisli Hamidiye Etfal Training and Research Hospital, Istanbul, Turkey; [4]Cardiology, Sisli Hamidiye Etfal Training and Research Hospital, Istanbul, Turkey; [5]Internal Medicine, Health Sciences University, Medical Faculty, Istanbul, Turkey*.

Background: Ankle-brachial index (ABI) is a non-invasive diagnostic marker for the diagnosis of atherosclerotic peripheral vascular disease(PVD) and is frequently used in subclinical PVD. In our study, we aimed to investigate the effect of peripheral artery disease on GFR loss in patients wih stage 3-4 chronic kidney disease(CKD).

Methods: Totally 82 patients with stage 3-4 CKD who applied to our hospital between November-December 2015 were included in the study. Demographic characteristics, laboratory findings and comorbidities of all patients were recorded. Those with ABI<0.9 were considered as PVD. Progression in CKD was accepted as at least 25% loss of GFR or development of ESRD.

Results: The mean age of the patients was 65.5 years (23-78), 30(36.6%) were female. The most common comorbities were hypertension (85%), diabetes mellitus (45%) and ischemic heart disease (32.9%), respectively. Four patients were died and six patients had progression in CKD during follow-up. PVD was observed in 25% of patients. The baseline and 24-month follow-up laboratory values of patients are shown in Table 1. There was no statistically significant relationship between PVD and renal deterioration (p=0.213), but when deaths were accepted as renal progression, a trend towards significance is found (p=0.09). Baseline higher proteinuria and higher uric acid levels were corralated with CKD progression in patients with non-PVD patients (p=0.02 and p=0.004, respectively), but this effect was not observed in patients with PVD.

Conclusions: Our study did not reveal any relationship between PVD and renal survival during a 24-month follow-up in patients with CKD 3-4. However, proteinuria and uric acid levels in patients with non-PVD, stage 3-4 CKD may be good markers for CKD progression.

Figure 1. Proteinuria and uric acid levels in patients with non-PVD, stage 3-4 CKD

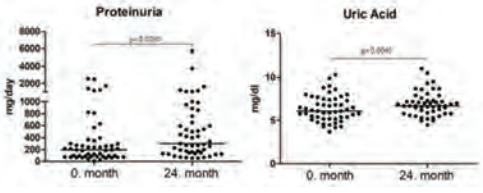

Table 1. Baseline and 24th month laboratory parameters

	Baseline (Mean ± SD)	24th Month (Mean ± SD)
GFR	39 ± 12	42 ± 16

Light Chain Amyloidosis in a Kidney Donor

Hania Shakeri,[1] Niloofar Nobakht,[1] Shaker Qaqish,[1] Anthony Sisk,[1] Farid Arman,[1] Ehsan Nobakht,[2] Mohammad Kamgar,[1] Anjay Rastogi.[1] *[1]University of California, Los Angeles, Los Angeles, CA; [2]George Washington University, Washington D.C, DC.*

Introduction: Light chain amyloidosis is a relatively rare plasma cell dyscrasia characterized by the formation of amyloid from immunoglobulin (Ig) light chains that leads to the deposition of Ig light chain Kappa and lambda in different organs, most importantly in kidney and heart. The clinical presentation depends on the organs involved, and the degree of involvement and includes proteinuria, decreased renal function and cardiomegaly with heart failure. The condition has been reported in kidney transplant recipients in the past, but not in kidney donors. The response to treatment depends on various factors, most important of them being the degree of proteinuria and glomerular filtration rate (GFR) at the baseline.

Case Description: Our case was a 51-year-oldfemale who had donated her kidney to her brother (suffering from ESRD as a result of IgA nephropathy). The donor's past medical history before donation included benign bilateral breast masses, and anxiety. Pre-donation imaging showed a non-significant punctate non-obstructing lesion in the left kidney. Past surgical history included laminectomy and appendectomy. She underwent an uncomplicated laparoscopic donor left nephrectomy. Two years post-donation, the patient was diagnosed with proteinuria as much as 4.8 gram and creatinine of 1.2 from baseline of 0.9 (Post-donation creatinine were 1.2, 1.3 and 0.9 at 6, 12and 24 months post-donation, respectively), and was referred for further follow-up. She underwent a kidney biopsy that showed global mesangial kappa restriction and apple-green birefringence in Congo-red stain, compatible with Ig light chain deposition disease. The treatment started with daratumumab which led to significant drop in kappa light chains (from 28.2 to 2.23 mg/L, shown in table 1) and improvements in the proteinuria and GFR.

Discussion: Ig light chain deposition disease is relatively rare, and involves kidney and heart the most. The response to treatment is highly depends on the initial proteinuria and GFR. Our patient had a good response to treatment, with decrease in proteinuria and increased GFR. The fact that the patient was post-nephrectomy and single kidney did not affect her prognosis.

Light chain levels pre and post donation

	Kappa(0.33-1.94)	Lambda(0.57-2.63)	Kappa/Lambda Ratio(0.26-1.65)
At time of diagnosis	28.2	1.46	19.36
After treatment	2.23	1.36	1.64

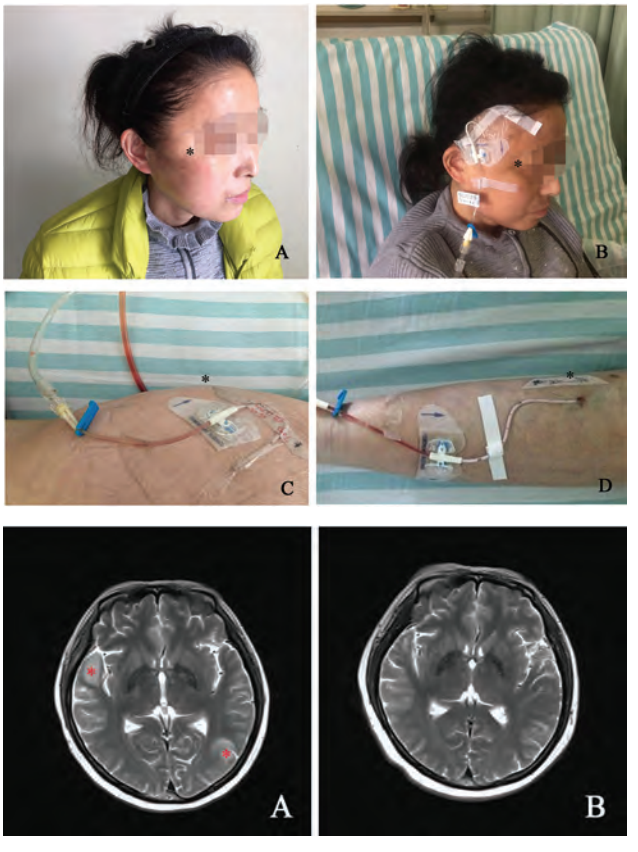
CKD with Multisystem Nocardia Infection

Ningning Wang,[1] Li Dong,[2] Chang Ying Xing,[5] Yaning Mei,[3] Yan Zhu,[4] Weiying Liu,[4] Ying Cui.[1] *[1]Department of Nephrology,The First Affiliated Hospital with Nanjing Medical University, Nanjing, China; [2]Department of Infectious Diseases, the First Affiliated Hospital of Nanjing Medical University, Nanjing, China; [3]Department of Microorganism, the First Affiliated Hospital of Nanjing Medical University, Nanjing, China; [4]Department of Nephrology, the Nanjing Second Hospital, Nanjing, China; [5]First Affiliated Hospital of Nanjing Medical University, Nanjing, China.*

Introduction: Here is a case of 42-year-old female with membranous nephropathy, chronic kidney disease (CKD G1A1), type 2 diabetes. She suffered multisystem nocardia infection (pulmonary and soft tissue infection, multiple brain abscesses) which is rare in clinic.

Case Description: She was diagnosed as pulmonary infection with cough and expectoration. In other hospitals, she was successively treated with multiple antibiotics and voriconazole after stopping Cyclosporin. Cystic masses were found on right temporal, buttocks and popliteal fossa, accompanied by pain and normothermia (Fig1). Chest CT and head MRI showed right lung infection and multiple brain abscesses. Routine culture of blood and soft tissue puncture fluid were all negative, while nocardia was positive. We reduced dose of Medrol and gave Smzco+ Linezolid+ Imipenem and cilastatin sodium+ Minocycline. Cardiopulmonary arrested and epilepsy took place suddenly and she was saved. Her renal function and urine protein was normal through the six-month follow up. Imaging examinations showed infection was controlled(Fig2).

Discussion: Nocardia is Gram-positive and conditional pathogenic bacteria. Lung is involved mostly often through hematogenous spread. Due to atypical manifestation and slow growth of nocardia, nocardiosis is easy to escape diagnosis. It's reported that the mortality rate is as high as 100% when combined with brain abscess. This case has susceptible factors of infection such as CKD, diabetes, long-term use of Medrol and immunosuppressive agents. Sensitive antimicrobial treatment should be continued for 6 to 12 months.



PUB155

Food Consumption, Eating Behaviors, and Nutritional Status in Poor CKD Mexican Patients

Nallely Barraza,[1] Patricia López,[1] Zyanya Reyes,[1] Eduardo D. Torres,[3,2] Rodolfo A. Moreno,[2,3] Guillermo Garcia-Garcia.[2,3] *[1]Cusur Universidad De Guadalajara, Ciudad Guzman, Mexico; [2]Hospital Civil de Guadalajara FAA, Guadalajara, Mexico; [3]CUCS University of Guadalajara, Guadalajara, Mexico.*

Background: CKD patients must consume food according to dietary recommendations and modify their eating behaviors to retard disease progression, maintain adequate nutrition, and reduce complications. We evaluated food consumption (FC), eating behaviors (EB), and nutritional status (NS) in pre-dialysis CKD patients.

Methods: Cross-sectional study in 40 CKD patients stages 3-4. A semiquantitative food frequency questionnaire was used to determine nutrient and FC; a behavioral questionnaire was applied to identify EB. NS was assessed by anthropometry.

Results: The median age was 52 y; 90% had deficient energy intake and 25% had inadequate protein intake. Most patients had deficient intake of lipids, carbohydrates and almost all vitamins and minerals, with the exception of vitamin B12, C and iron; 42.5% were overweight and 22.5% were obese; 15% had decreased muscle mass. The consumption of oils and fats, sugars with fat and sugary drinks were positively associated with BW, BMI, % body fat and waist circumference (Fig 1). The EB of "choice of foods by visual appeal", "the preparation of their food is in charge of another person" and "avoid consuming some type of food because it makes them feel bad" were associated with a minor muscle mass and body fat.

Conclusions: Eating behaviors and dietary factors were associated with nutritional status in patients with CKD. In addition, regardless of stage, FC was deficient in quality and quantity, together with a high prevalence of overweight and obesity. It is suggested the need to implement nutritional interventions with a multidisciplinary approach to improve the nutrition of CKD patients, to meet nutritional requirements, and to avoid disease progression to terminal stages and complications.

Results

	All n=40	Stage 3 n=15	Stage 4 n=25	p

Renal Artery Revascularization in the Era of Negative Clinical Trials: Pattern of Practice and Outcomes of a Single Center

Syed S. Zaidi,[1] Ajay P. Dhaygude,[1] Mohamed Elsayed,[1,2] Arvind Ponnusamy.[1] *[1]Renal Department, Royal Preston Hospital, Preston, United Kingdom; [2]University of Limerick, Limerick, Ireland.*

Background: Renal artery stenosis is not an uncommon finding in atherosclerotic old patients. However, certain subgroups of patients appear to benefit from revascularization therapy. With concerns regarding patient selection in clinical trials comparing medical therapy to the revascularization, clinical equipoise still exists. We describe our center experience in renal revascularization therapy.

Methods: Study cohort consisted of all consecutive patients undergoing renal angioplasty for atherosclerotic renal stenosis, through referral by renal team in Royal Preston Hospital from January 2016 to January 2018. Data on demographics, comorbidities, and indications for angioplasty were collected retrospectively. Studied outcomes were change in eGFR, mean difference in the number of anti-hypertension medications at 6 months post intervention and the proportion of patient with. Data analysed using SAS 9.4

Results: Thirteen patients were included, of whom 6 were females. Mean age at the time of intervention was 64.2 (±11.8) years old. All were hypertensive, (23% had Diabetes, 30.7% had heart failure, 84% had CKD and peripheral vascular disease was prevalent on 53.8%. Indications for revascularization (not mutually exclusive) were; pulmonary edema (23.8%), worsening renal function (46.1%) and refractory HTN (69.23%). Six (46.1%) patients had only one indication, while 4 patients (30.7%) had 2 indications and 3 patients (23%) had 3 indications. Mean number of anti-hypertensive medications at baseline was 3.6 ±1.6 and in six month it dropped to 2.5 ±1 (P = 0.02). Furthermore, the proportion of those with controlled blood pressure has increased significantly from 8 % to 83% (P= 0.004). Mean eGFR at the time of intervention was 37.0 ±27 ml/min.1.73m². This improved to 45.5 ± 28 ml/min.1.73m², but the difference did not reach statistical significance (P= 0.14).

Conclusions: Outcomes for patients selected for renal revascularitaion in Royal Preston Hospital were excellent. Despite the negative trials, renal angioplasty for atherosclerotic renal disease still has a positive role that is achieved through careful patient selection with a clinical indication in addition significant renal artery stenosis. Larger scope studies with meticulous patient selection of high risk are warranted.

PUB157

Relationship Between Renal Function and Development of Remission in Patients with Chronic Refractory Gout Treated with Pegloticase

Naomi Schlesinger,[1] N. L. Edwards,[2] Richard J. Johnson,[3] Anthony Yeo,[4] Peter E. Lipsky.[5] *[1]Rutgers, The State University of New Jersey, New Brunswick, NJ; [2]University of Florida College of Medicine, Gainesville, FL; [3]University of Colorado Denver, Aurora, CO; [4]Horizon Pharma, Lake Forest, IL; [5]AMPEL BioSolutions, Charlottesville, VA.*

Background: Criteria for remission in gout have been reported[1] and they include: serum urate <6 mg/dL, no flares in last 12 months, no tophi, pain <2, and patient global assessment of disease activity <2, each on a 10-point scale. Impaired kidney function is a recognized comorbidity of gout, but it is not known whether chronic kidney disease (CKD) impairs the response to gout treatment.

Methods: This analysis used results from two 6-month randomized controlled trials of pegloticase in patients with chronic refractory gout to address this issue. The analysis included 34 patients who responded to pegloticase administered at a dose of 8 mg every 2 weeks (q2w) with sustained serum urate reductions (<6 mg/dL) over 6 months.

Results: Overall, 29/34 (85.3%) of these patients met the proposed criteria for remission. eGFR was determined at baseline and patients were divided into CKD categories. CKD category had no significant effect on the percentage of patients achieving remission nor on the time required to develop a remission. Notably, no significant change in eGFR was noted in these patients.

Conclusions: These results suggest that renal dysfunction estimated by eGFR does not influence remission or time to reach remission in pegloticase-treated patients with chronic refractory gout, thus maintaining persistent urate lowering. PUB158

Addressing Metabolic Acidosis in CKD Patients with Liver Cirrhosis - No Good Deed

Srilakshmi Ravula,[1] Ramakrishna Thotakura,[3] Manisha Singh.[2] *[1]University of Arkansas Medical Center, Little Rock, AR; [2]University of Arkansas For Medical Sciences, Little Rock, AR; [3]UAMS, LITTLE ROCK, AR.*

Background: Uncorrected metabolic acidosis(MA) is detrimental in chronic kidney disease (CKD)with evidence of mortality benefit in correcting acidosis to bicarbonate(HCO3) levels of around 22 mmol/l. However, impact of correcting MA in liver failure with cirrhosis(LF-c)) is unclear. LF-c is a physiologically alkalotic state, with compensatory low HCO3. Correcting acidic milieu may provide overall benefit, however this commonly requires using sodium salts. This may be detrimental to LF-c patients' due to

sodium load resulting in increased interventions like paracentesis. We hypothesized that if there is evidence of MA as measured by blood gases(ABG/VBG), we can target a moderate correction of acidosis within the recommended sodium restriction.

Methods: We conducted a retrospective chart review to study outcomes in adults over 18 with MA and LF-calculated MELD score 0-39.

Results: Inpatient charts reviewed between 2015-17 had 14 patients with LF-c and CKD with MA proven by ABG/VBG. Of these, 3 were on oral NaHCO3 targeting near normal serum HCO3 level.

Conclusions: KDIGO recommends HCO3 level to 22 mmol/L to prevent CKD progression. However, it is unclear if we can imply the same to population with LF-c and CKD as such studies are unavailable. Our preliminary data shows no improved outcomes. We opine that we may target lower HCO3 levels to account for respiratory compensation and to prevent sodium overload. Our study is limited by sample size and observational data.

Effectiveness of PCSK9 Inhibitors in Dementia Patients with Chronic Renal Insufficiency

Alexander M. Swan,[2,1] Aye myat Mon,[3,4] Htet Htet Kyaw.[4] *[1]NHRTRT,LLC, AVENEL, NJ; [2]Rutgers New Jersey Medical School, Newark, NJ; [3]Pun Hlaing Siloam Hospital, YANGON, Myanmar; [4]NHRTRT, LLC, Avenel, NJ.*

Background: Based on 2017 data from Centers for Disease Control and Prevention, 15% of US population suffered from chronic kidney disease (CKD) and over 80% of end-stage renal disease patients were receiving long-term hemodialysis. In CKD patients, dementia is a common association and plays as an important factor that increases morbidity and mortality. PCSK9, the protein convertase enzyme, involves in degradation of low-density lipoprotein (LDL) receptors in the liver. PCSK9 inhibitors are proven to reduce LDL level in the blood by increasing available LDL receptors on the hepatocytes. Low plasma LDL subsequently reduces the risk of atherosclerosis, including the cerebral circulation. There is no report of the effect of PCSK9 inhibitors on dementia in CKD patients. Our study might be an initiation to this area.

Methods: This study was a non-randomized clinical trial study design. A total of 79 participants (39 males and 40 females; average age, 62) having chronic renal insufficiency with hypercholesterolemia and a certain degree of memory impairment was injected with PCSK9 inhibitor (Repatha 420 mg subcutaneous injection monthly) for 3 months. The severity of dementia was assessed and recorded at the start of the trial using Functional Assessment Staging Test according to Dementia Care Central. Patients were followed up biweekly to reassess the dementia stage and monitor any unwanted side effect of the drug. The targeted primary outcome was changes in the dementia stages and concurrent reduction of LDL levels.

Results: At the first follow-up visit, patients and their family members reported having increased energy and subjective improvement of memory. This effect has continued and the dementia stages gradually declined up to two stages below the initial stage at the end of the 3-month period. The LDL fell down from initial level of 185 mg/dl to 35 mg/dl after 3 months. No side effect was reported. The study is still ongoing.

Conclusions: The results clearly shows that PCSK9 inhibitor is effective in improving memory loss in those CKD patients. The hypothesis is that PCSK9 inhibitor improved cerebral circulation by halting or even reversing the process of atherosclerosis leading to the recovery of vulnerable brain areas with insufficient blood supply. However, more scientific approaches and researches in the larger study population are necessary to prove this hypothesis.

PUB160

A New Glomerular Filtration Rate Estimating Model for CKD Patients Using Ensemble Learning

Xun Liu. *The Third Affiliated Hospital of Sun-Yat-Sen University, Guangzhou, China.*

Background: Accurate estimating GFR is very important for clinical settings. However, since the CKD_EPI equation published in the NEJM on 2012, the performance of GFR estimating equation did not improved.

Methods: CKD patients in China from May 2011 to June 2015 were used as the development dataset and from July 2015 to June 2016 as the exteranl vailation dataset. sGFRs were measured by the DTPA kidnye scan callibrated to the 2 plasma sample DTPA serum clearance method.

Results: In the external validation dataset, eGFR by emsemble leaning improved bias and accuracy than the revised regression equatinos. The 30% accuracy of the 8 variables emsemble learning is 88%. Detailed imformation is showed in the figured attached

Conclusions: The emsemble leaning models achieved better performance than the revised equation models in GFR estimates.

Probiotic Supplements Prevented Oxonic Acid-Induced Hyperuricemia and Renal Damage

Fernando E. García-arroyo,[1] Guillermo Gonzaga,[5] Itzel Muñoz,[1] Monica G. Blas-Marron,[5] Edilia Tapia,[5] Virgilia Soto,[5] Natarajan Ranganathan,[3] Pari Ranganathan,[4] Usha N. Vyas,[4] Anthony Irvin,[3] Diana Ir,[6] Dan Frank,[2] Richard J. Johnson,[2] L. Gabriela Sanchez-Lozada.[1] *[1]Nephrology, INC Ignacio Chavez, Mexico City, Mexico; [2]University of Colorado Denver, Aurora, CO; [3]Kibow Biotech Inc, Newtown Square, PA; [4]Kibow Biotech Inc, Newtown Square, PA; [5]INC Ignacio Chavez, Mexico City, Mexico; [6]University of Colorado, Thornton, CO.*

Background: In chronic kidney disease, HU is extremely common, and uric acid (UA) excretion heavily relies on gut uricolysis by gut microbiotaMoreover, HU contributes to CKD physiopathology. Current therapy for lowering serum UA includes drugs that may produce undesired secondary effects. Therefore, this pilot study was designed to evaluate the potential of two probiotic supplements to reduce systemic uric acid concentrations and to evaluate whether hyperuricemic renal damage was prevented.

Methods: Groups of 6 rats each were followed by 5 weeks and allocated in C= Control; ND= Oxonic acid-induced hyperuricemia (HU) +regular diet; P= HU+placebo; F1= HU+ probiotics formula 1 and F2= HU+ probiotics formula 2. At the end of the study, systolic blood pressure measurement as well as blood samples and 16 h urine collections were taken. Then rats were sacrificed and kidneys were washed by perfusion, fixed and analyzed for arteriolar wall area using alpha-smooth muscle actin to mark the arteriolar vessels.

Results: Results are showed in Table 1

Conclusions: In conclusion, we demonstrated for the first time the ability of probiotics containing uricolytic bacteria to lower serum uric acid in hyperuricemic animals with beneficial consequences on blood pressure and renal disease. As probiotics supplements are innocuous for the human health, this might represent a safe therapeutic approach to treat HU.

The Transregional Collaborative Research Center SFB/TRR219: Mechanisms of Cardiovascular Complications in CKD

Heidi Noels,[2] Joachim Jankowski.[1] SFB-TRR219 *[1]RWTH Aachen, Aachen, Germany; [2]RWTH University Aachen, Aachen, Germany*.

Background: A new Research Center of the German Research Foundation (DFG) seeks understanding of the renal and cardiovascular interactions that underlie enhanced cardiovascular risk in patients with CKD, with the ultimate aim to trigger the development of novel treatment strategies to reduce cardiovascular morbidity and mortality in these patients.

Methods: Reducing the increased cardiovascular mortality in CKD patients through novel therapeutic strategies first requires the identification and understanding of the pathological mechanisms adversely affecting the cardiovascular system specifically in CKD. With exactly this goal two German universities, the RWTH University of Aachen and Saarland University, have initiated the Research Center to analyse in experimental and clinical studies the multi-factorial aspects of CKD-related cardiovascular morbidity and mortality.

Results: Some relevant mediators that affect renal, myocardial and vascular pathology have already been identified. However, their functions regarding the complex interactions between kidney, heart and vessel are still poorly understood. The consortium will characterize known and newly identified mediators relevant in CKD and seek understanding of the mechanisms underlying their effect on heart and vessels causing CKD-related CVD. The main mechanisms that will be investigated to underlie increased cardiovascular risk in CKD include calcification, inflammation, oxidative stress and fibrosis, in addition to alterations in thrombosis and neurohumoral activity. Secondly, SFB/TRR219 consortium will strive to identify novel mediators relevant in CKD with a strong impact on CVD. Also, the consortium will study the translational aspects by investigating novel mediators as potential biomarkers of CKD-related CVD, by analyzing the effect of novel interventions on CKD-related cardiovascular pathology, and by extending previously developed diagnostic tests for cardiovascular pathology to the context of CKD to aid its application into clinical practice.

Conclusions: In summary, the SFB/TRR219 is a German research consortium that seeks understanding of the renal and cardiovascular interactions that underlie enhanced CV risk in patients with CKD, with the ultimate aim to trigger the development of novel treatment strategies to reduce cardiovascular morbidity and mortality in these patients.

A Novel Model of Renal Vascular Disease in the C57BL/ 6 Mouse Strain

Julius E. Kieswich,[1] Jianmin Chen,[3] Samira Alliouachene,[2] Paul W. Caton,[6] Kieran Mccafferty,[5] Christoph Thiemermann,[3] Muhammad M. Yaqoob.[4] *[1]Centre for Translational Medicine and Therapeutics, LONDON, United Kingdom; [2]Queen Mary University, London, United Kingdom; [3]Queen Mary University of London, London, United Kingdom; [4]William Harvey Research Institute, London, United Kingdom; [5]NHS, LONDON, United Kingdom; [6]King's College London, LONDON, United Kingdom.*

Background: Vascular disease is prevalent in the chronic kidney disease (CKD) population having a 20 fold higher incidence of cardiovascular mortality compared to the population as a whole. Reno- cardiac syndrome (RCS), described as cardiovascular disease initiated by renal failure, is a growing world health problem thus necessitating the need for continued improvement of therapeutic strategies to combat it. Murine in vivo models contribute greatly to such research allowing for specific genetic modification and therefore reduced miscellany, however there is currently no reliable model of CKD in the most common genetically modified mouse strain, the C57BL/6. In this study we have manipulated an established model of CKD using adenine infused diet and prolonged the course of its pathology in order to achieve CKD and subsequent vascular disease in the C57BL/6 mouse strain.

Methods: 9 week old C57BL/6 male mice were administered a 0.15% adenine diet or control diet for 20 weeks.

Results: Administration of 0.15% adenine diet caused progressive renal failure resulting in renal vascular disease. The mice tolerated the diet well, weights being maintained with no mortality. At endpoint uraemia was confirmed by blood biochemistry which in the adenine fed mice showed significant increases in serum creatinine and urea, ($P<0.0001$) and a significantly reduced glomerular filtration rate as indicated by creatinine clearance ($P<0.05$). Immunoblotting of aortic tissues demonstrated classic features of vascular disease, that is increased apoptosis (caspase 3) and fibrosis (α-SMA) and increased levels of total Akt suggested a mechanistic pathway for this pathology. Haematoxylin and eosin staining illustrated the inflammatory state of the vasculature and immunohistochemistry for α-SMA further confirmed fibrosis.

Conclusions: We present a novel regimen of adenine diet which induces both CKD and reno-vascular disease in the C57/BL6 mouse strain. The non-surgical nature of this model makes it highly reproducible compared to other models currently available.

YAP/TAZ Upregulation During Kidney Injury Links Altered Metabolism to Fibrotic Response

Rohan Samarakoon,[1] Jiaqi Tang,[2] Erin E. Salter,[1] Roel Goldschmeding,[3] Paul J. Higgins.[2] *[1]Albany Medical Center, Albany, NY; [2]Albany Medical College, Watervliet, NY; [3]University Medical Center Utrecht, Utrecht, Netherlands.*

Background: Recent studies including ours link Hippo-YAP/TAZ pathway deregulation in kidney disease. YAP/TAZ upregulation during renal injury promotes maladaptive repair and transduces TGF-beta1 and mechanical signaling. Here we test the hypothesis that renal YAP/TAZ activation promotes metabolic reprograming associated with chronic kidney disease progression.

Methods: We investigated the potential relationship among YAP/TAZ, aerobic glycolysis and fibrosis using both in vitro and in vivo mouse models of renal injury.

Results: YAP and TAZ expression are persistently upregulated in the tubulointerstitium during obstructive nephropathy. Stable transduction of YAP or TAZ in renal epithelial cells promoted fibrotic factor induction (e.g., CTGF, fibronectin), dedifferentiation and G2/M cell cycle arrest relative to empty vector-expressing controls. Epithelial YAP/TAZ activation leads to SMAD3 activation and TEAD upregulation which are necessary for fibrotic response. YAP/TAZ overexpression also stimulated robust expression of hexokinase-1, phosphofructokinase and pyruvate kinase M2, three enzymes that catalyze irreversible steps of glycolysis. Pre-incubation with the YAP/TAZ inhibitor, verteporfin attenuated glycolytic reprogramming in YAP/TAZ expressing cultures. Concurrent induction of the glycolytic enzymes and YAP/TAZ is also evident in the ligated (UUO) mouse kidney compared to contralateral controls. Intraperitoneal administration of verteporfin not only attenuated fibrogenesis but decreased glycolytic enzyme expression in the obstructed kidneys compared to vehicle treated UUO controls.

Conclusions: Renal YAP and TAZ upregulation promotes glycolytic reprogramming and fibrotic epithelial dysfunction. Pharmacological inhibition of YAP/TAZ activation, conversely, attenuated aerobic glycolysis and renal fibrosis in mice, establishing novel pathological links between Hippo-YAP/TAZ deregulation and metabolic alterations in progressive CKD.

Study on the Correlation Between Serum NGAL Level and Clinical Progressive Risk Factors of Primary IgA Nephropathy

Li Cao,[1] Yali Zheng.[2] *[1]Ning Xia People Hospital, Yinchuan, China; [2]Ningxia People's Hospital, Yinchuan, China*.

Background: To investigate the correlation between serum neutrophil gelatinase-associated apolipoprotein levels(sNGAL) and the risk factors of primary IgA nephropathy and evaluate the early predictive value of sNAGL on the progression of IgA nephropathy.

Methods: Retrospectively analyzed 70 cases of primary IgA nephropathy, that diagnosed in the nephrology department of Ningxia People's hospital from April 2016 to August 2017. One-way ANOVA, bivariate Spearman correlation analysis and multivariate linear regression analysis were used to investigate the effect of sNGAL Correlation of serum levels with risk factors for the clinical progression of primary IgA nephropathy.

Results: The serum levels of sNGAL were positively correlated with blood pressure ($r=0.33$, $P=0.005$), urinary protein excretion ($r=0.371$, $P=0.002$), eGFR Correlation analysis showed statistically significant differences ($P<0.05$). The differences of sNGAL in 24h urine protein ($P=0.003$) and CKD staging ($P=0.000$) were statistically significant ($P<0.05$). Multivariate regression analysis showed that eGFR ($\beta= -0.509$, $P=0.000$) was an independent factor of sNGAL level.

Conclusions: sNGAL is closely related to renal dysfunction and proteinuria. Early detection of sNGAL can be used to assess renal function and predict the progression of the disease. tor of sNGAL level.

Alterations of the Lipid Profile in the Aging Kidney Identified by MALDI Imaging Mass Spectrometry

Su-Mi Kim, Dong-Jin Kim, Yu ho Lee, Yang gyun Kim, Ju young Moon, Sangho Lee. *Division of Nephrology Department of internal medicine Kyung Hee University College of Medicine, Seoul, Republic of Korea*.

Background: During aging, kidney experiences functional and physiological changes which are closely related with chronic kidney disease (CKD). There is increasing evidence supporting the role of lipid changes in the etiology of CKD.

Methods: To understand the role of lipids mediating various metabolic processes during aging, we conducted MALDI imaging mass spectrometry (MALDI IMS) analysis in kidneys harvested from young mice (2 months old, n=3) and old mice (24 months old, n=3).

Results: MALDI IMS analysis showed an increase in ceramide levels and a decrease in sphingomyelins (SMs) and phosphatidylcholines (PCs) levels in kidneys of old mice. Immunohistochemistry (IHC) confirmed elevation of PLA2 and Smase in kidneys of old mice.

Conclusions: Our MALDI IMS data showed the altered distribution of lipids on aged kidney as indicative for functional changes of the kidney with aging. Combined analysis of MALDI IMS and IHC confirmed lipidomic changes and expression levels of responsible enzymes as well as morphological changes.

PUB167

The Significance of NAD+ Metabolites and Sirtuins in CKD

Rina Kitahama,[1] Takeshi Kanda,[1] Hitoshi Minakuchi,[4] Hidenori Urai,[5] Arata Kurokochi,[7] Kazuhiro Hasegawa,[2] Hirobumi Tokuyama,[6] Shu Wakino,[1] Hiroshi Itoh.[3] *[1]Keio University, Tokyo, Japan; [2]Department of Internal Medicine, Tokyo, Japan; [3]Keio University School of Medicine, Tokyo, Japan; [4]school of medicine, Keio University, Tokyo, Japan; [5]Keio University, School of Medicine, Tokyo, Japan; [6]Internal Medicine, Keio University, Tokyo, Japan; [7]Keio University hospital, Tokyo, Japan.*

Background: Renal tissue fibrosis is a final common pathway toward the end-stage renal disease and the change in nicotinamide adenine dinucleotide (NAD+) metabolism contributes to the pathogenesis of renal dysfunction including fibrotic renal disease. The substrates of NAD+ synthesis such as nicotinamide (NAM) and nicotinamide mononucleotide (NMN) have become an emerging therapeutic target for kidney diseases by the activation of sirtuins. In this study, we examined the alteration of NAD+ metabolites in the unilateral ureter obstruction (UUO) model mice and CKD patients.

Methods: We measured NAD+ metabolite levels in the kidneys of UUO and sham-operated mice. In CKD patients, we recruited more than 25 subjects in each CKD stages and measured NAD+ metabolite levels in the serum.

Results: In the kidneys of UUO mice, renal NAM, NMN and NAD+ levels were significantly lower than in sham-operated mice. In contrast, the downstream products of NAD+ metabolites, N-methyl-2-pyridone-5-carboxamide (2-PY) and 4PY were accumulated in the kidneys of UUO mice. Sirtuin activity is regulated by NAD+ levels and Sirt1, Sirt3, and Sirt7 mRNA expression were significantly decreased in accordance with the increased fibrosis genes in the kidneys of UUO mice. In the CKD patients, across increasing CKD stages, gradual decreases in serum levels of NAM were found ($p<0.01$, for trend). On the other hand, the serum levels of 2PY and 4PY significantly increased respectively ($p<0.01$ for the trend test). In single regression analyses, NAM was significantly positively correlated with eGFR. 2PY and 4PY were negatively correlated with eGFR. Multiple regression analyses showed that eGFR was an independent explanatory variable for NAD+ metabolites after adjusting them with other factors such as age, BMI and HbA1c.

Conclusions: Substrates of NAD+ synthesis such as NMN and NAM decreased in both kidney and serum in chronic renal injury, which could contribute to the inhibition of sirtuin activity and the fibrosis in CKD. In CKD patients, NAD+ metabolites were strongly associated with renal dysfunction.

PUB168

Varying Nephrectomy Delay Time After Unilateral Ischemic Injury Allows Development of an Animal Model with a Controllable Degree of Renal Dysfunction

Lies Moonen,[1] Cristina Cuesta,[3] Patrick C. D'Haese,[2] Francisco J. Lopez-hernandez,[5] Carlos Martinez-salgado,[4] Benjamin A. Vervaet.[2] Laboratory of Pathophysiology, University of Antwerp *[1]University of Antwerp, Wilrijk, Belgium; [2]University Antwerp, Edegem, Belgium; [3]Institute for Biomedical Research of Salamanca (IBSAL), Salamanca, Spain; [4]Universidad de Salamanca, Salamanca, Spain; [5]IECSCYL - Hospital Universitario de Salamanca, Salamanca, Spain.*

Background: An important feature of the clinical course of CKD is the graded decline in renal function, divided into 5 stages (CKD1 to CKD5). Extrapolating data from animal studies to the clinical situation requires a good functional correlate between the target population and the experimental model. Based on the fact that an acutely injured kidney persistently loses renal mass in the presence of its healthy counterpart and an early nephrectomy (Nx) of the healthy kidney rescues the decay of the injured kidney, we hypothesized that a sufficiently delayed Nx would not allow efficient renal recovery of the injured kidney and that by varying the Nx delay time, one would be able to predefine the eventual degree of remnant renal function correlating with the clinically relevant CKD stages.

Methods: AKI was induced in male Wister rats by left ischemia/reperfusion (UIRI) for 60 min after which contralateral Nx was performed 3, 10 or 20 days later. Renal function was assessed by serum/urine creatinine and transcutaneous measurement of GFR 24 and 72 hours after Nx and weekly thereafter. Rats were euthanized 11 weeks after Nx. Kidneys were weighed and histology was evaluated by PAS stain.

Results: In all groups, 24h after Nx renal function was impaired. Early Nx (day 3) induced full recovery of renal function by week 11 starting from week 3. Late Nx (day 10, 20) led to a functional loss between 40% at week 3 and 20% at week 11 ($p<0.05$). There was no significant difference in renal function between groups of day 10 and 20. Nx induced compensatory hypertrophy/recovery in all groups as shown by an increased renal mass-to-body weight ratio from 2.9 mg/g (sham) to 4.6 mg/g (day 3) and 4.8 mg/g (day 10). Hypertrophy/repair was less pronounced when Nx was performed at day 20 (4.0 mg/g, $p<0.05$). Histological analysis confirmed hypertrophy and showed more cortico-medullary atrophy at day 10 and 20 as compared to day 3.

Conclusions: Early Nx rescues renal function, whereas sufficient delayed Nx does not allow a full functional recovery of the injured kidney, currently mimicking CKD2. Varying Nx delay time after UIRI thus can provide an experimental method to induce renal dysfunction of different but controllable severity.

PUB169

Uremic Toxins Activates Na/K-ATPase Oxidant Amplification Loop in Mouse Pre-Adipocytes Causing Phenotypic Change in Adipocyte and Oxidative Stress

David E. Bartlett, Richard B. Miller, Scott T. Thiesfeldt, Hari Vishal Lakhani, Rebecca Pratt, Cameron Brickman, Joseph I. Shapiro, Komal Sodhi, Smara Sigdel. *Marshall University Joan C. Edwards School of Medicine, Huntington, WV.*

Background: Experimental CKD leads to accumulation of uremic toxins(UT) in the circulation resulting in increased ROS production which, in turn, is known to activate Na/K-ATPase signaling. Studies in mouse model of obesity has shown that increased oxidative stress in plasma is due to increased ROS and cytokines production from dysfunctional adipocytes. We hypothesize that adipocytes exposed to UTs will activate Na/K-ATPase signaling causing redox imbalance in adipocytes. We will also demonstrate that Na/K-ATPase antagonist, pNaKtide, will attenuate these pathophysiological consequences. We will employ our lentivirus construct, lenti-adiponectin-NaKtide, to specifically target adipocytes.

Methods: 3T3-L1 cells were treated with varying concentrations of UTs, indoxyl sulfate (25, 50 and 100 μM) and p-cresol (100, 200 and 250 μM), with or without pNaKtide (1 μM) for 5 days in adipogenic media. Cells were treated as follows: vehicle IS alone, p-cresol alone, NaKtide alone, IS+NaKtide, p-cresol+NaKtide, pNaKtide alone, IS+pNaKtide, and p-cresol+pNaKtide. RT-PCR and Western blotting was used to evaluate changes in RNA and protein expression, respectively, of adipogenic markers (PPARγ, C/EBPα, aP2, FAS, Mest), oxidative stress markers (ROS, TBARS), apoptotic markers (Bcl2, Bad, Caspase 3 and 9) and inflammation markers (TNF-α, IL-6, MCP-1).

Results: Our results demonstrated that 3T3-L1 adipocyte cells treated with uremic toxins induced oxidative stress, apoptosis and inflammation through activation of Na/K-ATPase signaling ($p<0.01$). However, pNaKtide treatment ameliorated adipocytes dysfunction and restored cellular redox, further attenuating the pathophysiological consequences.

Conclusions: This study suggests that the Na/K-ATPase signaling activated by elevated levels of uremic toxins induce redox imbalance in adipocytes and causes apoptosis and inflammation. Our results support that transfection of 3T3-L1 adipocytes cell with pNaKtide transformed the phenotype of these dysfunctional adipocytes to that of healthy adipocytes. Our study demonstrates that Na/K-ATPase-Src feed-forward oxidant-amplification loop and/or adipocytes are potential targets for CKD intervention and presents a novel treatment for the pathophysiological condition.

PUB170

Sensing-Failure to Detect Energy Depletion Is a Novel Therapeutic Target for CKD

Hiroaki Kikuchi,[1] Emi Sasaki,[1] Naohiro Nomura,[1] Takayasu Mori,[1] Yoji A. Minamishima,[6] Naohiro Takahashi,[1] Taisuke Furusho,[2] Yohei Arai,[1] Shintaro Mandai,[5] Fumiaki Ando,[1] Kiyoshi Isobe,[1] Koichiro Susa,[3] Tatemitsu Rai,[4] Shinichi Uchida,[1] Eisei Sohara.[1] *[1]Tokyo Medical and Dental University, Tokyo, Japan; [2]Tokyo medical and dental university, Tokyo, Japan; [3]Brigham and Women's Hospital, Boston, MA; [4]Tokyo Medical & Dental Univ, Tokyo, Japan; [5]Nitobe Memorial Nakano General Hospital, Tokyo, Japan; [6]Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan.*

Background: Although it is known that the energy-status sensor 5-adenosine monophosphate (AMP)-activated protein kinase (AMPK) is inactivated in chronic kidney disease (CKD) status, to date, the mechanism of AMPK dysregulation in CKD remains unknown, and no study have shown the effects of AMPK activators on chronic stage of kidney injury, in which uremic condition has been substantially established. In this study, we hypothesized AMPK dysregulation in kidneys from subtotal nephrectomy (5/6 Nx) mice is caused by systemic factors, such as uremic metabolites.

Methods: Using capillary electrophoresis-time-of-flight mass spectrometry (CE-TOFMS), we specified several metabolites accumulated in kidney, muscle and heart in the CKD mice (n=4) compared to sham control mice (n=4). In HK-2 cells, murine skeletal myoblast cells (C2C12) and embryonic rat cardiomyocytes (H9C2), effects of uremic metabolites and AMPK activators on AMPK phosphorylation were assessed. Effects of selected uremic metabolites and AMPK activators on kidneys were assessed by immunoblotting, quantitative RT-PCR and histologic analysis.

Results: Principal component analysis (PCA) revealed remarkable differences of metabolome profiles in the 5/6 Nx kidney between sham-control mice and 5/6 Nx mice. Using metabolome analyses, we demonstrated that, in CKD kidneys, AMPK could not sense defective energy metabolism because of multiple uremic factors such as indoxyl 3-sulfate (IS). In consintent with this, AMP mimetics, 5-aminoimidazole-4-carboxamide-1-b-4ribofuranoside (AICAR), did not increase AMPK phosphorylation at Thr 172 and did not change profibrotic marker in 5/6 Nx mice kidney, despite the increased AMPK phosphorylation in kidneys from control sham mice. Direct AMPK activator A-769662, which bypasses the AMP sensing mechanism, ameliorated fibrogenic effects and energy status of the kidneys in a mouse model of CKD.

Conclusions: These results confirmed that AMP sensing failure caused by uremic metabolites is the key mechanism underlying the vicious cycle of energy depletion and CKD progression and can be a novel therapeutic target for CKD.

PUB171

NUAK1 Is a Novel Inhibitor of Fibroblast Hippo Activity and Driver of Kidney Fibrosis

Tianzhou Zhang,[1] Xiaolin He,[1] Cassandra Atin,[1] Mandeep K. Gill,[2] Liliana Attisano,[2] Darren A. Yuen.[1] *[1]St. Michael's Hospital, Toronto, ON, Canada; [2]University of Toronto, Toronto, ON, Canada.*

Background: Kidney fibrosis represents a final common damage pathway that is activated by nearly all forms of chronic kidney injury. Historically, studies have focused on TGF-beta as an important driver of fibrosis. Unfortunately, attempts to block TGF-beta have largely failed, in part due to the many non-fibrotic functions of this pleiotropic molecule. Recent work from our lab and others has shown that the Hippo pathway, a series of kinases that ultimately inhibit the transcription co-factors YAP and TAZ, is a critical inhibitor of fibrosis. Interestingly, the Hippo pathway is emerging as a central regulator of fibrosis, inhibiting fibrosis via both TGF-beta-dependent and -independent mechanisms. While AMP kinase (AMPK) is a well recognized regulator of the Hippo pathway, NUAK1 is a related kinase from the same serine/threonine kinase family that we recently have shown to be expressed by kidney fibroblasts.

Methods: The role of NUAK1 in the regulation of Hippo pathway activity and fibroblast activation was studied both genetically (NUAK1 silencing) or pharmacologically (using the NUAK inhibitor WZ4003) in NRK49F rat kidney fibroblasts both basally and in the context of TGF-beta stimulation. We generated tamoxifen-inducible fibroblast-specific NUAK1 knockout mice (Col1a2 Cre-NUAK1$^{f/f}$), and subjected them to unilateral ureteral obstruction (UUO).

Results: Both deletion and inhibition of NUAK1 resulted in increased Hippo pathway activity, as evidenced by increased YAP/TAZ phosphorylation, nuclear YAP/TAZ exclusion, and reduced expression of YAP/TAZ-inducible genes. NUAK1 inhibition also blocked basal and TGF-beta-induced fibroblast activation and expression of extracellular matrix genes. *In vivo*, fibroblast-specific NUAK1 deficiency protected against UUO-induced kidney fibrosis.

Conclusions: NUAK1 is a previously unrecognized fibroblast activator in the kidney, working at least in part through regulation of the Hippo pathway. Future efforts to inhibit NUAK1 may represent a novel anti-fibrotic strategy.

PUB172

RON Inhibition by Egr-1 siRNA Attenuates Epithelial Mesenchymal Transition and Fibrosis via Suppressing Smad and MAPK in Human Proximal Tubular Epithelial Cells

Jung Sun Park,[1] Hoon In Choi,[2] Donghyun Kim,[3] Eun Hui Bae,[3] Seong Kwon Ma,[2] Soo Wan Kim.[2] *[1]chonnam national university, Gwang Ju, Republic of Korea; [2]Chonnam National University Medical School, Gwangju, Republic of Korea; [3]Chonnam National University Hospital, Gwangju, Republic of Korea.*

Background: Receptor tyrosine kinases play important roles in the pathogenic processes of renal fibrosis. Egr-1 is a transcription factor that regulates genes that modulate fibrosis, and role as common transcription factor of receptor tyrosine kinase. This study investigated the anti-fibrosis effect by inhibition of Egr-1, an important transcription factor for receptor tyrosine kinase activation in RON overexpressed-HK-2 cells.

Methods: Stable cell lines for RON overexpression and the transfected cells of Egr-1 siRNA for RON inhibition were developed to examine the renal fibrosis and molecular mechanisms by RON in human renal proximal tubular epithelial (HK-2) cells. The protein expression of epithelial-mesenchymal transition (EMT)-related proteins N-cadherin, E-cadherin, vimentin and fibrosis-related proteins TGF-β, α-smooth muscle actin (αSMA), fibronectin as well as Smad family and MAPK signal pathway was determined by semiquantitative immunoblotting. Staining of receptor tyrosine kinase family was evaluated using confocal laser microscopy.

Results: RON overexpression increased the protein expression of EMT- and fibrosis-related proteins such as N-cadherin, E-cadherin, vimentin, TGF-β, αSMA, and fibronectin in HK-2 cells. Moreover, overexpression of RON increased phophorylation of Smad2/3 and smad-4, and Erk1/2, p38, and Jnk MAPK pathways. In contrast, RON inhibition by Egr-1 siRNA attenuated expression of EMT- and fibrosis-related proteins and decreased phosphorylation of Smad family and MAPK pathway. In addition, the Egr-1 siRNA silencing attenuated expression of IGFR, VEGFR, and PDGFR.

Conclusions: Inhibition of Egr-1 may exert anti-fibrotic effect by suppression of EMT via controlling Smad and MAPK signal pathways in HK-2 cells.

PUB173

Phosphorylation of PKM2 in Tubular Epithelial Cells Regulates Metabolic Reprogramming and Tubulointerstitial Fibrosis

Jing Luo, Hao Ding, Yang Zhou, Junwei Yang. *Second Affiliated Hospital, Nanjing Medical University, Nanjing, China.*

Background: Chronic kidney disease (CKD) is becoming the world's public health concern with high morbidity and mortality. Tubulointerstitial fibrosis is an inevitable pathologic outcomes of nearly all kinds of CKD no matter what the initial insult is. Structural and functional changes of tubular epithelial cells (TECs) during the pathogenesis contribute to the progression of fibrosis. Maintenance of the structure and function TECs is energy consuming and depends mainly on oxidative phosphrylation (OXPHOS). However, metabolic reprogramming from OXPHOS to glycolysis are defining features of injured TECs. Moreover, reprogramming toward glycolysis promotes TECs plasticity and extracellular matrix (ECM) accumulation, which is a newly discovered mechanism in renal fibrosis. Pyruvate kinase isozyme 2 (PKM2) is one of the key enzymes in glycolysis, whose dimerization after been phosphrylated critically determines the glycolytic reprogramming. In this study, we investigated the role of PKM2 in tubulointerstitial fibrosis.

Methods: Tubulointerstitial fibrosis was induced by unilateral urethral obstruction (UUO) and analyzed by morphologic staining and western blot. We generated proximal tubular cells specific PKM2 heterozygous mice to investigate its role on renal fibrosis. Shikonin, an inhibitor of PKM2 was given at the dose of 5mg/kg body weight.

Results: Phosphrylation of PKM2 in TECs was markedly increased accompanied with metabolic reprogramming towards glycolysis in obstructed kidney. *Pkm2*-deficient mice suffered UUO experienced less severe tubulointerstitial fibrosis and accumulation of ECM than wild-type (WT) mice. Shikonin inhibits the phosphrylation and activation of PKM2 and therefore attenuated the expression and accumulation of ECM in obstructed kidney. In primary TECs incubated with TGF-β1, shikonin treatment blocked the glycolysis and relieved the expression of fibronectin and collagen I, suggests that prevention of the phosphrylation and activation of PKM2 could mitigate metabolic reprogramming and reduce the production of ECM by TECs.

Conclusions: Phosphrylation and activation of PKM2 regulates the metabolism of TECs and is essential for prompting the expression of ECM and inducing renal fibrosis. Blocking the phosphrylation of PKM2 using shikonin might provide novel therapeutic strategy for CKD.

PUB174

Hepatocyte Nuclear Factors as Possible Mediators of Inflammation and Pathogenesis of Coronary Heart Disease in CKD

Elzbieta Sucajtys-Szulc, Boleslaw Rutkowski, Alicja Debska-Slizien. *Medical University of Gdansk, Gdansk, Poland.*

Background: The molecular background of CKD-related inflammatory state and renal fibrosis is rather obscure, though the most potent inflammatory biomarkers like CRP (C-reactive protein), MCP-1 (monocyte chemoattractant protein 1) and ICAM-1 (intracellular adhesion molecule 1) are linked with the pathogenesis of many CKD-related disorders, including cardiovascular diseases. Moreover, some data suggest that MCP-1 is involved in renal fibrosis. Recently, we have found that hepatocyte nuclear factors (HNFs) involved in the transcriptional regulation of several genes, were up-regulated in liver of CRF (chronic renal failure) rats. In this work, we analyzed the interplay between HNFs, MCP-1and ICAM-1 mRNA levels in liver of experimental CRF.

Methods: Rats with experimentally induced CRF (5/6 nephrectomy), pair-feds and controls (sham-operated) were used in the study. HepG2 cells were transfected with siRNA targeting *HNF-1α*. MCP-1, ICAM-1 HNF1α and HNF4α mRNA levels in liver and in HepG2 cells were determined using real-time RT-PCR.

Results: We found a significant coordinate up-regulation of *Mcp-1, Icam-1, Hnf1α* and *Hnf4α* expression in liver of CRF rats, when compared with pair-fed and control animals. These results suggest that HNFs may regulate expression of genes encoding MCP-1 and ICAM-1. To verify this we assessed the effect of *HNF1α* deregulation in hepatocellular model (HepG2 cells) by silencing its endogenous expression using small interfering RNA (siRNA) on MCP-1 and ICAM-1 mRNA levels. We found that the decrease in HNF1α mRNA by two different siRNA was associated with the decrease in MCP-1 and ICAM-1 mRNA level.

Conclusions: Obtained data allow us to recognize that HNFs may play an important role in the up-regulation of, *Mcp-1, Icam-1* genes in liver of CRF rats, and presumably in CKD patient. HNFs may be an essential element of molecular background of CKD-related inflammatory state and coronary heart disease.

PUB175

TSSC3 Overexpression Suppress Anoikis Resistance and Pro-Fibrotic Ability via Inhibiting PI3K-Akt Pathway in Myofibroblast

Huanzi Dai,[1] Yani He.[2] *[1]Daping hospital, Chongqing, Chongqing, China; [2]Daping Hospital, Chongqing, China.*

Background: Myofibroblast activation is the key event of renal interstitial fibrosis (RIF). Anoikis resistance is the hallmarker of active Myofibroblasts conferred by the continuous activation of the PI3K-AKT pathway. Our previous study found that TSSC3 enhanced the sensitivity of cancer cells to anoikis via Src-dependent PI3K/Akt pathway. We hypothesize that Myofibroblast anoikis induction by TSSC3 may suppress RIF by inhibiting the PI3K-AKT pathway.

Methods: Anoikis was induced by exogenous addition of RGD-containing peptides or placing cells in suspension. Myofibroblasts were established by stimulating HK-2 cells by TGF-β. We transfected TSSC3 overexpression adenovirus in HK-2, then experimented with Annexin V-FITC and CCK8 assay. We detected the expressions of molecules related to PI3K/AKT-mediated apoptosis signaling and fibrosis by qRT-PCR and WB analysis.

Results: TGF-β significantly increased α-SMA and decreased Villin expression in a time-dependent manner, suggesting that TGF-β facilitates the phenotypic activation of HK-2 toward myofibroblasts, and significantly fewer myofibroblasts than HK-2 underwent anoikis, demonstrating that TGF-β, simultaneous with the induction of myofibroblast differentiation, confers significant protection from anoikis. We observed that phospho-PY20 PI3K-P85 and phospho-Ser473 AKT expressions were significantly increased, but cleaved-caspase3 expression was significantly decreased in the myofibroblasts as compared with HK-2. Myofibroblasts displayed a stronger ability to resist anoikis, than HK-2, as evidenced by higher rates of proliferation and lower rates of apoptosis, which were partly reversed by LY294002 treatment, a pharmacologic inhibitor of PI3K-AKT pathway. TSSC3

overexpression obviously impaired growth and anoikis resistance of myofibroblasts, as well as reduced phospho-PY20 PI3K-P85, phospho-Ser473 AKT expressions and increased cleaved-caspase3 expression of myofibroblasts in suspension culture. Moreover, TSSC3 upregulation significantly inhibited mRNA and protein expressions of collagens type I, collagens type III, fibronectin, PAI-1, MMP-2 and MMP-9 in myofibroblasts.

Conclusions: These data suggest that TSSC3 attenuates anoikis resistance and profibrogenic ability of TGF-β induced myofibroblasts by mediating PI3K-Akt pathway, and may provide an effective way of targeting myofibroblasts by TSSC3 in RIF treatment.

PUB176

Chronic Interstitial Nephritis in Agricultural Communities (CINAC): A Toxin-induced Proximal Lysosomal Tubulopathy Involving Calcineurin Inhibition

Benjamin A. Vervaet,[1] Cynthia C. Nast,[2] Channa Jayasumana,[5] Gerd Schreurs,[4] Frank Roels,[8] Chulani A. Herath,[6] Swarnalata Gowrishankar,[7] Christiane I. Mousson,[10] Rajeewa T. Dassanayake,[3] Carlos M. Orantes,[9] Patrick C. D'Haese,[1] Marc E. De Broe.[4] *[1]University Antwerp, Antwerp, Belgium; [2]Cedars-Sinai Medical Center, Los Angeles, CA; [3]General hospital Polonnaruwa Sri Lanka, Polonnaruwa, Sri Lanka; [4]University of Antwerp, Lokeren, Belgium; [5]Faculty of Medicine, Anuradhapura, Sri Lanka; [6]Sri Jayawardenepura General Hospital, Colombo 5, Sri Lanka; [7]Apollo Hospitals, Hyderabad, HYDERABAD, India; [8]Ghent University, Gent, Belgium; [9]National Direction of Non-communicable diseases of Ministry of Health of El Salvador, San Salvador, El Salvador; [10]CHU Dijon Bocage, Dijon, France.*

Background: Almost 30 years after the detection of a chronic interstitial nephritis in agricultural communities (CINAC), there is no consensus on its etiology. Heat stress/dehydration and toxic agrochemical exposure are the two most likely etiologies. Also, there are no diagnostic criteria that can directly identify CINAC patients.

Methods: Thirthy-seven renal biopsies (24 Sri Lanka, 11 El Salvador, 1 India, 1 France) of patients with a diagnosis of CINAC (CKD 1-3A, 3B) were examined by light microscopy (LM) and electron microscopy (EM) in comparison to renal biopsies of patients with calcineurin inhibitor (CNI) toxicity (n=17), proteinuric nephropathies (n=15) and reduced renal function of various causes (n=39). A rat study was conducted comparing the histopathology of heat stress/dehydration with cyclosporine nephrotoxicity.

Results: In addition to previously described histopathological changes, CINAC patients demonstrated varying numbers of fine to coarse proximal tubular (PT) granules in preserved and atrophic tubules, showing silver positivity on Jones staining and autofluorescence. Immunofluorescence identified these granules as lysosomes. On EM, lysosomes were enlarged and had a unique dysmorphic morphology with medium electron dense matrix containing non-membrane bound dispersed electron dense aggregates and infrequently focal coarsely granular electron dense material. Identical lesions were only observed in patients on calcineurin inhibitor (CNI) therapy, in a subset of patients with light chain disease and in a patient with Lomustine nephrotoxicity. Some myeloma cells as well as Lomustine have reported CNI activity. Rats treated with cyclosporine for 4 weeks developed similar tubular cell lysosomal alterations, which were absent in the dehydration group.

Conclusions: A specific PT lysosomal lesion was detected associated with CINAC and CNI nephrotoxicity, suggesting CINAC patients are experiencing a tubulotoxic mechanism involving lysosomes and calcineurin inhibition, the latter being a known effect of pesticides.

PUB177

Bardoxolone Methyl Increases Nrf2 Activity, Reduces Inflammation, and Improves Mitochondrial Function in Autosomal Dominant Polycystic Kidney Disease Cells

Greg Miller, Isaac Trevino, Linda L. Hannigan, Brandon L. Probst, Deborah A. Ferguson, Christian Wigley. *Reata Pharmaceuticals, Irving, TX.*

Background: Bardoxolone methyl is currently in clinical trials for the treatment of rare chronic kidney diseases, including autosomal dominanant polycystic kidney disease (ADPKD; PHOENIX, Phase 2, NCT03366337) and Alport syndrome (CARDINAL, Phase 2/3, NCT03019185). Common features of chronic kidney diseases include inflammation, remodeling, and fibrosis. Bardoxolone methyl potently activates Nrf2, a transcription factor that counteracts these features by restoring redox balance, improving mitochondrial function, and inhibiting the production of pro-inflammatory mediators. Consistent with a broad effect on kidney function, in clinical trials bardoxolone methyl has been shown to improve estimated glomerular filtration rate (eGFR) in patients with type 2 diabetes and chronic kidney disease and in patients with Alport syndrome. In this study, we assessed whether bardoxolone methyl increases Nrf2 activity and inhibits inflammation in cells derived from renal cysts in patients with ADPKD.

Methods: We used two immortalized ADPKD cell lines, WT 9-7 and WT 9-12, and a normal human proximal tubule cell line, HK-2, to evaluate the effects of bardoxolone methyl.

Results: We found that bardoxolone methyl increased Nrf2 activity in all cell lines tested. Bardoxolone methyl also dose-dependently improved parameters of mitochondrial function, including spare respiratory capacity and maximal respiration, in the ADPKD cell lines. Consistent with the important role of inflammation in ADPKD, we observed higher basal levels of pro-inflammatory mediators in the ADPKD cell lines than in the HK-2 control cell line. Treatment with bardoxolone methyl significantly reduced the levels of C-C Motif Chemokine Ligand 2 (CCL2), also known as monocyte chemoattractant protein-1 (MCP-1).

Conclusions: In summary, bardoxolone methyl increased Nrf2 activity, improved mitochondrial function, and reduced inflammation in renal cell lines derived from patients with ADPKD. These results suggest that activation of Nrf2 by bardoxolone methyl may have the potential to improve the underlying molecular features of ADPKD.

Human Mesenchymal Stem Cells and Canine CKD

Camila E. Rodrigues,[1] Jose Manuel Condor Capcha,[1] Talita R. Sanches,[1] Fernanda Chacar,[2] Douglas Caragelasco,[2] Priscila Q. Gouveia,[1] Irene L. Noronha,[3] Marcia Kogika,[2] Lucia Andrade.[1] *[1]University of Sao Paulo School of Medicine, São Paulo, Brazil; [2]Veterinary School, University of São Paulo, São Paulo, Brazil; [3]University of Sao Paulo, Sao Paulo, Brazil.*

Background: Chronic kidney disease (CKD) is common in dogs, and conservative treatment is the best option even in advanced CKD. Here, we used human umbilical cord mesenchymal stem cells MSCs (huMSCs) to treat canine CKD, with the aim of slowing its progression.

Methods: We evaluated huMSC phenotypes and tested cells for multilineage differentiation. At baseline (T0), dogs with stage 2 or 3 CKD were randomized to i.v. injection of placebo (CKD2-p, n=5; CKD3-p, n=6) or 10^6 huMSC/kg (CKD2-msc, n=3; CKD3-msc, n=7). We measured serum creatinine (sCr) and the urinary protein:creatinine (UPC) ratio monthly until month 12 (T12). Urinary albumin was determined by urine exosomes on Western blots. Fibroblast growth factor 23 (FGF23) was quantified initially in normal dogs, then at T0 and T6 in dogs with CKD.

Results: Survival at T12 was similar among the groups. Although renal disease was more severe in CKD3-msc dogs than in CKD3-p dogs at T0, both groups showed similar sCr at T12 (Figure 1). The delta UPC ratio (T12 vs. T0) was lower in treated dogs than in untreated dogs, as was urinary albumin (Table 1). For FGF23 in normal and CKD dogs, the area under the receiver operating characteristic (ROC) curve (AUC) was 0.8, and the delta FGF23 (T6 vs. T0) was smaller in treated dogs than in untreated dogs (Table 1).

Conclusions: As a treatment for CKD, huMSCs show promise. Supported by FAPESP.

Funding: Government Support - Non-U.S.

PUB179

TFP5 Specifically Inhibits Deregulated Activity of Cdk5 Protects Pancreatic Cells from High Glucose Toxicity and Recovers the Secretion of Insulin

Yali Zheng.[1,2] *[1]Ningxia People's Hospital, Yinchuan, China; [2]Ningxia medical University Affiliated ningxia renmin hospital, Yinchuan, China.*

Background: Cdk5 may play an important role in the pathology of diabetes mellitus. We previously demonstrated that viral-infected CIP, a 126-residue truncated fragment of p35, effectively and specifically inhibited Cdk5/p25 hyperactivity, restored insulin secretion and rescued Min6 cells from apoptosis induced by high glucose. Because of its large size, however, the CIP molecule is unlikely to be a successful therapy in vivo. We identified a smaller peptide, TFP5, spanning CIP residues Lys^{245}–Ala^{277} (24 amino acid) which is a more effective inhibitor of hyperactive Cdk5.

Methods: We used Mouse pancreatic beta cells Min6 cells and the db/db mice as the in vitro and In vivo models to do the research experiments. TFP5 and scrambled peptide (SCB) peptide were commercially synthesized by Peptide 2.0 (Chantilly, VA, USA). Cells were treated with TFP5 or SCB (500nM). Animals were divided into 4 groups (C57/B6 + SCB, C57/B6 + TFP5, db/db + SCB, and db/db + TFP5). All cells and pancreases samples were prepared for further experiments by using immunohistochemical studies and biochemical analysis. One-way ANOVA was used for the data analysis.

Results: First, the in vitro experiments showed that TFP5 derived from p35, effectively inhibits Cdk5 hyperactivity in Min6 cells and inhibits Cdk5 overactivation induced by high glucose stimulation and recovers insulin secretion in Min6 cells. Secondary, The study found that TFP5 protects both Min6 cells and db/db mice pancreatic cells from high glucose induced apoptosis, and reduce hyperactivation of Cdk5 and recover insulin secretion in

both Min6 cells and pancreases of db/db mice. Furthermore, the study also found that TFP5 reduced inflammation in pancreatic islets by significantly reducing expression of TGFβ1,TNFαand IL1β.

Conclusions: We demonstrated that TFP5 protects or rescues Min6 cells from apoptosis induced by chronic high glucose stress, and rescued db/db mice from diabetes pathology. These data suggest future studies of TFP5 should provide insight as to the mechanism of drug action as a means of further insight into the etiology of diabetes.

Spontaneously Diabetic Rhesus Monkeys Develop Albuminuria and Glomerulopathy Resembling Human Diabetic Nephropathy

Xiaoyan Zhou,[1] Stacey L. Conarello,[1] Nicholas T. Gatto,[1] John L. Valentine,[1] Kara Pearson,[1] Amy F. Loughlin,[1] Chris Regan,[1] Katerina Vlasakova,[1] Warren Glaab,[1] Maarten Hoek,[2] Andrea K. Houghton,[1] Geoffrey Varty.[1] *[1]Merck & Co., Inc., Kenilworth, NJ; [2]Third Rock Ventures, Redwood City, CA.*

Background: Diabetic nephropathy (DN) remains a leading cause of end-stage renal disease, despite the availability of current treatment options. Over the past two decades, a number of new pathways and drug targets have emerged from rodent models. However, limited success has been achieved with the development of novel treatments for DN. Lack of translation from rodent models to clinical practice is the main challenge. In an attempt to develop a translatable animal model, we systematically characterized metabolic phenotypes in rhesus monkeys and assessed the renal function and structure.

Methods: A colony of 161 rhesus monkeys was longitudinally phenotyped for 6 years using intravenous glucose tolerance testing and DEXA scan for their spontaneous development of metabolic diseases. Among these monkeys, 42, 95, and 24 were identified as healthy, dysmetabolic, and diabetic subjects, respectively. We selected 17 healthy, 14 dysmetabolic, and 23 diabetic monkeys for albuminuria assessment by urine albumin/creatinine ratio (ACR) and glomerular filtration rate (GFR) evaluation by iohexol clearance. We also examined kidney samples at necropsy from 5 diabetic monkeys for histopathological changes.

Results: The metabolic characteristics of diabetic monkeys are aligned with clinical manifestations of type II diabetic patients as exemplified by insulin resistance, reduced β cell response, and hyperglycemia. Approximately 50% of the diabetic monkeys exhibited albuminuria (ACR: 142.9 ± 18.4 vs. 4.5 ± 1.2 μg/mg in healthy group) and hyperfiltration (GFR: 1.58 ± 1.11 vs. 1.32 ± 0.05 ml/min/kg in healthy group). Kidney histopathology from 3 out of 5 diabetic monkeys showed minimal to mild mesangium and Bowman's capsule thickening, tubular epithelium degeneration, and interstitium fibrosis.

Conclusions: Our data demonstrate that spontaneously diabetic rhesus monkeys develop albuminuria and glomerulopathy resembling human DN. Follow-up studies examining disease progression and response to current standard of care therapy in the DN monkey model is warranted.

PUB181

Glomerular Thrombomodulin Expression Is Decreased in Patients with Diabetic Nephropathy

Cleopatra C. Van Aanhold,[1] Manon Bos,[1] Ingeborg M. Bajema,[2] Jan A. Bruijn,[3] Hans J. Baelde.[1] *[1]Leiden University Medical Center, Leiden, Netherlands; [2]LUMC, Leiden, Netherlands; [3]Leiden University Medical Center, Dept. Pathology, Leiden, Netherlands.*

Background: Diabetic nephropathy (DN) is characterized by endothelial dysfunction. Thrombomodulin is a key regulator of coagulation and inflammation on endothelial cells. Previously, it was demonstrated that thrombomodulin-mediated protein C activation inhibits apoptosis and inflammation in DN in vivo (Nat Med, 2007). Additionally, a complement-inhibitory role of thrombomodulin was described in DN in vivo (Thromb Haem, 2012). Collectively, these studies suggest that thrombomodulin could be involved in the development of DN. However, the role of thrombomodulin in human kidneys with DN remains elusive. Hence, we here investigate thrombomodulin expression in glomeruli of patients with and without DN.

Methods: We investigated the presence of glomerular thrombomodulin expression in 94 autopsy cases with diabetes and DN, 57 with diabetes without DN and 38 controls without diabetes and without renal disease. Sections of the kidneys were stained with thrombomodulin and scored semi-quantitatively. Researchers were blinded to the clinical data of the patients. Additionally, thrombomodulin mRNA expression was measured in microdissected glomeruli from renal biopsies of patients with DN (n=28) and controls (n=10).

Results: Thrombomodulin expression was 1.7 times lower in patients with diabetes, compared to non-diabetic controls (p=0.004). No difference in thrombomodulin expression was observed between diabetic patients with and without DN. Thrombomodulin mRNA levels of DN cases were not significantly different compared to those of control cases.

Conclusions: Thrombomodulin expression is decreased in glomeruli of patients with diabetes. Since glomerular mRNA levels for thrombomodulin are not changed, our data suggest that this loss is a result of increased thrombomodulin degradation. We hypothesize that decreased thrombomodulin expression plays a role in inflammation and complement activation in DN. Restoration of thrombomodulin levels could be a therapeutic goal to prevent the development in DN.

PUB182

Pathogenesis of the Insulin-Resistant Diabetes Induced by Deleting the Gene Encoding Canonical Transient Receptor Potential 1 (TRPC1) Channel: Role of Gene Dosage, Epigenetics, Adiponectin, and Leptin

Bonnie Eby,[4] Meghan M. Pantalia,[5] Alexander Lau,[4] Richard M. Atkins,[3] Usman A. Khan,[3] Leonidas Tsiokas,[6] Kai Lau.[1,2] *[1]University of Oklahoma Health Science Center, Oklahoma City, OK; [2]Medicine, VA Hospital & Medical Center, Oklahoma City, OK; [3]University of Oklahoma College of Medicine, Oklahoma City, OK; [4]University of Oklahoma Heath Sciences Center, Oklahoma City, OK; [5]Columbia University, New York, NY; [6]University of Oklahoma Health Sciences Center, Oklahoma City, OK.*

Background: Null mice raised by mating -/- ♂ with -/- ♀ showed sustained hyperglycemia & persistent hyperinsulinemia during glucose tolerance test (GTT) vs wild type (wt) raised by mating wt ♂ with wt ♀. Insulin resistance by HOMA was increased 8 fold, but HOMA beta cell function was normal. As null mice ate & weighed more, & as caloric restriction abolished these differences, our data support the role of hyperphagia, possibly due to hypothalamic neuron leptin resistance without TRPC1 channels.

Methods: We studied adipokines, environmental & genetic factors, including gene dosage, in this diabetic phenotype while minimizing epigenetics & hyperphagia in breeders & dams, using only ♂ littermates born to +/- breeders.

Results: 9-week-old null ♂ born to -/- breeders & nursed by -/- dams had severe random hyperglycemia (171 vs. 98 mg %) vs wt born to +/+ breeders & raised by +/+ dams. In contrast, null mice born to +/- breeders & nursed by +/- dams had minimal hyperglycemia (119 vs 171 mg %), implying anti-diabetic effects by a single maternal wt allele. Conversely, wt born to +/- breeders & nursed by +/- dams were hyperglycemic vs wt born to +/+ breeders & nursed by +/+ dams (118 vs 98 mg %), reflecting pro-diabetic effects of maternal haploid deficiency. These wt were as hyperglycemic as null littermates born to the same +/- breeders & nursed by the same +/- dams (118 vs 119 mg %). These data support the role of non-genetic parental influences. From 5th to 30th week, null but not +/- mice were obese vs wt. At 29 weeks, during GTT, both null & +/- mice were equally diabetic, with glucose (in mg %), respectively of 230 & 234 vs. 183 in wt at 20 min, 219 & 229 vs. 155 in wt at 60 min, & 179 & 188 vs 134 in wt at 90 min. These data support the role of both alleles in glucose homeostasis. In null mice, adiponectin was down (5.7) vs. wt (6.4) & +/- (6.2 μg/ml), but leptin up (2.3 vs. 1.3 in wt & 1.8 ng/ml in +/-).

Conclusions: We conclude: 1. Diploid TRPC1 gene deletion produces hyperphagia & obesity. 2. Haploid deficiency suffices to produce diabetes, associated with reduced adiponectin & increased leptin. 3. Non-genetic parental factors, via epigenetics & hyperphagia, markedly alter glucose homeostasis independent of genotypes.

PUB183

Benefits of Exercise Training in Obesity-Induced CKD Mice Model: Involvement of AMPK Signalling and Autophagy

Florian Juszczak,[2,1] Inès Jadot,[1] Maud Vlassembrouck,[2] Céline Walentynowicz,[2] Olivia Botton,[1] Alexandre Legrand,[3] Nathalie Caron,[1] Anne-Emilie Decleves.[2] *[1]University of Namur, Namur, Belgium; [2]Laboratory of Molecular Biology, University of Mons, Belgium, NIMY (MONS), Belgium; [3]University of Mons, Mons, Belgium.*

Background: Obesity is a major contributor of progressive renal disease and is largely due to a combination of sedentary lifestyle and a high energy intake. Excessive caloric intake is associated to lipid accumulation in adipose tissue but also in non-adipose tissues, leading to deleterious cellular responses. In a previous work, we identified the role of AMPK in ectopic lipid depositions in proximal tubular cells in mice fed a high-fat diet (HFD). Moreover, lysosomal dysfunction and stagnant autophagy flux were highlighted. Here, the effect of exercise training (ET) in obese mice on renal lipotoxicity and autophagy pathway was investigated.

Methods: C57BL/6J male mice were randomized to a low-fat diet (LFD - 10% calories from fat) or a HFD (60% calories from fat) during 20 weeks. After 12 weeks on diet, mice were subjected to an endurance ET protocol on a treadmill for 8 weeks or no ET.

Results: Mice fed a HFD exhibited a significant increase in body weight combined to increases in plasma levels of NEFA and cholesterol. Moreover, they also developed insulin resistance. ET showed body weight stabilization and beneficial effects on plasma lipid profiles in HFD mice. In addition, hyperglycemia and insulin resistance were also clearly improved by ET. Regarding the renal function, ET improved albuminuria and proteinuria induced by obesity. We also demonstrated a decrease in ectopic lipid accumulation in proximal tubular cells in trained groups. This result was correlated to the inhibition of Acetyl-CoA carboxylase by phosphorylation mediated by AMPK activity. Interestingly, we showed a stagnation of autophagy flux in the kidney of obese mice that was restored in ET group by the regulation of autophagy-related proteins.

Conclusions: These results suggest that ET leads to beneficial effects on obesity-related metabolic disorders and regarding the kidney function and structure in mice fed a HFD. Particularly, we demonstrated the activation of AMPK and the improvement of autophagy flux by ET.

Interleukin-15, a Myokine for Preserving Podocyte Mitochondrial Function During Diabetic Nephropathy

Yin Li,[1] Wenbo Zhao,[1] Zhaoyong Hu,[2] Hui Peng.[1] [1]*the Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China;* [2]*Baylor College of Medicine, Houston, TX*.

Background: Exercises can improve the prognosis of diabetic nephropathy (DN), however, the underlying mechanism remains unclear. Here, we further explore how exercise ameliorates DN via muscle-kidney communication.

Methods: To explore the mechanism, PGC-1α was overexpressed in mouse muscle (mPGC-1α) to mimic persistent exercises and crossed with db/m mice or STZ injection to generate mPGC-1α mice with diabetes. In vitro, we isolated podocytes and used cultured podocyte cells to evaluate mitochondrial function.

Results: we found that glomerulosclerosis and podocyte mitochondrial damage induced by diabetes were limited in mice with mPGC-1α. What is more, plasma from mPGC-1α mice prevented podocyte cells and its mitochondria injury in high glucose. Then we found out Interleukin-15 (IL-15), one of myokines upregulated by mPGC-1α, exhibited the similar protective effects on the cultured podocytes. Besides, we discovered that the IL-15-mediated protection were produced by enhancing OPA1 to improve podocyte mitochondrial dynamics.

Conclusions: These findings provided insights into the new role of IL-15 in mediating muscle-kidney crosstalk to ameliorate the progress of DN by maintaining podocytes mitochondrial homeostasis via OPA1.

Increased Urinary Prorenin and Soluble Prorenin Receptor Excretion in Early Type 1 Diabetes

Nirupama Ramkumar,[1] Deborah Stuart,[3] Donald E. Kohan.[2] [1]*University of Utah, Salt Lake City, UT;* [2]*University of Utah Health Sciences Center, Salt Lake City, UT;* [3]*University of Utah Health Sciences, SALT LAKE CITY, UT*.

Background: Activation of the intra-renal, rather than systemic renin angiotensin system (RAS) has been suggested to play a role in the development of diabetic kidney disease. In this study, we examined plasma and urinary prorenin/renin levels and urinary soluble prorenin receptor (sPRR) levels in a murine model of Type 1 diabetes.

Methods: Male C57BL/6 mice were injected with streptozotocin (STZ) 50mg/kg at 3 months of age and metabolic balance studies conducted at 10 weeks post-injection. In a separate experiment, renal medullary renin and prorenin receptor mRNA was quantified using RT-PCR in 10 week old male Akita mice.

Results: STZ injected mice developed hyperglycemia within 4 weeks of injection (STZ: 335 ± 35 vs control: 145 ± 22 mg/dL) and remained hyperglycemic at 10 weeks. At 10 weeks post-injection, STZ injected mice had significant polyuria (STZ: 20.9 ± 5.9 vs controls 1.8 ± 0.4 ml/day), increased water intake (STZ: 26.2 ± 5.9 vs controls: 6.2 ± 0.9 ml/day) and lower body weight (STZ: 28.3 ± 1.3 vs controls: 23.6 ± 1.4 grams) despite similar food intake. Compared to controls, urinary angiotensinogen, total prorenin/renin and sPRR levels were increased in STZ injected mice; these increases were proportionally greater than the trend in increased urinary microalbumin excretion (Table 1). In particular, urinary sPRR excretion was markedly increased in STZ injected mice compared to controls. In contrast, plasma renin concentration and sPRR were similar between the controls and STZ injected mice. Similalry, 10 week old male Akita mice bearing a mutated *Ins2*gene, demonstrated a 4.8 fold increase in renal medullary renin mRNA expression and a 1.5-fold increase in renal medullary PRR expression.

Conclusions: Taken together, these results demonstrate early activation of the intra-renal RAS in Type 1 diabetes. These changes occur independent of the systemic RAS.

Funding: Private Foundation Support

Tale 1. Plasma and urine RAS components in early Type 1 diabetes

	Control (N=6)	STZ injected (N=5)	P value
Plasma renin concentration (ng/ml/hr)	134.6 ± 36.7	75.6 ± 12.6	0.09
Plasma sPRR (ng/ml)	24.8 ± 3.7	23.7 ± 4.9	0.43
Urine albumin (µg/day)	32.7 ± 7.3	69.5 ± 26.1	0.07
Urine angiotensinogen (ng/day)	133.6 ± 9.8	556.2 ± 160	0.005
Urine total prorenin/renin (ng/day)	5.7 ± 2.2	19.0 ± 4.8	<.001
Urine sPRR (µg/day)	ND	67.1 ± 22.3	<.001

Role of the Inducible Calbindin-D28k Protein in Advanced Glycation End Products-Associated Renal Proximal Tubule Cell Injury

Chih-Kang Chiang,[1,2] Kuan-yu Hung,[3] Shing-Hwa Liu.[1] [1]*Institute of Toxicology, School of Medicine, National Taiwan University, Taipei, Taiwan;* [2]*Department of Integrated Diagnostics & Therapeutics, National Taiwan University Hospital, Taipei, Taiwan;* [3]*Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan*.

Background: Diabetic nephropathy is a common diabetic complication associated to calcium dyshomeostasis. Previous studies suggested that diabetes-associated advanced glycation end products (AGEs) are associated with the increase of extracellular matrix proteins synthesis and renal fibrosis induction. Protein expression of calbindin-D28k, which plays a role in the calcium reabsorption in the renal distal convoluted tubules, has been shown to be increased in diabetic kidney. However, the role of calbindin-D28k induction in diabetic kidney is still unknown.

Methods: Human renal proximal tubule cell (HK-2) were transfected with/without calbindin-D28k siRNA and then treated with AGEs for 48hours. THe expression of several critical proteins were determined by Western blotting. Cell viabilit was evaluated by MTT assay. The expression of calbindin-D28k in renal tissue of db/db mice were detected by immunohistochemistry.

Results: We found that calbindin-D28k could be induced in the proximal tubules of the db/db diabetic mouse kidney. The increase of AGEs and extracellular matrix (ECM) proteins were also observed in the db/db diabetic mouse kidney. We further explored the role of calbindin-D28k in AGEs-induced human renal proximal tubule cell (HK2) injury and fibrotic changes. AGEs significantly induced the expression of calbindin-D28k in HK2 cells, but not in mesangial cells. AGEs also significantly induced the expressions of fibrotic molecules, ECM proteins, epithelial-mesenchymal transition (EMT) markers, and endoplasmic reticulum (ER) stress-related molecules in HK2 cells. Calbindin-D28k-siRNA transfection significantly reduced the cell viability and markedly enhanced the protein expressions of fibrotic factors, EMT markers, ER stress-related molecules, phosphorylated smad 2/3, and phosphorylated p38 in AGEs-treated HK2 cells. Treatment with 4-phenylbutyric acid, a chemical chaperone, significantly counteracted the AGEs-induced ER stress and EMT markers expressions in HK2 cells.

Conclusions: These findings suggest that the inducible calbindin-D28k plays a protective role against AGEs-induced ER stress and EMT induction and cell injury in renal proximal tubule cells. Calbindin-D28k may serve as a predicted marker for proximal tubule injury/fibrosis or a therapeutic target for diabetic nephropathy.

PUB187

Phosphorylation and Nuclear Translocation of PKM2 in Renal Tubule Regulates the Activation of NLRP3 Inflammasome in Diabetes

Ting Cai,[2] Yang Zhou,[1] Junwei Yang.[1] [1]*Second Affiliated Hospital, Nanjing Medical University, Nanjing, China;* [2]*Nanjing Medical University, Nanjing, China*.

Background: Diabetic kidney disease (DKD) is one of the major causes of renal failure. Activation of NLRP3 inflammasome in tubular cells contributes to the progression of DKD. However the underlying mechanisms that regulate NLRP3 inflammasome remain poorly understood.

Methods: In this study, streptozotocin (STZ) was injected intraperitoneally at the dose of 40mg/kg/day for 5 consecutive days to induce diabetic mouse model. Random blood glucose level greater than 16.7mmol/L tested 2 weeks later was considered as diabetes. Diabetic mice were sacrificed at 1, 2 and 4 weeks after confirmation of diabetes. *In vivo*, primary tubular cells (PTCs) were treated with 30mmol/L of glucose for indicated time points.

Results: NLRP3 inflammasome were markedly activated in both diabetic kidneys and in high glucose-treated PTCs as demonstrated by increased expression of NLRP3, ASC, cleaved caspase-1, cleaved IL-1β and cleaved IL-18. Phosphorylation of PKM2 was observed in diabetic kidneys and PTCs under high glucose condition. Moreover, western blot and immunohistochemistry staining showed nuclear translocation of PKM2 in tubular epithelial cells. Treatment with shikonin, an inhibitor of PKM2 activity, attenuated PKM2 phosphorylation and nuclear translocation. Furthermore, shikonin blocked the high glucose-induced activation of NLRP3 inflammasome in PTCs.

Conclusions: Our study suggests that phosphorylation and nuclear translocation of PKM2 promotes the activation of NLRP3 inflammasome and contributes to inflammation in diabetes. Pharmacological inhibitors targeting the activation of PKM2 may be a novel therapeutic strategy for DKD.

PUB188

Quantitative Proteomics Identifies Interaction Proteins for Decoy Receptor DcR2 in Diabetic Nephropathy

Jia Chen,[1] Yani He.[2] [1]*Daping hospital, Chongqing, Chongqing, China;* [2]*Daping Hospital, Chongqing, China*.

Background: Decoy receptor 2 (DcR2), a transmembrane receptor of tumor necrosis factor-related apoptosis inducing ligand (TRAIL), is a cellular senescent marker. DcR2 plays a crucial role in the progression of diabetic nephropathy (DN), but the interaction proteins for DcR2 not clear.

Methods: 139 DN patients which diagnosed by renal biopsy were enrolled. Renal DcR2 expression was detected immunohistochemically. Associations between renal DcR2 and renal functional parameters and pathological damage scores were evaluated. Double staining was undertaken for DcR2 with its ligand TRAIL, and antagonistic receptor DR4 in renal tissue. Co-immunoprecipitation (Co-IP) were analyzed for the DcR2 with TRAIL and DR4 in high glucose (HG) induced-primary tubular epithelial cells (PTECs). Co-IP combining with LC-MS/MS were screened the interaction proteins for DcR2.

Results: DcR2 was primarily expressed in renal proximal tubules. The percentage of renal DcR2 were higher in DN than control, correlated with renal functional parameters and scores of renal tissue damage. DcR2 was not co-expressed with TRAIL, DR4 in DN, and not binding to TRAIL, DR4 in vitro. Quantitative proteomics identified 59 differentially expressed proteins (DEPs) in HG, while 52 DEPs were detected specifically in HG. These DEPs are involved in endothelial cell migration, negative regulation of extrinsic apoptosis, ion homeostasis, regulation of keratinocyte differentiation, removal of superoxide radicals, hydrogen peroxide catabolic process, skeletal muscle tissue regeneration.

Conclusions: We explored the interaction proteins for DcR2 in high glucose-induced PTECs with quantitative proteomics, which will help to elucidate the mechanisms of DcR2 in renal tubular cells in DN.

Funding: Government Support - Non-U.S.

PUB189

Dipeptidyl Peptidase Inhibitor Linagliptin Induced Effects on Cardiac miRNA Expression in GLP-1 Receptor Knock-out Mice with 5/6 Nephrectomy

Franziska Wiech,[1] Marcel Rolser,[1] Ines Jakob,[1] Ogsen Gabrielyan,[1] Oleg Tsuprykov,[2] Ahmed A. Hasan,[2] Thomas Klein,[1] Berthold Hocher,[2] Denis Delic.[1] *[1]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany; [2]University of Potsdam, Potsdam, Germany.*

Background: Chronic kidney disease (CKD) is a growing health problem with diabetes mellitus and hypertension being main drivers to its development and progression. Additionally, CKD is associated with an increased risk for the development of cardiovascular disease. Growing pre-clinical evidence indicates that the dipeptidyl peptidase (DPP)-4 inhibitor linagliptin (LIN) exerts beneficial renal and cardioprotective effects. However, clinical outcome data are still missing and also the exact molecular mechanisms remain unclear. Experimental studies suggest the involvement of the GLP-1/GLP-1 receptor (GLP-1r) pathway as a potential mechanism underlying the beneficial effects of DPP-4 inhibition in CKD.

Methods: Here we investigated regulation of microRNAs (miRNAs) in cardiac tissue (using the Nanostring nCounter technology) of 5/6 nephrectomized mice after LIN treatment (12 weeks, ~3-5 mg/kg/d in chow) in wildtype and GLP-1r knock-out mice. miRNAs are short non-coding RNA species which are important post-transcriptional regulators of gene expression and are implicated in the pathogenesis of diabetic nephropathy.

Results: Analysis of variance (ANOVA) ($p<0.05$) resulted in a deregulation (up or down) of 15 miRNA species between sham and 5/6 nephrectomized animals. Most of the deregulated miRNA species are involved in cardiac fibrosis, cardiomyopathy and cardiac hypertrophy processes, such as miR-1, miR-133b, miR-30d, miR27b, miR-690 and miR-142-3p. In particular, the ameliorative effects on the expression of the cardiomyocyte protective miR-142-3p were observed in 5/6 nephrectomy plus LIN treated animals. Deregulation of miRNAs in GLP-1r knock-out mice were consistent but effects of LIN were less prominent.

Conclusions: The data suggest cardioprotective effects of LIN via upregulation of miR-142-3p in a model of 5/6 nephrectomy induced uremic cardiomyopathy.

PUB190

Antioxidant Improves Diabetic Nephropathy and Cardiac Function in Diabetes Induced Renocardiac Syndrome

Firoozeh Farahmand. *Nephrology, SLU, Saint Louis, MO.*

Background: Diabetes mellitus(DM) is strongly associated with renocardiac syndrome (RCS) in a nationally representative population. RCS is characterized by primary renal failure that progressively leads to cardiac dysfunction. Pathophysiological mechanisms underlying initiation and maintenance of this interaction are complex and poorly understood. Furthermore, because of the development of resistance to standard therapies, targeting renocardiac remodelling process to develop novel therapies is essential. Evidence suggest oxidative stress play a major role in kidney-heart pathophysiological cross talk. The purpose of this study was to investigate wheather there is oxidative stress in this experimental model of RCS & if antioxidant treatment attenuate renocardiac injury

Methods: DM was induced in rats by streptozotocin(STZ)-induced pancreatic injury causing renal injury similar to human diabetic nephropathy. Animals were randomly divided into 3 groups, CONT+Carvediol(CARV), DM and DM+CARV. CARV was adminstered orally for 8 wks. At 8 wks animals underwent echocardiography to measure LV end-diastolic dimension (LVEDD), LV end-systolic dimension (LVESD), left ventricular ejection fraction (LVEF), and left ventricular fraction shortening (LVEF). After sacrificing the animals, Kidneys and hearts were examined by Hematoxylin Eosin (HE) staining and periodic acid Schiff base(PAS). Kidney and heart antioxidant enzymes, and lipid peroxidation were determined

Results: In STZ-induced diabetics rats increase in renal and myocardial lipid peroxidation and decrease in antioxidants enzymes were associated with vacuolar degeneration of tubules; PAS positivity staining intensity in glomeruland basement membrane and thickening as well as significant prolongation of isovolumic relaxation time (IVRT) (38 ± 8 vs. 25 ± 6 ms, $p < 0.0001$), elevation of LV end-diastolic pressure (8 ± 6 vs. 2 ± 1 mm Hg, $p = 0.05$) and increased chamber stiffness. CARV improved kidney histopathological altereations and cardiac dysfunction that was associated with increase in antioxidant defense in the kidney and the heart and decrease lipid peroxidation

Conclusions: Our results suggest that in this model of renocardiac syndrome oxidative stress play a role in mediation of Kidney-Heart pathological cross talk and carvideolol with its significant antioxidant properties attenuate diabetic nephropathy and diabetic cardiomyopathy.

PUB191

Effects of Soluble Guanylyl Cyclase Stimulation or Activation on Blood Pressure and Renal Hemodynamics in Diabetic Rats

Rohit Patel,[1] Yiling Fu,[1] Winnie Huang,[1] Ser Khang,[1] Agnes M. Benardeau,[2] Scott C. Thomson,[1] Volker Vallon.[1] *[1]Department of Medicine, University of California, San Diego & VA San Diego Healthcare System, San Diego, CA; [2]Bayer Pharma AG, Wuppertal, Germany.*

Background: The second messenger, cGMP, influences blood pressure (BP) and renal hemodynamics. It is locally formed by soluble guanylyl cyclase (sGC). The activity of sGC can be enhanced by sGC "stimulators" or "activators", which target the enzyme in two different redox states, the nitric oxide (NO)-sensitive reduced enzyme and the NO-insensitive oxidized enzyme, respectively. Little is known about the relative effects of these agents on BP versus renal hemodynamics in diabetes mellitus (DM).

Methods: Acute effects of sGC stimulator BR9902 and sGC activator BR9904 were determined on mean arterial BP (MAP) and renal hemodynamics under terminal barbiturate anesthesia in 3 groups of rats: non-diabetic Wistar Froemter (WF) rats (CON); streptozotocin-diabetic WF rats, a model of type 1 DM (T1DM); and Goto-Kakizaki rats (GK), a non-obese model of type 2 DM (T2DM). Increasing doses of each compound were tested in individual animals in consecutive 20 min periods, and compared with vehicle. MAP was measured via femoral artery catheter; GFR and RBF by renal FITC-sinistrin clearance and perivascular ultrasonic transit time flow probe, respectively. n=6-8/group.

Results: BR9902 and BR9904 induced similar dose-dependent reductions in MAP among the 3 groups. The highest dose of either drug (1 mg kg^{-1} $30min^{-1}$) lowered MAP by 20-30%. Basal GFR and RBF were higher in T1DM and GK versus CON. Qualitative effects of BR9902 and BR9904 on RBF and GFR are shown in a table.

Conclusions: Systemic infusion of BR9902 or BR9904 lowers MAP, which challenges the kidney to autoregulate. Overall hemodynamic autoregulation is more efficient in WF rats (CON or T1DM) than in GK rats, and is more efficient during BR9902 than BR9904. From the latter we infer the existence of drug effects on sGC within the kidney that differ between BR9902 and BR9904, and therefore potentially between stimulators and activators of sGC. When dosed to lower blood pressure by 20-30%, both agents reduced glomerular hyperfiltration in GK-T2DM but not in WF-T1DM.

Determinants of Renal Outcomes of Type 2 Diabetic Patients with Biopsy Proven Kidney Disease

Hui Zhuan Tan, Jia Liang Kwek, Choong Meng Chan, Jason Choo Chon Jun. *Singapore General Hospital, Singapore, Singapore.*

Background: We aimed to look at renal outcomes of patients with Type 2 diabetes mellitus (T2DM) who were biopsied and determine the risk factors associated with progressive CKD.

Methods: We retrospectively analyzed patients with T2DM with estimated glomerular filtration rate (eGFR) (MDRD) >30ml/min/m^2 who underwent kidney biopsy from 2007 to 2015 in our tertiary hospital with at least 1 year of follow-up. Outcomes of interest were progressive CKD defined by doubling of serum creatinine or ESRD. Survival curve was obtained using Kaplan-Meier analysis. Clinically relevant risk factors in univariate analyses were adjusted using Cox proportional hazards model.

Results: The cohort included 70 patients, median age 55.2 (IQR: 49.0, 61.4) years and duration of T2DM 102.0 (45.0, 183.0) months. The predominant ethnic group was Chinese (82.9%) with a median follow-up of 42.5 months (27.0, 71.3). Ninety percent of patients received renin-angiotensin-aldosterone-system blockade prior to biopsy and nephrotic range proteinuria was the most common indication for biopsy (77.1%). Forty-three patients had isolated DKD (Group 1) and 27 patients had isolated NDKD (Group 2). Four patients with mixed DKD and NDKD were excluded from analysis in view of small numbers. In Group 1, the median eGFR (MDRD) was 54.3 ml/min/m^2 (42.9, 72.8) and Group 2 was 72.2 ml/min/m^2 (43.8, 90.6). Sixteen patients (59.3%) from Group 2 received immunosuppression or disease specific therapy. Twenty-two patients (51.2%) from Group 1 and 8 patients (29.6%) from Group 2 had progressive CKD. ESRD occurred in 17 patients (39.5%) from Group 1 and 4 patients (14.8%) from Group 2, at median interval of 53.0 (38.6, 67.4) months from biopsy but median time to ESRD was not reached in patients from Group 2. Nine patients, all from Group 1, had died. Kaplan-Meier analysis showed that time interval to progressive CKD was significantly longer in Group 2 patients compared to patients in Group 1 ($p=0.026$). The independent risk factors to progressive CKD were DKD, baseline systolic blood pressure and baseline urine protein/creatinine ratio by Cox's proportional hazards model.

Conclusions: T2DM patients with DKD have significantly worse renal outcomes compared to patients with NDKD. Early biopsy to differentiate NDKD should be considered as disease-specific treatment can be given to achieve better renal survival.

PUB193

Association of Plasma Soluble CD146 with Arteriosclerosis and Cardiovascular Events in Patients with Diabetic Nephropathy

Yiyun Wang, Ying Fan, Niansong Wang, Yang Fei. *Shanghai 6th People's Hospital affiliated to Shanghai Jiaotong University, Shanghai, China.*

Background: Diabetic nephropathy is an independent risk factor for arteriosclerosis. Patients with both DN and arteriosclerosis have poor prognosis due to the lack of early symptoms and specific markers. Endothelial cell injury plays a crucial role in arteriosclerosis. CD146, an endothelial marker, was used to reflect the severity of endothelial dysfunction. We aim to find out if CD146 can evaluate the severity of arteriosclerosis and predict cardiovascular events in patients with DN at early stages.

Methods: A total of 105 DN patients at CKD stage 1-3 were enrolled and another 94 diabetic patients without DN entered the control group. Plasma soluble CD146 (sCD146) was measured. Doppler ultrasounds of carotid and lower extremity artery were performed. All DN patients were retrospectively followed up for a medium duration of 28 months. The association between sCD146 and arteriosclerosis was assessed in DN patients. Kaplan-Meier curve was used to evaluate the predictive value of sCD146 in cardiovascular events.

Results: Plasma sCD146 was upregulated in DN patients compared with control group. sCD146 level was shown to be correlated with the intima-medium thickness of both carotid and lower extremity arteries. High level of sCD146 was proved to be an independent risk factor for the prevalence of carotid plaques and the instability of plaques in both carotid and lower extremity arteries. Survival analysis showed that patients with higher level of plasma sCD146 were more likely to have cardiovascular events.

Conclusions: Plasma sCD146 is associated with arteriosclerosis in patients with early stages of DN and can also predict their cardiovascular events.

Kidney Biopsy in Type 2 Diabetes Patients with CKD

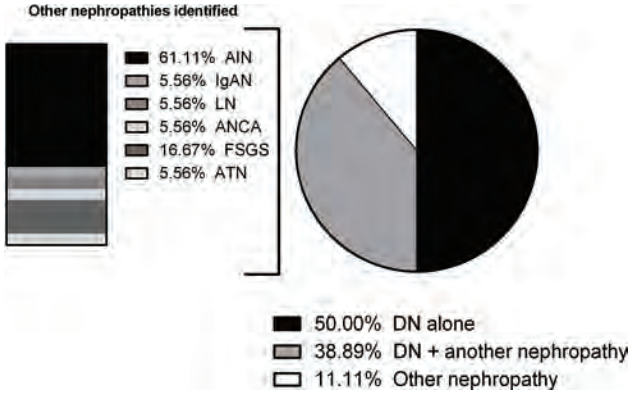
Javier Soto-Vargas, Manuel S. Preciado, Julio A. Gutierrez-Prieto, Isela Márquez magaña, Francisco Fuentes Ramirez, Renato Parra Michel. *Universidad de Guadalajara, Centro Universitario de Ciencias de la Salud, Especialidad en Nefrologia, Hospital General Regional No 46 del IMSS, Guadalajara, Mexico.*

Background: T2D represent the most frequent cause of CKD worldwide. Reduced GFR and albuminuria are considered hallmark for the diagnosis of diabetic nephropathy (DN), but recently, there are growing concerns of the sensibility of these markers to identify DN from other nephropathies. Our objective was to describe the prevalence of biopsy proven DN and other nephropathies in patients with T2D.

Methods: During March 2017 to February 2018, we prospectively biopsied 35 with diagnosis of T2D and CKD and had no contraindications for the kidney biopsy. All histological results were read by a nephropathologist.

Results: The mean age was 52 ± 11.9 years, and 17 (77.2%) were female. The average BMI was 27.5 ± 5.1 kg/m^2, 31 (86.1%) had HTN, and baseline GFR was 56 ml/min (IQR 39.4-74.9). The mean time with T2D was 13 ± 7.5 years, and 21 (58.3%) had history of diabetic retinopathy. The sCr at the time of the kidney biopsy was 1.9 mg/dL (IQR 1.1-3.4), the main indications for the kidney biopsy were nephrotic syndrome in 17 (47.2%), nephrotic range proteinuria in six (16.7%), rapid progression of CKD in six (16.7%), AKI in two (5.6%), rapid progressive glomerulonephritis in one (2.8%), and two with subnephrotic proteinuria (5.6%). The histologic findings were isolated DN in eighteen (50%) patients, fourteen (38.9%) had DN + other glomerulopathy, and four (11.1%) had a non-DN glomerulopathy (Figure 1). None of the clinical or biochemical analysis was associated with the histological diagnosis or predicted the severity of the glomerular sclerosis in patients with DN.

Conclusions: The kidney biopsy is a useful tool to stablished a correct diagnosis and severity of the CKD in patients with T2D. Reduce GFR and albuminuria are not useful to differentiate DN from other glomerulopathies, nor stablish severity of the histological appearance.



Kidney bipsy results of T2D patientsAIN, acute intersticial nephritis; LN, lupus nephritis; FSGS, focal segmental glomerulosclerosis; ATN, acute tubular necrosis.

PUB195

Validation of the 2007 Kidney Disease Outcomes Quality Initiative Clinical Practice Guideline for the Diagnosis of Diabetic Nephropathy and Nondiabetic Renal Disease in Chinese Patients

Xiaomin Liu, Zheyi Dong, Weiguang Zhang, Qian Wang, Xiangmei Chen. *Chinese PLA General Hospital, Beijing, China.*

Background: Diabeties mellitus has overtaken infection and immunological factors as the most common cause of chronic kidney disease and end-stage renal disease. Pathological results of DM patients with CKD could be diabetic nephropathy (DN) and nondiabetic renal disease (NDRD), the prognosis and treatment of which are different. The Kidney Disease Outcomes Quality Initiative (KDOQI) guideline (2007) is a widely accepted guideline for the clinical diagnosis of DN and NDRD. Our study sought to verify its diagnostic ability in the Chinese population.

Methods: We included 773 DM patients who underwent a renal biopsy at the Chinese PLA General Hospital from 2007 to 2016. All the patients were divided into three groups according to their renal biopsy: isolated DN, isolated NDRD, and isolated DN combined with NDRD. The calculation were performed under two conditions:isolated DN vs. isolated NDRD and isolated DN vs. non-DN [NDRD with and without DN].

Results: Good sensitivity and poor specificity were found for the prediction of NDRD in the Chinese population. Rapidly decreasing estimated glomerular filtration rate, systemic disease, refractory hypertension, and the existence of "grey area" patients may have contributed to the poor diagnostic ability.

Conclusions: The diagnostic ability of the KDOQI guideline (2007) for DN and NDRD was unsatisfactory. The high sensitivity and low specificity of the guideline made it more suitable as screening criteria rather than diagnostic criteria.

Funding: Government Support - Non-U.S.

Prediction of non-diabetic renal disease

	Isolated DN vs. Isolated NDRD	Isolated DN vs. non-DN
Sensitivity	96.14%	93.92%
Specificity	40.63%	40.63%
PPV	75.77%	75.82%
NPV	85.85%	77.12%
Kappa Statistic	0.286; P<0.001	0.268; P<0.001

PUB196

Comparison of the Risks of Cardiovascular Disease for Patients with Diabetic Kidney Disease Between Those Treated by Diabetologists and Nephrologists

Masanori Ishizaka,[1] Hiroaki Io,[1] Hiroyuki Inoshita,[2] Takanori Nakano,[1] Masayuki Maiguma,[1] Yoko Matsuyama,[1] Yusuke Suzuki.[3] *[1]Juntendo University Nerima Hospital, Tokyo, Japan; [2]Koto Hospital, Tokyo, Japan; [3]Juntendo University Faculty of Medicine, Tokyo, Japan.*

Background: Patients with diabetic kidney disease are managed by not only diabetologists, but also nephrologists. In this study, we examined the risk of cardiovascular disease for patients with diabetes mellites between those treated by diabetologists and nephrologists.

Methods: We randomly selected 200 and 30 outpatients with diabetes mellites managed by diabetologists and nephrologists, respectively. All of patients showed microalbuminuria during the four months from May to August, 2017. We analyzed sex, age, estimation glomerular filtration rate (eGFR), albuminuria, hemoglobin, HbA1c, and blood pressure correlation with past history of the cardiovascular diseases.

Results: Both age and microalbuminuria levels were significantly higher in the diabetes patientstreated by diabetologists with cardiovascular disease than those without cardiovascular disease. In contrast, a significant difference was not found in the age and the microalbuminuria levels of the diabetes patients treated by nephrologists with cardiovascular disease and those without cardiovascular disease. In outpatients with diabetes mellites managed by diabetologists, CKD stage 2 (eGFR 60-90ml/min) was the most stage (51.8%). In outpatients with diabetes mellites managed by nephrologists, CKD stage 3 (eGFR 30-60ml/min) was the most stage (40.0%). In multivariate analysis, age (cutoff levels : 68 years old), eGFR (cut off levels : 81.7 ml/min) and albuminuria (cut off levels : 197 mg/gCr) were independently associated factors of the cardiovascular diseases in outpatients by diabetologists. In outpatients by nephrologists, eGFR (cut off levels : 59.0 ml/min) was only independently associated factor of the cardiovascular diseases. In comparison with the severity classification of chronic renal failure, age, eGFR and albuminuria were independently risk factors for cardiovascular disease in CKD stage G1-2 group, but in CKD stage G3-5 group, both were not related factors.

Conclusions: Outpatient with diabetic kidney disease managed by nephrologist were in an advanced phase more than those managed by diabetologists. And this study suggested that the eGFR was more risk factor on cardiovascular disease than age and albuminuria in outpatients managed by nephrologists.

PUB197

Echocardiographic Findings in Type 1 Diabetics with End-Stage CKD

Rita Calça,[1] Tiago J. Carvalho,[3] Patricia Q. Branco,[2] Maria augusta C. Gaspar,[1] Rita Birne,[1] Eduarda Horta,[1] Carla A. Reis,[1] Maria joão Andrade.[4] *[1]Hospital Santa Cruz, Carnaxide, Portugal; [2]Santa Cruz Hospital, Carnaxide, Portugal; [3]Hospital de Santa Cruz, Queluz, Portugal; [4]Hospital Santa Cruz, CHLO, Lisbon, Portugal*.

Background: Diabetes mellitus(DM) and chronic kidney disease(CKD) are independent risk factors for the development of cardiovascular(CV) disease. They have been associated with changes of cardiac structure, function, and an excess risk of coronary artery disease(CAD). The aim of this study was to evaluate the echocardiographic findingsin patients with DM type1 and end-stage CKD.

Methods: 48 consecutive patients undergoing stress echocardiography prior to renal +/- pancreatic transplantation between December2008 and December2014 at a single center, were evaluated. At baseline, a complete comprehensive 2D and Doppler exam was performed, including evaluation of global longitudinal strain(GLS).

Results: Mean age was 42.3±7.1years-old, mean DM duration was 24.4± 6.0 years and mean HbA1c was 8.7 ±1.7%. The prevalence of other major atherosclerotic risk factors was: hypertension 69.4%, dyslipidemia 44,4% and smoking 36.1%. 4 patients had history of CAD with previous coronary angioplasty. At baseline, 38.5% were on hemodialysis(HD) and 25.6% on peritoneal dialysis(PD); 7.7% had previous renal transplant and 28.2% patients weren't on renal replacement therapy(RRT). 63.6% had left ventricular(LV) hypertrophy(LVMI>115g/m^2 for men, >95g/m^2 for women) and 45.3% had left atrial enlargement (LAE>34ml/m^2). Although LV ejection fraction was preserved in 72.9%, LV dysfunction as assessed by abnormal GLS(> -18%) was observed in 72,9%. 5 patients had neither LV dysfunction nor hypertrophy. 34.4% had rest elevated LV filling pressure(E/e' >13). No differences between HD, PD and no RRT groups. 6 patients (12,5%) had ischaemic response, 5 of whom underwent coronary interventions. During follow-up (5.6, 4.2-6.9 years), 14.3% had hospitalizations of any cause and 3 were hospitalized for CV causes. These 3 patients had both LV dysfunction and hypertrophy and 1 had ischaemic response. At the end of follow-up 50% of patients had transplant (mostly kidney-pancreas). No patient died.

Conclusions: Cardiac abnormalities are frequent in relatively young patients with DM type 1 and end-stage CKD. Most of them have LV hypertrophy and preserved ejection fraction, despite LV dysfunction. CAD is also frequently present and can be demonstrated by stress echocardiography, allowing for coronary intervention before renal transplantation.

PUB198

Stakeholder Perspectives on Implementing Personalized Medicine in Diabetic Kidney Disease

Michelle Pena,[1] Nienke Idzerda,[1] Gert J. Mayer,[2] Friedrich Schulze,[5] Jeannette Soderberg,[6] Dennis L. Andress,[4] Maria F. Gomez,[3] Hiddo J. Lambers Heerspink,[1] Dick de Zeeuw,[1] Peter G. Mol.[1] for Work Package 6 of the BEAt-DKD Consortium *[1]University Medical Center Groningen, Groningen, Netherlands; [2]Medical University Innsbruck, Innsbruck, Austria; [3]Lund University, Malmö, Sweden; [4]AbbVie, North Chicago, IL; [5]Boehringer Ingelheim International GmbH, Ingelheim, Germany; [6]JDRF, Paris, France*.

Background: The Innovative Medicine Initiative BEAt-DKD consortium aims to discover and implement novel biomarkers for personalized medicine in diabetic kidney disease (DKD). Gaining stakeholder opinions and perspectives are important in this process. We describe here the opinions and perspectives of stakeholders obtained during focus group meetings.

Methods: Stakeholder focus groups were held with members of European regulatory agencies, health technology assessors, physician groups, and patient organizations. BEAt-DKD consortium partners included academia, pharmaceutical industry, and patient advocacy. General and stakeholder specific topic lists were developed by BEAt-DKD members. A background presentation on personalized medicine in DKD was given, and then an open discussion was held, moderated by an academia BEAt-DKD member. Themes discussed included: 1) determining whether there is a need for personalized medicine in DKD, 2) what additional evidence is needed, 3) identification of the pros and cons within each stakeholder environment, 4) identification of hurdles for implementation, and 5) engagement with other stakeholders.

Results: Attendees of the focus groups included representatives from European regulatory agencies (n=7), health technology assessors (n=4), physicians (n=5), and patients (n=4). BEAt-DKD partners included academia (n=6), pharmaceutical industry (n=3), and patient advocacy (n=1). Main points that came out of the stakeholder focus groups are presented in the table.

Conclusions: Implementing personalized medicine in DKD is complex, and early engagement of stakeholders in the developmental process is important. Different stakeholders have different priorities, and achieving the goal of implementing personalized medicine in DKD will only happen if we can align stakeholder goals.

Funding: Commercial Support - The BEAt-DKD project has received funding from the Innovative Medicines Initiative 2 Joint Undertaking under grant agreement No 115974. This Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation programme and EFPIA., Government Support - Non-U.S.

Stakeholder	Perspective on personalized medicine in DKD
European regulatory agencies	Need for prospective clinical trial evidence before regulatory qualification of a novel methodology.
Health technology assessors	Assessment of budget impact and cost effectiveness for new biomarkers is necessary but financial priorities vary from country to country.
Physicians	Better risk stratification and more precise options for treatment need to be developed and included in clinical practice guidelines.
Patients	Extra time for medical procedures and shared medical decision making should be considered. Benefit to quality of life is a higher priority than clinical endpoints.

PUB199

Pattern of Non-Diabetic Renal Diseases (NDRD) in Patients with Diabetes Mellitus at State Run Tertiary Care Center

Umesh L. *Institute of nephrourology, Bangalore, India*.

Background: Introduction A wide spectrum of non-diabetic nephropathy, including both glomerular and tubulo-interstitial lesions are reported in patients with Diabetes mellitus. Their precise diagnosis requires histological examination of kidney tissue. **Aim** We carried out this study to find the clinical, laboratory, and pathological features of non diabetic renal disease (NDRD) in diabetes mellitus(DM) patients. We also examined if any significant differences in clinical profile between the NDRD and diabetic nephropathy(DMN) groups

Methods: The demographic, clinical, and biochemical data of patients with DM (defined by ADA) who underwent renal biopsy in this institute for a duration of from 2012 august to october 2017 were analyzed prospectively. 220 patients were included in the study. Data were collected from inpatient file, monitor sheets, histopathological reports.

Results: Materials & methods: The demographic, clinical, and biochemical data of patients with DM (defined by ADA) who underwent renal biopsy in this institute for a duration of from 2012 august to october 2017 were analyzed prospectively. 220 patients were included in the study. Data were collected from inpatient file, monitor sheets, histopathological reports.

Methods: The demographic, clinical, and biochemical data of patients with DM (defined by ADA) who underwent renal biopsy in this institute for a duration of from 2012 august to october 2017 were analyzed prospectively. 220 patients were included in the study. Data were collected from inpatient file, monitor sheets, histopathological reports.

Conclusion: In this study, incidence of NDRD was 38%, DMN 42% AND combined was 20%. Chronic kidney disease (CKD),nephrotic syndrome(NS) and acute kidney injury(AKI) were the most frequent clinical presentation. Acute interstitial nephritis(AIN),post infectious glomerulonephritis(PIGN) and chronic tubulointerstitial disorder (CTID) were commonest NDRD. These results suggest that prevalence of different category of biopsy-proven renal disease in diabetic patients depends on the usual prevalence of renal disease in the total population, according to the geographical area and ethnic characteristics and NDRD is merely a coincidental in DM. 58% of patients in the study had NDRD [either isolated or combined]. This study showed isolated NDRD in 38%, this result is similar to that reported in India and other regions with incidence of isolated NDRD were less than 50%.

PUB200

Novel Biomarkers for Detecting Endothelial Dysfunction and High Cardiovascular Risk in Patients with Early Diabetic Kidney Disease

Ane karoline Medina neri,[1] Gdayllon Cavalcante meneses,[2] Renan Lima alencar,[1] Marina De paulo sousa fontenele nunes,[1] Mariane Souza rodrigues,[1] Igor Pinho saraiva,[1] Elizabeth De francesco daher,[2] Ricardo Pereira silva,[2] Geraldo B. Silva Junior.[1] *[1]University of Fortaleza, Fortaleza, Brazil; [2]Federal University of Ceara, Fortaleza, Brazil*.

Background: Diabetic kidney disease (DKD) is the most common cause of chronic kidney disease (CKD) worldwide, and the main cause of death is cardiovascular disease. We identified endothelial dysfunction and high cardiovascular risk among patients with early DKD using novel biomarkers.

Methods: A total of 128 patients with type 2 diabetes mellitus were enrolled in this study. They were all followed in a primary care facility in Fortaleza, Brazil, and had no previous history of cardiovascular or kidney disease. Blood samples were collected for lipid and glycemic profiles, FGF-23, Syndecan-1 and VCAM-1. We assessed cardiovascular risk (CVR) through the scores: Framingham lipids category (lipids FRE) and body mass index (BMI FRE), Brazilian Cardiology Society (SBC) score and UKPDS risk engine.

Results: Patients aged 56±10 years, and 68.8% of whom were women, with a mean diabetes diagnosis time of 7±6 years. The CVR stratification showed higher rates of high risk by lipids ERF (68.8%), BMI (78.1%) and SBD/SBC/SBEM score (98.4%). There were higher levels of VCAM-1 among patients with high CVR (lipids FRE), higher levels of VCAM-1, Syndecan-1, FGF-23 and microalbuminuria, and lower GFR among patients with high CVR (UKPDS) (Table 1).

Conclusions: DKD is associated with high CVR since its early stages. Novel biomarkers (VCAM-1, Syndecan-1, FGF-23) are useful for early detection of high risk patients. A longitudinal evaluation of these patients is required to assess the outcomes and the role of these novel biomarkers as predictors of prognosis.

Table 1. Association of novel biomarkers with cardiovascular risk (CVR) among patients with early stage diabetic kidney disease.

Biomarker	High CVR	Low CVR	p
Lipids FRE score			
VCAM-1 (ng/mL)	1155±254	964±336	0.02
Microalbuminuria (mg/24h)	41±75	21±53	0.01
UKPDS score			
VCAM-1 (ng/dL)	1273±280	1119±249	0.01
Syndecan-1 (ng/mL)	33±11	29±13	0.04
FGF-23 (pg/mL)	3121±5689	1077±2108	0.03
GFR (mL/mn/1.73m2)	83±14	95±16	0.002

PUB201

Retinopathy Predicts Rapid Decline in Renal Function in Ethnic Minorities with Diabetic Nephropathy

Amit J. Joshi, Mohan C. Abraham, Ambarish Athavale, Peter D. Hart. *Cook County Health and Hospitals System, Chicago, IL.*

Background: Retinopathy is seen in 66% of adult patients with type II diabetes (T2DM) and diabetic nephropathy and indicates advanced microvascular disease. However, association of retinopathy with progression of diabetic kidney disease is unknown. In our clinical practice, we have observed that certain patients with T2DM have a rapid decline in renal function, but it is unclear if any clinical parameters are associated with this presentation.

Methods: We retrospectively examined the Stroger Hospital kidney biopsy database from 2010 to 2017 and identified 57 cases of biopsy proven diabetic nephropathy. Indications for biopsy were either rapid decline in eGFR [defined as eGFR loss > 5ml/min/1.73m^2/ yr, KDIGO, Kidney Int. (suppl) 2013] or presence of a competing diagnosis. 29 of these cases had proliferative or non-proliferative retinopathy confirmed by an Ophthalmologist.

Results: In patients with more than 12 months of follow up (n=37), mean annual decline in eGFR was –15.9 (-11.2 to -20.1) ml/min/1.73m^2. The rate of decline in eGFR was significantly associated with presence of retinopathy (p=0.018) and hypoalbuminemia (serum albumin < 3.5 g/dL, p=0.002). There was a trend suggesting decline in eGFR correlated with severity of proteinuria (p=0.08). eGFR decline was not associated with hematuria ethnicity or gender (p ≥ 0.17).

Conclusions: In African-American and Hispanic patients with Diabetic nephropathy, presence of diabetic retinopathy correlated with rapid decline in eGFR and lower serum albumin despite RAAS blocker therapy.

Baseline demographic and clinical parameters (number, %)

Age: 54.3 ± 11.6 years	Male: Female 29:28	African American: 25 (44%), Hispanic: 26 (46%), Caucasian 3 (5%), Others: 3 (5%)
Proteinuria: 6.0 ± 4.7 g/g Cr Serum Albumin: 3.2 ± 0.6 g/dl Microscopic hematuria: 20 (35%)	Retinopathy: 29 (51%) No retinopathy: 19 (33%) No information: 9 (16%)	eGFR at biopsy: 35 ± 24 ml/min RAAS blockers use: 51 (89%)

PUB202

Potential Effectiveness and Mechanisms of Chinese Herbal Medicine for Diabetic Kidney Disease: Survival and Pharmacology Network Analysis on a Population-Based Clinical Database

Hsing-Yu Chen,[1,2] Yung-Chang Chen,[3] Hau-tieng Wu.[4,2] *[1]Chang-Gung Memorial Hospital, Taoyuan City, Taiwan; [2]Department of Mathematics, University of Toronto, Toronto, ON, Canada; [3]Chang Gung Memorial Hospital, Keelung branch, Keelung, Taiwan; [4]Duke University, Durham, NC.*

Background: Diabetic kidney disease (DKD) causes a great healthcare burden. In addition to western medicine (WM), Chinese herbal medicine (CHM) is attracting attention in the eastern culture societies. This study aims at exploring the mortality of CHM users and the potential mechanisms of CHM.

Methods: From 2004 to 2012, WM cohort (WM only, n=207,277) and CHM cohort (CHM with or without WM, n=26,522) were selected from all incident DKD patients in Taiwan's National Health Insurance Research Database. Risk of mortality was the study endpoint. To explore the potential mechanisms, pharmacology network analysis with pathway over-presentation tests were used.

Results: To the end of 2012, the cumulative incidence of mortality was 47.9% in WM cohort and 30.5% in CHM cohort (hazard ratio: 0.48 (99%CI: 0.45-0.51, p<0.001). The top 5 most prevalent CHM considerably covered the same target proteins as WMs used for DKD, and for WM uncovered proteins, cell cycle-related pathways were found most extensively.

Conclusions: CHM may be beneficial for DKD. Further studies are still needed for the clinical practicability.

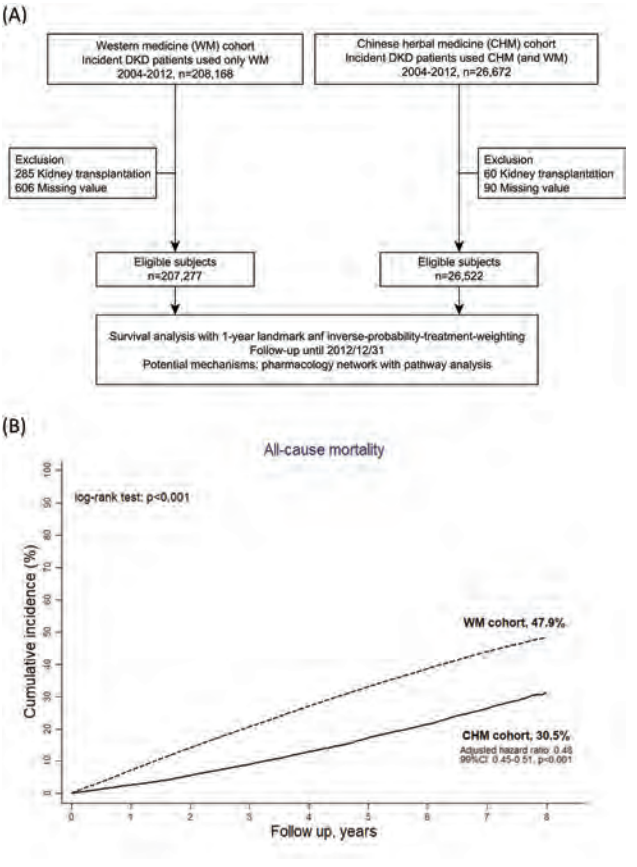


Fig1.(A) Flow diagram**(B)**Survival analysis

Efficacy and Safety of Valsartan Combined with Huangkui Capsule for Diabetic Kidney Disease: A Meta-Analysis

Meifang Liu,[1] Yanmei Zhang,[1] Xusheng Liu,[3,2] Lei Zhang.[4,2] *[1]The Second Affiliated Hospital of Guangzhou University of Chinese Medicine, Guangzhou, China; [2]Guangdong Provincial Hospital of Chinese Medicine, Guangzhou, China, Guangzhou, China; [3]The Second Affiliated Hospital, Guangzhou University of Chinese Medicine, Guanghzou, China; [4]Guangzhou university of Chinese Medicine, Guangzhou, China.*

Background: Diabetic kidney disease (DKD) has been a global public health problem and a huge economic burden to developing countries. Currently, as for DKD populations, medication options limited in angiotensin receptor blockers and angiotensin-converting enzyme inhibitors. Huangkui capsule, a Chinese patent medicine, has showed renal protective potential in experiments and retrospective studies. This meta-analysis will

systematically review the efficacy and safety of Valsartan combined with Huangkui Capsule for DKD patients.

Methods: We searched CENTRAL, MEDLINE, PubMed, Embase and Chinese databases including China National Knowledge Infrastructure, China Biology Medicine disc and Wanfang database from inception to August, 2017, to collect randomized clinical trials in adult patients (aged ≥18 years). According to the inclusion and exclusion criteria, two reviewers screened literature and extracted data separately and in parallel. The main outcomes were urinary albumin excretion rate (UAER), serum creatinine (SCr), 24-hour urinary protein (24h-UTP) and blood urea nitrogen (BUN) assessed by random-effects meta-analyses with RevMan 5.3. The quality of included studies was evaluated by the diagram of risks and bias provided by Cochrane collaboration.

Results: Nine RCTs from China were included with a total of 652 population. The analyses showed that combined therapy of Chinese and routine medicine was superior to routine medicine in decreasing UAER [MD=-9.70 ug/min, 95%CI(-13.1, -5.69), *P*[[FF1C;0.00001, low quality] and SCr [MD=-2.84 umol/L, 95%CI(-4.66, -1.03), *P*=0.002, low quality], the results had significant differences (*P*<0.05). However, the outcomes of 24h-UTP [MD=-0.31g/24h, 95%CI(-0.63, 0.00), *P*=0.05] and BUN [MD=-0.22 mmol/L, 95%CI(-0.47, 0.04), *P*=0.10] were similar between groups. The findings were robust to subgroup and sensitivity analyses. Six included studies mentioned adverse effects, summarized as gastrointestinal symptoms without detailed data.

Conclusions: Valsartan combined with Huangkui capsule could have a better clinical effect than using Valsartan alone in decreasing UAER and SCr but not 24h-UTP or BUN for DKD patients. However, the safety profile is unclear, and the quality of evidence is poor according to the grading of recommendations assessment, development, and evaluation approach, calling for high quality randomized, controlled RCTs.

PUB204

Unexpected Etiology of ESRD in a Young Man with Unknown Past Medical History

Albert M. Osei,[1,2] Edwin Okyne,[1] Peter D. Hart,[1,2] David J. Cimbaluk.[3] *[1]Medicine, John H. Stroger Jr. Hospital of Cook County, Chicago, IL; [2]Medicine, Rush University Medical Center, Chicago, IL; [3]Pathology, Rush University Medical Center, Chicago, IL.*

Introduction: Patients without access to the US health care system may have unidentified and untreated common medical conditions that may lead to severe and irreversible kidney disease. This case illustrates the consequences of lack of access to primary healthcare and the role of kidney biopsy in elucidating etiology of severe kidney disease in the context of paucity of prior clinical data

Case Description: A 32 year old Hispanic man was seen in a public hospital emergency department with one week history of progressive left visual loss and periorbital headache. BP was 186/116mmHg and systemic exam was unremarkable except for left eye depigmented vitreous hemorrhage suggestive of "hypertensive" retinopathy. Laboratory data showed non-fasting glucose -110mg/dl, serum creatinine -5.0mg/dl (eGFR 13ml/min), urine protein-8.75g/gCr and A1C -6%. All serological tests were negative and urine microscopy was unrevealing. Ultrasound showed normal size but echogenic kidneys. BP was 132/72 after two days on Nifedipine 30mg daily. Kidney biopsy done (Figure 1) showed "diabetic glomerulosclerosis with advanced global scarring (17 of 22 glomeruli) and severe interstitial fibrosis and tubular atrophy involving 90% of the cortex"

Discussion: Kidney biopsy was done in this patient because of his young age, normal size kidneys and uncertainty about the etiology and reversibility. The finding of "hypertensive" retinopathy and presumed hypertensive nephrosclerosis was not consistent with the nephrotic range proteinuria and the ease of BP control with monotherapy. Although up to 42% of US adults with undiagnosed diabetes may have CKD, it is very unusual for ESRD to lead to the diagnosis of "burnt-out diabetes". It is likely that access to basic primary care would have identified diabetes mellitus sooner and adequate treatment would have delayed or prevented this unfortunate outcome.

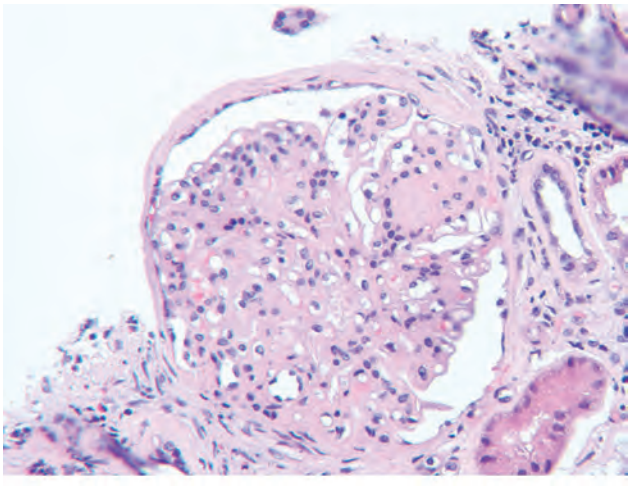

Figure 1

PUB205

Improving Inpatient Diabetic Management in Haemodialysis Patients: A Quality Improvement Project

Dhaarica Jeyanesan, Oscar Swift. *Renal Medicine, East and North Hertfordshire NHS Trust, Stevenage, United Kingdom.*

Background: The prevalence of diabetes is set to increase to 4.4% from 2.8% by 2030[1]. Some of the most vulnerable and severely affected patients are those with end-stage renal failure (ESRF) requiring haemodialysis. Until recently, sufficient UK national guidance to support healthcare professionals with the management of this particular population was lacking. In 2016, the Joint British Diabetes Society and Renal Association produced guidelines[2] covering the extensive and distinct needs of a diabetic patient with end stage renal failure on haemodialysis. Ongoing concern over the impact of hypoglycaemia on both cerebral function and risk of stroke mandates the need to optimise glycaemic control in this patient cohort.

Methods: Using this guidance as a framework, we have reviewed our own management of inpatient diabetic haemodialysis patients at Lister Hospital, Stevenage, a tertiary nephrology unit in the UK. We have applied quality improvement methodology using a "plan, do, study, act" model to the guidance to improve inpatient care.

Results: Initial results following baseline data collection over a two week period identified 12 haemodialysis inpatients with diabetes. 50% of these patients suffered a hypoglycaemic event, and 100% of this subgroup had a pre-dialysis capillary blood glucose (CBG) measurement of less than 7mmol/litre. No patients received bespoke insulin regimens to include reduced insulin dosage on dialysis days. Further investigation revealed issues with communication of hypoglycaemic episodes between nurses and doctors; acute dialysis staff using separate paperwork to document pre- and post-dialysis CBG measurements and discrepancies of management of pre-dialysis CBGs of less than 7mmol/litre, as well as poor inspection rates for diabetic foot ulcers (33%).

Conclusions: Primary interventions included notification and education of the relevant teams to ensure CBG measurements pre and post- dialysis were recorded on inpatient drug charts, which are easily accessible for all clinical staff, ensuring adequate pre-dialysis carbohydrate supplementation as per guidelines if pre-dialysis CBG measurements are less than 7mmol/litre and improved notification of hypoglycaemic events. Further quality improvement cycles are ongoing and will hopefully demonstrate an improvement in the management of diabetic haemodialysis patients in the areas described.

PUB206

Cost-Saving and High Efficiency of a Semi-Quantitative Screening Method for Detecting Microalbuminuria in Patients with Diabetes

Yaerim Kim,[1] Myoung-Hee Kim,[2] Dong Ki Kim.[1] *[1]Seoul National University Hospital, Seoul, Republic of Korea; [2]Eulji University, Seongnam-si, Gyeonggi-do, Republic of Korea.*

Background: Microalbuminuria is an important biomarker for diabetic nephropathy and cardiovascular complications. While quantitative measurement using turbidimetric immunoassay is the standard method for detecting microalbuminuria, it requires high cost and specialized laboratory equipment. In this study, we aimed to assess the diagnostic accuracy and verify the cost-saving effect of semi-quantitative urinary albumin-creatinine ratio (uACR) test as a screening tool for microalbuminuria in diabetic patients.

Methods: A total of 1,881 urine samples from patients with diabetes were analyzed between June 2017 and January 2018. Patients with low estimated glomerular filtration rate (eGFR) of <60 ml/min/1.73m^2, or abnormal urinary dipstick test were excluded. After investigating precision and reproducibility of the semi-quantitative method using URiSCAN® 2ACR, a cost-saving analysis was performed. To measure the economic burden of false negative results, probabilities of clinical outcomes were calculated using systematic literature review and subsequent meta-analyses. Information on annual medical costs was obtained from Korea healthy insurance review and assessment service. Statistical information of population and mortality rate according to age was extracted from Korean statistical information service.

Results: The coefficients of variation (CV) in within-run precision for albumin and creatinine were less than 5% in both. Between-run CVs for albumin and creatinine ranged up to 8% and 5% in positive result samples. Compared with the quantitative method, URiSCAN® 2ACR showed a sensitivity of 93.5% and 81.3% and specificity of 61.4% and 63.1% in patients with diabetes and diabetic patients with normal eGFR and normal dipstick result, respectively. False positive and false negative rate were 30.5% and 3.2%, respectively. After adjusting medical costs including the risk of disease progression, URiSCAN® 2ACR could save 9.86 USD per person for a year.

Conclusions: A semi-quantitative uACR test showed eligibility as a screening test for microalbuminuria in diabetic patients. This method would minimize the time required and inconvenience and enormously reduce the national health costs as well.

PUB207

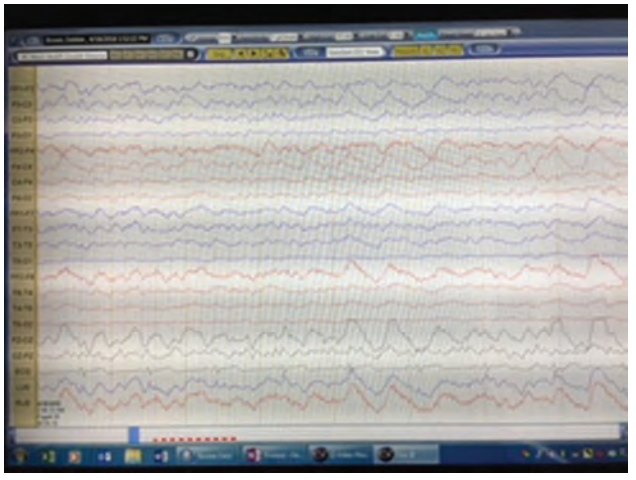
Dialysis Induced Diffuse EEG slowing – A Diagnostic Dilemma

Samir C. Gautam,[1] Padam Hirachan,[1] Sahitya Bhandari,[2] Binu Pannachan,[1] Orlando A. Ricalde.[3] *[1]Mississippi Nephrologists LLC, NATCHEZ, MS; [2]Natchez Clinic Company, NATCHEZ, MS; [3]Merit Health Natchez, Natchez, MS.*

Introduction: Patient undergoing dialysis in ESRD have multiple cardio-cerebrovascular complications and it is very difficult to tease out those complications as some which are yet to be defined. We present a unique case where a patient has frequent syncopal episodes without major identifiable cause.

Case Description: This is a 60 year old African American female with history of DM2, HTN, CVA and ESRD on IHD for 4 years. Her EDW is 68.5 kg and most of the times she is without significant Intradialytic weight gain. Over last 6 months, she has been having recurrent passing out episodes during dialysis, without any clinical and biochemical evidence of fluid or electrolyte shifts or infections. At various stages of her single dialysis treatment, she slowly goes into drowsiness and then goes into an unresponsive episode. In spite of EDW adjustment and the minimal UF rate she persistently has been having these episodes. Following this, she underwent extensive cardiovascular and cerebrovascular work-up, which were unremarkable. Her echocardiogram showed EF was 40-50%, normal stress test. CT of the brain and carotid anatomy were unremarkable. Her MRI and MRA of the brain were remarkable for old minor strokes. She then underwent EEG which was also unremarkable. Lastly, she underwent video EEG during dialysis, at which point it showed diffuse slowing of electrical activity which wasn't present when she wasn't on dialysis.

Discussion: ESRD patients are at risk for sleep disorders as insomnia, restless leg syndrome, sleep-disordered breathing and excessive daytime sleepiness. Abnormal EEG changes have been shown in patients with chronic uremia and dialysis disequilibrium syndrome only. We present a case who has been on a IHD with intradialytic altered mental status for 6 months, depicting intradialytic EEG changes. The video EEG showed diffuse slowing of electrical activity (as shown in the Images) without any definitive diagnosis.



PUB208

Rituximab Therapy After ESRD in Lupus Patients Is Used for Thrombocytopenia

Vipawee S. Chat,[1] Jennifer L. Waller,[1] Rhonda E. Colombo,[1] Stephanie L. Baer,[2] Erin vanessa S. Spearman,[1] Lufei Young,[1] Mufaddal Kheda,[1] Leighton R. James,[1] N. Stanley Nahman.[1,2] *[1]Augusta University, Augusta, GA; [2]Augusta VA Medical Center, Augusta, GA.*

Background: Lupus nephritis (LN) is a serious complication of SLE that may lead to dialysis. Rituximab (RTX) is used in refractory LN prior to dialysis, and in acute cases, used after starting dialysis in an attempt to induce remission. In a pilot study, we queried the USRDS for patients with ESRD from lupus and found 68 who received RTX, however the mean time of administration of the drug was > than 1 year after starting dialysis, suggesting indications other than LN. To assess indications for RTX therapy in lupus patients with ESRD we re-queried the dataset for diagnostic indications for using the drug in this setting.

Methods: Incident dialysis cases in the USRDS from 2006-2010 were queried for ESRD from SLE using the code 7100 from CMS Form-2728. The indications for RTX in ESRD lupus patients were assessed using ICD-9 diagnosis coding found in the hospital, detailed, and physician-supplier claims files.

Results: There were 3,307 ESRD patients identified with ESRD secondary to SLE with a mean±SD age of 41±15 years, 82% female, 53% black and 40% white. RTX infusion was documented in 68 (2.1%) patients. RTX(+) patients were younger (37±15yrs) but otherwise did not differ from the SLE group. 36 patients had a diagnosis associated with the RTX infusion, including lupus (41.7%); thrombocytopenia (28%); cancer (17%); rheumatoid arthritis (8.3%); and miscellaneous causes (14%). The data shows that in these ESRD patients, RTX is given most commonly for unspecified lupus indications and thrombocytopenia (TCP). The lack of specific indications for RTX infusion in 32 of the 68 patients is unclear, however, in the 36 patients with a clear diagnosis, the administration of RTX for TCP was evident, and suggests that clinicians are encountering and treating autoimmune TCP in lupus patients on dialysis.

Conclusions: These data indicate that among patients with ESRD from lupus who were treated with RTX, ongoing SLE activity is the most common indication. The second most common indication was TCP, presumably of an autoimmune nature. We would speculate that extra-renal immune activity may remain high in some SLE patients on dialysis, in particular presenting as TCP. The high rate of TCP in dialysis patients in general, and perhaps SLE patients in particular, suggests consideration of active lupus as a cause.

PUB209

Dieulafoy's Ulcer on Hemodialysis Therapy: A Report of Two Cases

Hiroyuki Deguchi. *Saiseikai-Sendai Hospital, Satsumasendai-City, Kagoshima Pref., Japan.*

Introduction: Dieulafoy's ulcer accounts for approximately 5% of all gastrointestinal hemorrhages. These ulcers are characterized by a ruptured artery that runs in the submucosal layer, and may be attributed to various abnormalities including dilation, micro-aneurysm, angiodysplasia and so on. Prior studies have established chronic kidney disease (CKD) as a risk factor for gastrointestinal hemorrhage, as angiodysplastic lesions are often seen in patients with CKD. Here we present a report of two cases of Dieulafoy's ulcer in the stomach and rectal colon.

Case Description: Case 1: A 76-year-old man with a past medical history of longstanding diabetic nephropathy presented to our hospital's Accident and Emergency department and underwent emergency hemodialysis. The patient suffered a bout of hemoptysis on post admission day 7, requiring emergency esophagogastroduodenoscopy (EGD). Endoscopic findings showed an ulcer on the lesser curvature of the stomach with pulsatile bleeding. The bleeding was successfully stopped via gripping with a hemostat. A second EGD done the following day showed no residual active bleeding. Case 2: A 69-year-old woman with end stage renal disease on hemodialysis therapy since 2008 presented to our hospital with sepsis. Antibiotics were started And on post admission day 7, bloody bowel discharge was observed twice, along with low blood pressure and anemia. An urgent colonoscopy examination performed showed an ulcer in the rectal Rs region with pulsatile bleeding. We cauterized the ulcer with forceps to confirm hemostasis. A second colonoscopy examination done the following day showed no active residual bleeding.

Discussion: Dieulafoy's ulcer is an important cause of gastrointestinal bleeding and is often diagnosed late. It has a tendency to cause severe, life-threatening, recurrent gastrointestinal bleeding but is amenable to life-saving endoscopic therapy. In addition, hemodialysis has been associated with gastrointestinal hemorrhage due to the use of heparin with hemodialysis therapy and uremia-induced platelet dysfunction. Fortunately, we were able to stop the bleeding in both cases. However, it is not always be easy to achieve hemostasis in bleeding ulcers and may even be fatal especially in patients on dialysis therapy. As such, gastrointestinal bleeding such as Dieulafoy's ulcer in dialysis patients is associated with a higher risk of mortality.

PUB210

Regional Differences in the Epidemiology of Incident ESRD in Arkansas: Developing an Understanding of Disparities

Nadia M. Alqurini,[1] Monica Kothari,[1] Andrea K. Easom,[1] Nishank Jain,[2,1] Manisha Singh.[1] *[1]University of Arkansas for Medical Sciences, Little Rock, AR; [2]Little Rock VA Hospital, Little Rock, AR.*

Background: End-stage renal disease (ESRD) Network 13 that includes Arkansas, Louisiana and Oklahoma has the third highest adjusted incidence rate of ESRD in the nation. Furthermore, epidemiology of ESRD and pre-ESRD nephrology care for the state is unclear.

Methods: Using ESRD Network 13 data for incident ESRD cases from January through December 2016, we describe regional differences in the epidemiology and pre-ESRD nephrology care within the five regions of Arkansas [central, northwest, northeast, southwest and southeast].

Results: For the year 2016, 0.9% (n=1,212) of the total U.S. incident ESRD patients were Arkansans. 14% of them were <45 years of age, 21% ≥75 and 47% female-proportions similar to the national demographics. Patients ≥85 years comprised around 5% of the total incident cases in the central (metropolitan) and the southeast (rural) regions of Arkansas compared to <1% in the other regions. 33% of incident cases were African Americans compared to 26% in the U.S. There was no difference in the proportion of Arkansans choosing hemodialysis compared to the U.S. (89% vs. 88%). 87% of them started hemodialysis using a central venous catheter at the first ESRD service date- with the highest rate (93%) in the southeast region (the most rural region of the state). Within the regions, no one started peritoneal dialysis in the southwest region of Arkansas. Pre-ESRD nephrologist and renal-dietician care was received by 56% (n=605) and 4.8% (n=52) Arkansans compared to the national average of 64% (n=76,052) and 7.8% (n=9,274), respectively.

Conclusions: Using the Renal Network-13 data rather than the USRDS annual data report, we were able to gather data for Arkansas that are more recent and region-specific. We observed that a higher proportion of African American and Arkansans ≥85 years started dialysis. Dismal access to- and dramatic regional differences in pre-ESRD care may be contributing to the disproportionate burden of incident ESRD patients in Arkansas. These data can be basis for region-specific efforts to improve nephrology care that is urgently needed in order to develop a CKD action plan for the state of Arkansas.

PUB211

Risks of Cardiovascular Death(CVD) in Maintenance Hemodialysis Patients with Diabetic Nephropathy

Hajime Hirano, Haruhito Azuma. *Osaka medical college, Takatuki City, Japan.*

Background: Prevention of the development of CVD, which is the major cause of death, is key to improving prognosis. We had investigated factors associated with CVD mortality risk in maintenance dialysis patients. In this study, an additional analysis was performed on data in hemodialysis patients with diabetic nephropathy compared with those having other underlying diseases. And furthermore, we investigated factors that influence CVD mortality risk in hemodialysis patients with diabetic nephropathy.

Methods: This retrospective study was conducted with 201 outpatients with hemodialysis at our Blood Purification Therapy Center and our other related hemodialysis facilities (57 diabetic nephropathy and 144 others). Logistic regression analysis was conducted with outcome- measured as CVD death. Hemoglobin levels and blood pressure values before and after dialysis were summed up at 3, 6, and 12 months (Σ). A curve was obtained by changes in blood pressure per month and the area under the blood pressure curve (AUC) was calculated.

Results: Diabetic nephropathy was the highest mortality risk among underlying disease groups. A comparison with other underlying diseases revealed that significant differences were found for the variables older age (p<0.001) and a shorter history of hemodialysis (p<0.001) in patients with diabetic nephropathy. There was no significant difference in anemia control between two groups. Poor blood pressure control and higher dose of erythropoietin were found in patients with diabetic nephropathy. The multivariate analysis of risk factors for mortality in patients with diabetic nephropathy showed that smoking (odds ratio(OR): 4.71 [95%CI: 1.97~11.26, p<0.001], history of ischemic heart disease (OR: 2.56 [95%CI: 0.95~6.85, p=0.061], age (OR: 1.07 [95%CI: 1.03~1.13, p=0.002], and a history of dialysis therapy (OR: 0.78 [95%CI: 0.69~0.87, p<0.001] were risk factors.

Conclusions: Introduction to hemodialysis for patients with diabetic nephropathy, given higher CVD mortality risk, it is important to actively prevent the development of CVD shortly after hemodialysis. Furthermore, higher smoking rates with higher CVD mortality risk associated with smoking among patients with diabetic nephropathy suggested that smoking cessation is important for patients with diabetic nephropathy to improve their prognosis.

PUB212

Relationship Between Malnutrition and Hypervolemia in Peritoneal Dialysis and Hemodialysis

Guilherme P. Santa Catharina, Erica A. Guimarães, Lilian Cordeiro, Benedito J. Pereira, Hugo Abensur, Rosilene M. Elias, Bruno C. Silva. *University of São Paulo, São Paulo, Brazil.*

Background: Malnutrition and volume overload increase morbidity and mortality rates in patients on peritoneal dialysis (PD) and hemodialysis (HD). Bioelectrical impedance analysis (BIA) can assess both nutritional and tissue hydration status in these patients.

Methods: BIA was performed prior to dialysis in a cross-sectional, unicentric study that included 71 patients on PD and 109 on HD. Data provided from BIA were: extracellular water/total body water ratio (ECW/TBW), fat free mass (FFM), fat percentage (FP) and phase angle (PA), which is an objective measure of nutritional status.

Results: Median PA was 4.5° (4.0; 5.2) and 5.8° (4.4; 6.8) in PD and HD respectively, p=0.0001. Median ECW/TBW was 0.403 (0.39; 0.41) and 0.39 (0.38; 0.4) in PD and HD respectively, p=0.0001. A negative correlation between ECW/TBW and PA was found in HD (r=-0.680, p=<0.0001) and PD (r=-0.665, p<0.001), with a statistically different slope of the curves (p<0.001). FFM and FP were similar between groups.

Conclusions: Patients on HD presented better nutritional status and lower volume overload in comparison to PD. Patients with poor nutrition status (lower PA) presented higher volume overload (higher ECW/TBW) in both HD and PD groups. The correlation is greater in HD patients.

Patients characteristics

	PD (n=71)	HD (n=109)	p
Gender (% male)	46	50	0.65
Age (years)	54 (38;65)	49 (32;60.5)	0.09
Weight (Kg)	60.9 (55.8;69)	65.4 (56.4;77.4)	0.04
BMI (Kg/m2)	23.7 (21;26.4)	24.8 (21.7;28.3)	0.05
ECW/TBW	0.403 (0.39;0.41)	0.390 (0.38;0.4)	0.00
FFM (Kg)	47.1 ± 10.8	49.3 ± 11.6	0.21
Fat (%)	24.2 ± 12.1	25.7 ± 11.9	0.42

PUB213

Characterization of N-Terminal Pro B-Type Natriuretic Peptide and its Predictive Value for Longer-Term (7-Year) Survival in Maintenance Dialysis Patients

Yuji Sato,[1] Akihiro Minakawa,[2] Tatsunori Toida,[2] Ryuzoh Nishizono,[3] Masao Kikuchi,[2] Shouichi Fujimoto.[3] *[1]University of Miyazaki Hospital, Miyazaki, Japan; [2]University of Miyazaki, Kiyotake, Japan; [3]University of Miyazaki, Miyazakishi, Japan.*

Background: In a non-end-stage kidney disease (ESKD) population, NT-proBNP levels are significantly higher in women, the elderly, and those with lighter body weight; however, these characteristics have not been clarified in dialysis patients. In addition, NT-proBNP levels are predictive of 2-year survival in dialysis patients (Kawagoe C et al. Renal Failure 2018).

Methods: Differences in NT-proBNP levels were determined according to sex, age, and dry weight. The association between baseline NT-proBNP levels and mortality (total deaths, non-malignancy-related deaths, and malignancy-related deaths) was analyzed.

Results: A total of 875 dialysis patients (43.1% women, mean age 67.8 years old, median dialysis vintage 77 months) without atrial fibrillation were followed for up to 7 years. Baseline mean (SD) of log NT-proBNP; men vs. women was 3.67 (0.51) vs. 3.74 (0.51) pg/mL, p=0.04. Therefore, the findings showed borderline significance according to sex. A sex difference was not observed in younger patients (29-69 years old), but was prominent in elderly patients. As in those without ESKD, NT-proBNP levels increased with age, and the relationship between NT-proBNP and dry weight showed a significant negative correlation. During 7 years of follow-up, 34.1% died (30.6% due to non-malignancy-related death; 3.4% due to malignancy-related death). The Kaplan-Meier survival estimate showed a clear survival difference for total and non-malignancy-related deaths between quartiles of log NT-proBNP, but not for non-malignancy-related deaths. In univariable and multivariable analysis, the log NT-proBNP was strongly associated with total and non-malignancy-related deaths. This association was also observed when patients were divided according to sex, quartile of age, and quartile of log NT-proBNP, but was not seen in association with dry weight quartiles in women (Q2 and Q3).

Conclusions: In dialysis patients, NT-proBNP levels showed differences according to sex (men<women), however, this difference was not observed in younger patients. NT-proBNP levels are strongly associated with longer-term survival. However, NT-proBNP levels might have different significance in midsize women. Additional study is needed to clarify these findings in dialysis patients.

PUB214

Restless Legs Syndrome Effectively Treated with Constant-Pressure Predilution On-line Hemodiafiltration, A Case Report

Shunichiro Urabe,[1] Motoko Kato,[1] Emi Hiyama,[1] Asami Kurii,[1] Toru Hyodo,[2] Makoto Kitamura,[3] Miho Hida,[3] Yasuhisa Kurata,[3] Kenichi Kokubo.[4] *[1]Eijin Clinic, Hiratsuka, Japan; [2]Eijin Clinic and Cambodian Association of Nephrology, Hiratsuka, Japan; [3]Kurata Hospital, Hiratsuka, Japan; [4]Kitasato University School of Allied Health Sciences, Sagamihara, Japan.*

Introduction: We encountered a case of unstable predilution on-line HDF due to elevated transmembrane pressure (TMP) when performing constant-speed predilution on-line hemodiafiltration (HDF) as treatment for restless legs syndrome (RLS) in a dialysis patient, necessitating frequent adjustments of console settings such as the amount of dialysate and TMP. Here, we report the effectiveness of incorporating a newly developed constant-pressure predilution on-line HDF system as a preventive measure against unstable on-line HDF and frequent adjustment of settings when treating dialysis patients with RLS.

Case Description: A 55-year-old man who had suffered from RLS and been undergoing constant-speed on-line HDF with 45-L target predilution and an ABH-21P hemodiafilter. The symptoms of RLS rated 10 on the International Restless Legs Syndrome Rating Scale (IRLS). The α_1-microglobulin (α_1-MG) removal rate was only 27.8%, so the hemodiafilter was subsequently replaced with a PEPA hemodiafilter. However, episodes of elevated TMP exceeding 250 mmHg occurred after the replacement and were managed by reducing dialysate flow rate. This resulted in the replacement of 40.7±4.50 L, with removal of 30.4% of α_1-MG. The total amount of albumin (Alb) leakage in dialysate waste was 5.3 g. Therefore, we incorporated a newly developed fully automated console GC-110N (JMS Ltd, Japan) with a built-in automated dialysate infusion system to establish a constant-pressure predilution on-line HDF that maintains TMP below 200 mmHg. The amount of replacement was maintained at approximately 43.5±6.98 L and the α_1-MG removal rate was 39.5%, with no need to manually reduce the flow rate. The Alb leakage in dialysate waste was 7.9 g. The patient has maintained an IRLS rating of 0 with no RLS symptoms for the past 4 years.

Discussion: Using the constant-pressure mode enabled achieved the clinical endpoint, namely, resolution of RLS with no need to manually reduce the flow rate. The GC-110N console enables predilution on-line HDF at constant pressure or speed and also has a postdilution mode. Further study is needed to investigate the appropriate use of each mode, but the availability of this console is beneficial for dialysis patients by offering more treatment options.

PUB215

Demographic and Clinical Characteristics Are Associated with Physical Function Among Patients Receiving In-Center Hemodialysis

Kirsten L. Johansen,[1] Lorien S. Dalrymple,[2] Norma J. Ofsthun,[2] Barbara A. Grimes,[1] Dugan Maddux,[2] Franklin W. Maddux.[2] *[1]University of California, San Franicsco, San Francisco, CA; [2]Fresenius Medical Care North America, Waltham, MA.*

Background: Poor physical functioning is a pervasive disturbance among patients receiving maintenance hemodialysis, ranked by patients as of high importance and associated with higher mortality. However, few studies have examined demographic and clinical characteristics associated with physical functioning and change over time.

Methods: We collected longitudinal data from the Kidney Disease Quality of Life (KDQOL) survey administered as part of clinical care to 243,792 patients receiving in-center HD between Jan. 1, 2010 and Dec. 31, 2016. We used multivariable linear mixed modeling to examine changes in the Physical Component Summary (PCS) score over time and associations between patients' demographic and clinical characteristics and PCS.

Results: Median age was 62 years, dialysis vintage 2 years; 57% were men, 48% white, 31% black, and 14% Hispanic. PCS declined by 0.16 points per year (95% CI 0.11,0.20). Older, female, and white patients had lower PCS, as did those with comorbid conditions and at both extremes of BMI (Figures). Low hemoglobin and catheter use were also associated with lower PCS.

Conclusions: Potentially modifiable factors, such as low hemoglobin, catheter use, and high BMI, were associated with lower physical functioning.

Efficient Removal of Large Solutes by Pre-Dilution On-line Hemodiafiltration Improves the Quality of Life of Dialysis Patients

Kenji Sakurai,[1] Takeshi Saito,[1] Hiromi Hosoya,[1] Yoshitaka Kurihara,[1] Yasuhisa Wakabayashi,[1] Daisuke Ishii,[2] Akihiro C. Yamashita.[3] *[1]Hashimoto Clinic, Sagamihara, Japan; [2]Kitasato University Hospital, Sagamihara Kanagawa, Japan; [3]Hosei University, Tokyo, Japan.*

Background: Efficient removal of middle and large solutes is crucial for treating complications in dialysis patients. Here, we switched HD to pre-dilution on-line HDF (preHDF) in stable dialysis patients and observed changes in their health-related quality of life (QOL) for 6 months to assess the clinical effects of preHDF. Although the Medical Outcomes Study 36-Item Short-Form Health Survey is internationally used to assess health-related QOL, we used its shortened version SF-8.

Methods: We included 19 patients on maintenance HD (M/F, 13/6; age, 52.7±11.8 yrs), all of whom switched from HD to preHDF. HD was performed with a super high-flux dialyzer (blood flow rate [Qb], 253.2±24.5 mL/min; dialysate flow rate [Qd], 500 mL/min). After switching, preHDF was performed with a high-spec hemodiafilter (Qb, 260.0±20 mL/min; total Qd, 600 mL/min; Vs, 45.5 L/session). Both HD and preHDF were performed for 4 h/session, 3 times/wk. The removal efficiency was assessed in terms of Kt/V for urea, reduction rates of b_2-microglobulin (MG, 11.8 kDa) and a_1-MG (33 kDa). Changes in QOL were assessed with SF-8.

Results: Kt/V was 1.53±0.23 for HD, showing no significant change during the observation period. Compared with the b_2-MG reduction rate for HD, the rates were significantly higher at the time of switching to preHDF (74.0±4.4→81.7±3.0%) and 1, 3, and 6 months later. Compared with the a_1-MG reduction rate for HD, the rates were significantly higher at the time of switching to HDF (31.8±7.6→39.2±7.2%) and 1 and 6 months later. The SF-8 scores on all subscales increased after switching to preHDF. The Physical Component Summary (PCS) and Mental Component Summary (MCS) scores (calculated from 8 subscale scores) increased after switching to preHDF. The MCS scores were significantly higher for preHDF than HD. Moreover, the patients presented markedly fewer unidentified complaints and appeared more active.

Conclusions: After switching to highly efficient preHDF, b_2-MG and a_1-MG reduction rates significantly increased, despite no changes in Kt/V. The SF-8 scores on each subscale and PCS and MCS scores also increased. These results indicate that enhanced removal of solutes in the LMWP range is beneficial for the internal environment of patients, consequently, their health-related QOL is improved.

PUB217

Trend of Serum Albumin Among the Japanese Dialysis Population

Norio Hanafusa, Ken Tsuchiya, Kosaku Nitta. *Tokyo Women's Medical University, Shinjuku-ku, Japan.*

Background: Serum albumin (Alb) is one marker of protein-energy wasting (PEW) related to poor survival. Hypoalbuminemia is associated with both inflammation and malnutrition. Therefore, maintaining appropriate Alb levels requires appropriate protein intake and management against inflammation. This study investigated the trend of serum Alb, C-reactive protein (CRP), and normalized protein catabolic rate (nPCR) among the Japanese dialysis population.

Methods: We used summary table data of the Japanese Society for Dialysis Therapy (JSDT) Renal Data Registry for 2001–2015. Numbers of patients and averages and standard deviations of the values were provided by age groups with width of 15 years. We investigated the trend of mean values of Alb, CRP, and nPCR for patients of 45 years or older using Joinpoint analysis. The proportions of the patients with low Alb, low nPCR, and high CRP were also investigated with different cut-off values. For each analysis, numbers of joinpoints and the annual percent change (APC) were evaluated.

Results: APCs of mean Alb values were negative during the entire period (Figure). However, APCs of mean nPCR values were negative, whereas those of CRP values were not significant. These results indicate that Alb and nPCR values have been declining, although CRP values were stable. The proportions of patients with hypoalbuminemia, low nPCR, and high CRP exhibited similar trends. All age groups showed similar trends.

Conclusions: Serum Alb in Japanese dialysis population seems to be decreasing overall, which might have some association with the decline in protein intake rather than the increase in inflammation, irrespective of the patient age. It might be necessary to increase the protein intake against PEW. Future studies might be required investigate the Alb trend with protein intake increased.

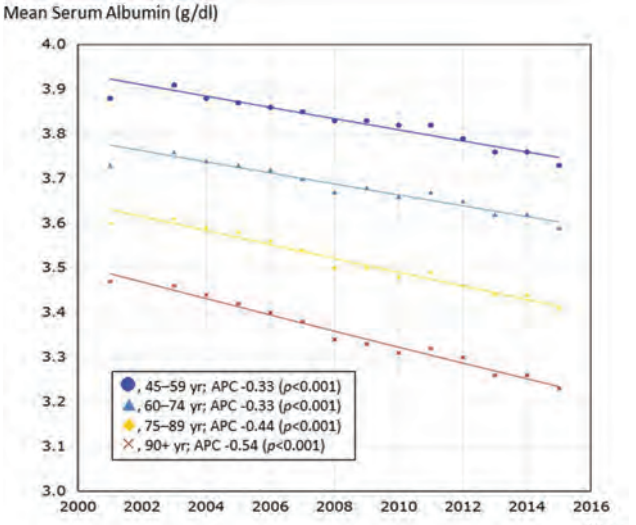

Figure. Trend of Mean Serum Albumin by Age Group
APC, annual percent change.

The First Cambodian Dialysis Registry: The Facts of ESRD Therapy in Cambodia

Pichthida Thim,[1] Toru Hyodo,[2] Sopheaktra Tan,[3] Sam-Oudum Kim,[1] Elin Phon,[1] Hy Chanseila,[4] Sokhom Pho,[1] Kamol Svay,[1] Sovandy Chan,[1] Lim Vadhana.[1]
[1]Cambodian Association of Nephrology, Phnom Penh, Cambodia; [2]Eijin Clinic and Cambodian Association of Nephrology, Hiratsuka, Japan; [3]Cambodian Association of Nephrology, Phnom Penh, Cambodia; [4]Cambodian association of nephrology, Phnom penh, Cambodia.

Background: The number of hemodialysis (HD) patients keeps increasing, yet statistical data is still inexplicit in Cambodia. CAN has started the dialysis registry since 2017.

Methods: This is a cross-sectional study which was conducted on patients (n=407) who received HD in August 2017, from 5 hemodialysis centers in Phnom Penh capital city, Cambodia. Retrospective data such as age, gender, demographic, underlying diseases, HD frequency per month, and each HD session duration are deliberately collected and analyzed using SPSS.

Results: New patients make up 9.3%. Number of female patients is slightly lower than male (42.8% and 57.2%, respectively). Mean age is 52 years old (±SD15). Adult age group (25-64 years old) accounts for the highest number of patients (73.5%). Hypertensions, coexistence of hypertension and diabetes mellitus and kidney diseases are the common underlying diseases (46.7%, 31%, 13.9% accordingly). However, diabetes mellitus alone is responsible for 8.1%. The mean of HD frequency per month is 7.5 times (±SD2.3). HD session is 4-hour long.

Conclusions: The present condition of hemodialysis in Cambodia is gradually progressing forward, but it is still insufficient. Poor adherence to HD treatment needs to be tackled. Primary and secondary preventions of hypertension and diabetes mellitus are crucial.

PUB219

Risk Factors for Infectious Diseases in Patients with End-Stage Kidney Disease Undergoing Hemodialysis

Masataka Banshodani,[1] Hideki Kawanishi,[1] Misaki Moriishi,[1,3] Naoko Takahashi,[2] Sadanori Shintaku,[1] Shinichiro Tsuchiya.[1] *[1]Tsuchiya General Hospital, Hiroshima, Japan; [2]Omachi Tsuchiya Clinic, Hiroshima, Japan; [3]Nakajima Tsuchiya Clinic, Hiroshima, Japan.*

Background: In the recent years, increased hospitalization rate for infectious diseases in patients undergoing hemodialysis (HD) has become a problem. Herein, we examined the risk factors of infectious diseases in patients undergoing HD.

Methods: Based on the Carlson comorbidity index (CCI), age, sex, primary cause of end-stage kidney disease (ESKD), dialysis vintage, body mass index (BMI), serum calcium, phosphorus, magnesium, albumin, hemoglobin, alkaline phosphatase (ALP), and parathyroid hormone values in patients with ESKD who underwent HD three times a week at three dialysis centers in 2009, risk factors for emergency hospitalization due to infectious diseases from January 2010 to December 2014 were evaluated.

Results: Among the 708 patients undergoing HD, 142 had emergency hospitalizations for infectious disease (ID group: 90 men [63%]; mean age, 67.6 years; mean dialysis vintage, 8.5 years) during the study period, whereas 566 did not have emergency hospitalizations for infectious disease (control group: 340 men [60%]; mean age, 66.0 years; mean dialysis vintage, 8.4 years). The proportion of nephrosclerosis (as primary cause of ESKD) (7.7%, P=0.01) and ALP levels (298 U/I, P=0.03) were significantly higher and BMI (21.2 kg/m^2, P = 0.046) was significantly lower in the ID group than those in the control group (3.2%; 267 U/I; 21.8 kg/m^2). Moreover, CCI (5.01) was higher in the ID group than that in the control group (4.75), but the difference was not significant (P = 0.1). In the Cox proportional hazard model, CCI (hazard ratio [HR], 1.095; 95% confidence interval [CI], 1.001-1.193), nephrosclerosis (HR, 1.539; CI, 1.085-2.076), and ALP levels (HR, 1.002; CI, 1.001-1.003) were significant predictors of emergency hospitalization for infectious diseases.

Conclusions: This study evaluated the risk factors of emergency hospitalization for infectious diseases in patients undergoing HD; however, further investigation is required.

PUB220

Measurement of Body Composition in Hemodialysis Patients During One-Year Frequent Dialysis

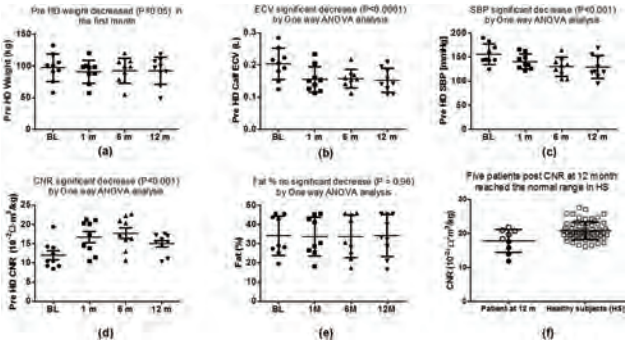
Fansan Zhu,[1] George A. Kaysen,[1,3] Shubho R. Sarkar,[4] Fredric O. Finkelstein,[5] Nathan W. Levin,[1,2] Nicholas A. Hoenich.[1,6] *[1]Renal Research Institute, New York, NY; [2]Mount Sinai School of medicine, New York, NY; [3]University of California, Davis, Davis, CA; [4]Kidney Care of Morris County, Basking Ridge, NJ; [5]Yale University, New Haven, CT; [6]Institute for Cellular Medicine, Newcastle University, Newcastle, United Kingdom.*

Background: The primary aim of this study was to evaluate the effect of increased frequency of dialysis (FHD) on changes in extracellular volume (ECV), systolic blood pressure (SBP), calf normalized resistivity (CNR) and fat percentage. Since ECV is not a useful target for denoting dry weight, we explored CNR as an alternative measure.

Methods: In 12 stable HD patient's treatment frequency was changed from 3times/week to 6 times/week HD (FHD). SBP, body weight and body mass index (BMI) were measured pre and post HD. Calf resistance at 5 kHz (R_5) was measured using a bioimpedance device (Hydra 4200). The data collected was used to calculate calf resistivity (Rho=R_5*area/length), normalized resistivity (CNR=Rho/BMI) and calf extracellular volume (cECV). Body fat percentage (Fat%) was measured by Futrex body composition analyzers (Futrex 6100, Futrex Tech, Inc.). All measurements were performed at baseline (BL) and thereafter monthly for up to one year.

Results: Nine patients completed one year of FHD. Data were presented at BL, and at first, six and twelve months. Compared to BL, body weight, cECV and SBP decreased significantly (Fig.1 a, b and c). CNR increased significantly by the first month but did not change thereafter (Fig. 1 d). Fat % did not change significantly (Fig.1 e). Antihypertensive drug dosing decreased significantly from baseline by month six and remained stable thereafter. The post HD CNR in five of nine patients reached the range of normal (>18.5 10^{-2}*Ohm*m^3/kg for males and >19.1 10^{-2} *Ohm*m^3/kg for females) after one year FHD (Fig.1 f).

Conclusions: Increasing the frequency of dialytic treatment, results in a reduction in ECV and increase in CNR, accompanied by a reduction in SPB. As a consequence, anti hypertensive medication was reduced. Body composition did not change except reduction of fluid status. Based on this small study which needs to be confirmed in a larger group of patients, increase in CNR was associated with decrease in fluid status which provides a goal for HD treatment.



PUB221

Conscious Survey of Japanese Physicians and Actual Trends in Proton Pump Inhibitor Prescription for Hemodialysis Patients

Hiroo Kawarazaki,[1] Akio Nakashima,[4] Masahide Furusho,[3] Takeshi Nakata.[2] *[1]Department of Nephrology, Inagi Municipal Hospital, Inagi, Japan; [2]Department of Endocrinology Metabolism, Rheumatology and Nephrology, Oita University, Oita, Japan; [3]Department of Nephrology, Iizuka Hospital, Iizuka, Japan; [4]Department of Nephrology and Hypertension, Jikei University School of Medicine, Tokyo, Japan.*

Background: Proton pump inhibitors (PPIs) are widely prescribed but less is known about prescription in hemodialysis (HD) patients. We conducted 1) a conscious survey directed to Japanese physicians about PPI prescription to HD patients and 2) gathered clinical data on all HD patients from 3 clinics to elucidate factors related to PPI prescription.

Methods: 1) A conscious survey was conducted through email to physicians dedicated to HD practice. In addition, 2) patient characteristics and blood test data were retrieved from every HD patient in 3 in-center clinics who have been on HD for more than a year.

Results: 1) 200 physicians replied the survey and 60% would continue PPIs after 8 weeks prescription for gastric ulcer (GU) or gastroesophageal reflux disease (GERD) concerning relapse. The major reason for stopping PPIs was concern of adverse effects such as chronic diarrhea. 58% woulld choose to keep prescribing patients already on PPIs with unclear indications. 86% considered HD patients to be a high risk group for peptic ulcers (PUs). 2) Data from 374 HD patients were retrieved. Average age was 72 years, 63% male, and average HD vintage was 5.5 years. The cohort consisted of 41% diabetic kidney disease, 22% cardiovascular disease (CVD), 16% peripheral artery disease (PAD), 19% cerebral artery disease (CAD), 49% took anti-platelets, and 66% took PPIs. Those prescribed PPIs had higher ratio of CVDs (28% vs 12%), PADs (21% vs 5%), CADs (24% vs 5%), and anti-platelets (56% vs 37%). Further, though Hb were similar (11.2mg/dl), those on PPIs had higher ratio of iron prescribed (76% vs 71%), lower TSAT (26% vs 27%), and lower serum ferritin (78ng/ml vs 96ng/ml).

Conclusions: Japanese physicians frequently prescribed PPIs to HD patients and regarded them as a high risk group for PUs. More than half of the physicians would choose to keep HD patients on PPIs prescribed for unclear indications. Those with artherosclerotic diseases and anti-platelet medication had higher predisposition on PPIs.

PUB222

The Current Prevalence and Prognosis of Frailty in Japanese Patients with Hemodialysis

Hidemi Takeuchi,[1,2] Haruhito A. Uchida,[1] Nozomu Otaka,[1] Yuki Kakio,[1] Yuka Okuyama,[1] Ryoko Umebayashi,[1] Hitoshi Sugiyama,[1] Hidetoshi Kanai,[2] Jun Wada.[1] *[1]Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan; [2]Kokura Memorial Hospital, Kitakyushu, Japan.*

Background: The problematic expression of patients with hemodialysis is the frailty. Patients with hemodialysis easily fall into frailty due to the potential pathophysiological factors, such as physical deconditioning, chronic inflammation, and decreased anabolic hormones. Frailty is associated with severe mortality in several countries. However, the prevalence and prognosis of the frailty in Japanese patients with hemodialysis remain unknown. The purpose of this study is to identify the current status of Japanese hemodialysis patients with frailty.

Methods: This study is a multicenter investigation, which was conducted at 6 institutions. The subjects were all hemodialysis patients. To evaluate the frailty status, we used the modified Fried's frailty phenotype model, adjusted for the Japanese. In addition, we prospectively investigated the patients' survival, hospitalization and developed complications.

Results: Of the 542 patients, 385 patients including 82 patients with frailty (21.3 %), 203 with pre-frailty (52.7 %) and 100 without frailty (26.0 %), were enrolled in this study. At baseline, participants were 67.2 ± 11.9 years of age with more male gender (62.4 %) than female. With an average follow-up period of 17.1 months, a total of 41 patients died; 13.4% of patients with frailty, 11.8% with pre-frailty and 6.0% without frailty. The mean survival time of patients with frailty, pre-frailty and without frailty were 16.7, 17.1 and 17.6 months, respectively (Log-Rank P-value = 0.197). The mean hospitalization-free period of patients with frailty, pre-frailty and without frailty were 14.2, 16.0 and 16.7 months, respectively (Log-Rank P-value < 0.001), furthermore, significant differences were found among all groups in the post-hoc analysis. Similarly, significant differences were found in the analysis of the developed complications (Log-Rank P-value = 0.006).

Conclusions: The prevalence of frailty in Japanese patients with hemodialysis was relatively lower, and the frailty had less influence on the mortality, compared with the other countries. However, the frailty has the influence on healthy life expectancy, that is, higher rate of the hospitalization and complications were observed as the frailty status goes severe.

PUB223

A Simple Score to Identify the Potential Need for Intensive Hemodialysis Within a Facility

Allan J. Collins,[1,2] Debabrata Ray,[1] Kristine Kubisiak,[1] Eric D. Weinhandl.[1,2] *[1]NxStage Medical, Inc., Victoria, MN; [2]University of Minnesota, Minneapolis, MN.*

Background: Wider application of intensive hemodialysis (HD) requires reorganization of staff and patient scheduling and/or greater utilization of home HD. Tools that identify dialysis facilities with greater need for intensive HD may be useful. In a pilot study, we constructed a simple score that identifies potential need for intensive HD in a facility, insofar as need is reflected by plausible indications.

Methods: We used data from Dialysis Facility Compare, CROWNWeb, and Medicare claims to characterize facilities in a dialysis provider organization. For each facility, we calculated 3 metrics from data accumulated in 2013-2014: (1) the percentage of HD patient-months with ultrafiltration rate (UFR) >10 mL/hour/kg; (2) the percentage of HD patient-months with serum phosphorus >5.5 mg/dL; and (3) the heart failure (HF) hospitalization rate among HD patients with Medicare as primary payer. For each metric, we estimated deciles among facilities and transformed the metric to a scale from 1 (lowest decile) to 10 (highest decile). For each facility, we set the "need score" equal to the sum of metric scores.

Results: We identified 1546 facilities. Mean percentages of HD patients-months with UFR >10 mL/hour/kg and serum phosphorus >5.5 mg/dL were 32.6% and 35.5%, respectively, and the mean HF hospitalization rate was 15.6 admissions per 100 patient-years (PY). As displayed, the distribution of the need score was symmetric. There were 143 (10.8%) facilities with a score ≥24 points; these facilities had higher prevalence of high UFR, higher prevalence of hyperphosphatemia, and mean HF hospitalization rate of 24.7 admissions per 100 PY.

Conclusions: Facility scores that quantify plausible indications for intensive HD may be used to target therapy in local populations. Further study is needed to refine methodology, with consideration of hypertension and long post-dialysis recovery time.

Infective Endocarditis in Hemodialysis Population - Experience from Center in India

Amit Kumar,[1] Sunil Prakash,[2] Ashwini Goel.[3] *[1]BLK SuperSpeciality Hospital New Delhi, New Delhi, India; [2]Nephrology, BLK Super Speciality, New Delhi, India; [3]Nephrology, BLK Super Speciality Hospital, NEW DELHI, India.*

Background: Hemodialysis (HD) population is at increased risk for infective endocarditis (IE) due to impaired nutrition and vascular access, with its associated morbidity and mortality. Aim of present study is to present our data of patients with IE in HD population.

Methods: This was retrospective analysis from BLK Hospital, New Delhi, India. Data was collected from May 2015 to April 2018. All patient who underwent maintenance dialysis with a diagnosis of CKD were included. Patients diagnosed with Infective endocarditis based on clinical as well as echocardiographic (trans thoracic(TTE) or trans esophageal (TEE) criteria were identified. There demographic parameters, clinical presentation, and clinical outcome was recorded

Results: Out of 457 patients who underwent dialysis, 6 patient (1.31%, 4 male and 2 female) developed IE. Mean age was 41.3 years. 3 patients had temporary dialysis catheter, one had permacath and 2 had AVF as vascular access. Average duration on dialysis was 10.3 months. Duration of fever before diagnosis was 18.3 days (range 7 to 45 days). A pre-existing heart disease was present in 1/3rd of patients. Staph Auerus was identified in 2 and both were on dialysis catheter. Staph epidermiditis was identified in 1 patient and blood cultures were sterile in three. Only 1 patient was diagnosed with trans thoracic echocardiography while trans esophageal echocardiography was required in 5. Aortic valve was involved in 3, mitral valve in 2 and tricuspid valve was involved in one patient. One patient expired, one developed reactive arthritis as complication of IE. one developed red

man Syndrome and emboilc infarct to brain and one developed Steven Johnson Syndrome as drug related toxicity.

Conclusions: Infective endocarditis in not uncommon in Indian population and diagnosis is often delayed. Resulting in high morbidity and mortality. High Index of suspicion is required for early diagnosis. When suspected trans esophageal echocardiography should always be considered.

Clinical Feature of patients with Infective Endocarditis

Patient	Duration of fever (Days)	Organism isolated	Valve Affected	Duration of Treatment (Weeks)	Diagnosed with (TTE/TEE)	Complications	Outcome
1	12	Staph. Aureus	Aortic	4	TEE	Reactive Arthritis	Cured
2	14	Staph Aureus	Mitral	6	TEE	Stevens Johnson Syndrome	Cured
3	23	Sterile	Aortic	4	TEE	Red Man Syndrome, Embolic Infract	Cured
4	7	Staph. Epidermidis	Mitral	3	TTE	Expired	Expired
5	45	Sterile	Aortic	6	TEE	Nil	Cured
6	7	Sterile	Tricuspid	4	TEE	Nil	Cured

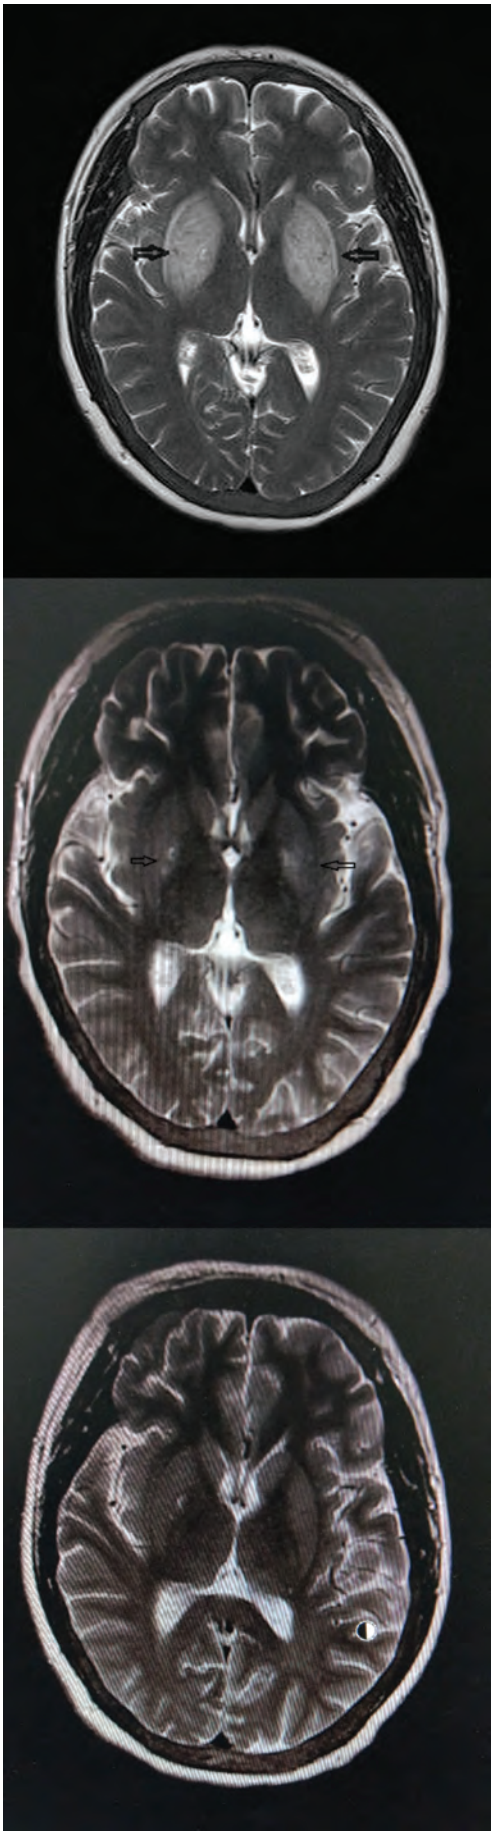
Syndrome of Uremic Encephalopathy and Bilateral Basal Ganglia Lesions in Non-Diabetic Hemodialysis Patient

Fanna Liu,[1] Wenyu Gong,[2] Lifan Mei.[3] *[1]The First Affiliated Hospital of Jinan Universtiy, Guangzhou, China; [2]The First Affiliated Hospital of JiNan University, Guangzhou, China; [3]Zhongshan Boai Hospital, Zhongshan, China.*

Introduction: Uremic encephalopathy (UE),the toxic metabolic encephalopathy, is an uncommon complication resulting from endogenous uremic toxins in patients with severe renal failure, and the syndrome of UE range from mild inattention to coma. The imaging findings of UE include cortical or subcortical involvement, basal ganglia involvement and white matter involvement. The basal ganglia type is uncommon, previous cases reported Asian patients with diabetes mellitus (DM) are usually affected by it

Case Description: A 32-year-old woman with history of non-diabetic hemodialysis for 3 years suffered from severe involuntary movement and Brain magnetic resonance image (MRI) showed symmetrical T2-weighted imaging (T2WI) and T2/fluid-attenuated inversion recovery (T2FLAIR) hyperintense nonhemorrhagic lesions in bilateral basal ganglia. She was diagnosed with UE as syndrome of bilateral basal ganglia lesions, due to a combined effect of uremic toxins and hyperthyroidism. After treatment with high frequency and high flux dialysis, hyperbaric oxygen therapy and declining parathyroid hormone, she was complete remission with normal body movement and discharged.

Discussion: UE is an unfamiliar toxic metabolic encephalopathy with typical CT/MR neuroimaging including bilateral vasogenic or cytotoxic edema at the cerebral cortex or basal ganglia region, producing a spectrum of brain abnormalities that range from mild inattention to coma. UE with basal ganglia involvement is uncommon and generally seen in Asian patients with DM. In our case, the patient had non-diabetic UE with typical bilateral basal ganglia lesions presented with involuntary movement. Recognizing this syndrome seems to be more and more important, especially considering its diagnostic and prognostic implications.



PUB226

Utilization of Sharesource Connect™ (SSC) Continuous Renal Replacement Therapy (CRRT) Data from Two Pediatric Centers: What Can We Learn?

Rita D. Sheth,[2] Lieuko Nguyen,[1] Peter D. Yorgin.[1] *[1]Rady Children's Hospital San Diego, San Diego, CA; [2]Loma Linda University, Loma Linda, CA.*

Background: Baxter SSC displays de-identified, downloadable, customizable CRRT data for each center, including filter life, dialysis dosing and fluid removal that facilitates center and inter-center data assessment relative to benchmark data from adult programs.

Methods: All de-identified data for SSC downloaded from Prismaflex machines at Loma Linda University Children's Hospital (LLUCH) + Rady Children's Hospital San Diego (RCHSD) from Jun - Dec 2017 was included for pooled and comparative analysis.

Results: 36 patients using 98 Prismaflex circuits (total 4823 treatment hrs) were included in the analysis. Mean delivered CRRT dose was 44 mL/kg/min despite mean circuit time loss of 14.5%. Mean hemofilter life: 43 hrs; 54.5% circuits reached desired end points of max filter life or treatment end. 10/98 filters were lost due to clotting. Inter-institutional differences are noted in Table. Overall outcomes were similar between LLUCH and RCHSD.

Conclusions: CRRT is a common treatment offered to critically ill pediatric patients with AKI. SSC provides a data-rich dashboard for CRRT programs, allowing real-time identification of CRRT parameters. Current study data is limited, but using pooled data from more comparable pediatric centers may assist in developing pediatric-specific CRRT metrics and quality benchmarks for pediatric CRRT programs. Due to data de-identification, SSC data allows easy data sharing between centers and could allow comparison with historical values from ppCRRT registry data. The de-identified data made it impossible to determine patient specific details and patient outcomes related to the CRRT dose or fluid removal. The display of pediatric data relative to adult norms without size standardization can be confusing. There is an opportunity 1) for more pediatric centers to share SSC data to identify better CRRT practices and develop quality metrics. 2) to obtain more granular, patient specific data 3) for Baxter to create a Pediatric/Adolescent versions of SSC.

	LLUCH	RCHSD	p-value
# Patients (average#/month)	19 (2.7)	17 (2.4)	0.38

Development and Implementation of a Training Program for Intravenous Administration of Calcimimetic

Becky Brosch, Brenda K. Shrader, Sharon Brandl, Nataliya Wilson, Parker Calbert, Carrie Chamblin, Jennifer E. Snyder, George R. Aronoff, Deborah A. Benner. *DaVita, Inc., Denver, CO.*

Background: The intravenous (IV) calcimimetic Parsabiv (etelcalcetide) was approved by the FDA for the treatment of secondary hyperparathyroidism in hemodialysis patients in February 2017. The package insert states that the medication requires refrigeration and is to be administered at the end of treatment during rinse back via IV push into the venous chamber or IV push after rinse back via the venous access followed by 10 mL normal saline. To prepare for use of Parsabiv at our organization, a pilot was conducted among select clinics to optimize clinical management and gain operational experience.

Methods: Here, we describe a Parsabiv administration training program for clinical staff that was developed over the course of the pilot.

Results: Initial training included aspects related to storage, handling and post-treatment administration. In the early phases of the pilot program, senior clinical staff conducted on-site visits to pilot clinics. During these visits and through direct observation, it was discovered that the standard practice of vial inversion and use of 1 inch needles made it more difficult to draw up the full prescribed dose. Through a troubleshooting process, clinicians identified that the full dose could be drawn up more effectively by tilting the vial 30-45 degrees (not inverting) and using a 1.5 inch needle. Based on this experience and in preparation for wider use through the organization, a training program was developed to educate nurses on this technique. The essential elements of this education program include mandatory online training modules with video demonstrating the appropriate draw techniques, check-lists, post-training evaluations, and quarterly clinic audits. Additionally, these experiences were shared with the drug manufacturer and their education materials were modified to include a description of this technique as a best practice.

Conclusions: This work demonstrates the value that pilot programs can provide, allowing issues to be identified and addressed prior to large-scale implementation of new clinical practices.

PUB228

Achievement of KDIGO Hemodialysis Targets with Stepwise Increasing Comorbidity Burden: A European Multicenter Analysis

Szymon Brzosko,[1,2] Joao M. Frazao,[3] Maciej B. Drozdz,[4] Werner Kleophas,[5] Abdulkareem Alsuwaida,[6,7] Mahesh Krishnan,[8] Stefan H. Jacobson.[9] *[1]DaVita Poland, Bialystok, Poland; [2]Department of Nephrology, Medical University of Bialystok, Bialystok, Poland; [3]Nephrology and Infectiology Research and Development Group, INEB, and School of Medicine, Porto University, Portugal, Porto, Portugal; [4]DaVita Poland, Krakow, Poland; [5]DaVita Germany, Dusseldorf, Germany; [6]King Saud University, Riyadh, Saudi Arabia; [7]DaVita Saudi Arabia, Riyadh, Saudi Arabia; [8]DaVita, Inc, Denver, CO; [9]Danderyd Hospital, Stockholm, Sweden.*

Background: Hemodialysis (HD) patients often have multiple comorbidities that add to the complexity and burden of their clinical and subjective symptoms. Comorbidities and frailty also result in decreased life expectancy and high mortality rates.

Methods: We assessed 1,246 prevalent HD patients from 13 DaVita centers in Europe (Poland 8 centers, n=482; Portugal 5 centers, n=764) and analyzed achievement of KDIGO treatment targets that contribute to outcomes: adequacy (spKt/V > 1.2), anemia (Hb 10-12 g/dL on ESA, Ferritin 200-800 μg/L, TSAT 20-50%), CKD-MBD (phosphorus ≤ 5.5mg/dL, calcium ≤ 10.2 mg/dL, iPTH 150-600 pg/mL) and type of vascular access (AVF or CVC). We considered median Charlson comorbidity index (CCI) and added stepwise: median age (>70 yrs), median BMI (<25 kg/m^2), median albumin (<39 g/L) and diabetes (yes) in relation to the comorbidity burden.

Results: Mean (SD) age was 62 (14) years for patients with CCI ≤ 7 and 76 (10) for patients with CCI > 7 ($p<0.001$) with no differences in gender, dialysis vintage, treatment time per week, and ESA dose. The percentage of patients achieving KDIGO targets is shown (Table).

Conclusions: Comorbidities and frailty pose substantial challenges for the provision of optimal HD care. This large real-world retrospective study demonstrates that elderly, more-frail patients with comorbidities still had an AVF rate of ≥70% and achieve KDIGO targets as well as patients with lower CCI.

Cancer Incidence and Characteristics in the Dialysis Patients: A Nationwide Cohort Study

Soon Kil Kwon,[1] Hye-Young Kim,[1] Sun Moon Kim,[2] Hyunjeong Cho.[2] *[1]Nephrology, Chungbuk National University College of Medicine, Cheongju, ChungBuk, Republic of Korea; [2]Chungbuk National University Hospital, Cheongju, Republic of Korea.*

Background: As population of ESRD patients are increasing, detecting and managing cancer in the ESRD should be emphasized. It is known that CKD is associated with malignancy risk, as population of ESRD are increasing, detecting and managing cancer in the dialysis should be emphasized. However, it is still not recognized the incidence of cancer in ESRD, and the difference of primary cancer site is also unveiled. We investigated the incidence of cancer among the large numbers of dialysis patients using national health insurance data to inform cancer screening in dialysis clinic.

Methods: The data were obtained from Korean National Health Insurance Service (KNHIS) which contains reimbursement record from all medical facilities across the country. The dialysis cohort included patients who claimed any procedures or materials for both hemodialysis and peritoneal dialysis, based on the Korean electronic data interchange codes (O7020 for hemodialysis; O7061 for peritoneal dialysis). Cancers were defined by compatible ICD-10 codes of C00.0 to 99.9 as cancers. Proportional difference in independent variables between the ESRD cohort and control were analyzed using the Wald chi-square test.

Results: Total 45,312 patients and controls were observed for 17,1329.45 and 220,464.18 person years respectively. Incidence of cancer was 463.8 vs 244.8 per 10,000 person-year. Hazard ratio of cancer in ESRD is 2.008 ($p < 0.001$). The most common malignancy in the ESRD patients is liver cell carcinoma same as control. ESRD showed markedly higher incidence of oral cavity and neck area cancer (OR 9.28, $p < 0.0001$) which was second most common site in the dialysis patients. The kidney cancer were also higher (OR 5.81, $p < 0.0001$), but prostate and stomach were less than control (OR 0.78, $p < 0.0001$; 0.88, $p = 0.0305$, respectively). Cancer incidence was markedly incrased by patients' age. Patients older than 60 showed 7 times risk than younger patients below 20 years of age (OR 7.725 in 60-69; 6.877 in 70-79; 7.647 in > 80 years old; all $p < 0.0001$). There was no difference between dialysis modalities, and no difference with economic satus.

Conclusions: Patients on dialysis treatment should be considered the incidence of head and neck malignancy, and all patients should be screened to detect oral cavity and pharynx cancers as well as liver and common site of malignancies in the dialysis clinic.

PUB230

Lower-Extremity Muscle Strength and Survival in Hemodialysis Patients with Peripheral Artery Disease

Manae Harada,[1,2] Takaaki Watanabe,[1,2] Shohei Yamamoto,[1] Yuta Suzuki,[1] Ryota Matsuzawa,[3] Naoyoshi Aoyama,[3] Atsushi Yoshida,[2] Atsuhiko Matsunaga.[1] *[1]Kitasato University Graduate School of Medical Sciences, Sagamihara, Japan; [2]Sagami Circulatory Organ Clinic, Sagamihara, Japan; [3]Kitasato University Hospital, Sagamihara, Japan.*

Background: Hemodialysis (HD) patients with peripheral artery disease (PAD) have an elevated mortality risk compared to those without PAD, and there is a need to identify factors that increase the mortality risk in these patients. Although lower-extremity muscle strength is one of the risk factors of mortality in HD patients, the association between lower-extremity muscle strength and mortality risk in HD patients with PAD is unclear. In this study, we investigated the prognostic significance of lower-extremity muscle strength in a cohort of HD patients with PAD.

Methods: A total of 148 outpatients (mean age, 67.9 ± 11.2 years, 42.6% male) undergoing maintenance HD therapy 3 times a week at an HD center and who were diagnosed with PAD with an ankle-brachial index of <1.00 or toe-brachial index of < 0.70 at baseline were monitored for 4 years. Clinical characteristics including age, sex, body mass index, time on HD, comorbid conditions, and blood biochemical data were obtained at baseline. In addition, maximum voluntary isokinetic knee extensor strength (leg strength), which reflects lower-extremity muscle strength, was measured using a handheld dynamometer (μTas F-1; Anima, Japan). Leg strength data were divided by dry weight and expressed as a percentage. Participants were categorized into two groups by a leg strength cutoff value of 40%. A Cox proportional hazards regression model was used to assess the contribution of leg strength to all-cause mortality.

Results: During a median follow-up of 38.0 months, 30 patients died. With a multivariate Cox model, the hazard ratio in the group with a leg strength <40% was 2.36 (95% confidence interval; 1.05–5.30) compared with that in the ≥40% group.

Conclusions: Decreased lower-extremity muscle strength was associated with survival in HD patients with PAD.

PUB231

The Multifactorial Key(s) to Deciding for the Timely Creation of Dialysis Access – An Exploratory Study

Ying-ying Seow,[1] Konstadina Griva,[2] Pei Shing Seow,[3] Zack Goh Zhong Sheng,[4] Jason Choo Chon Jun,[5] Jia Liang Kwek.[6] *[1]Renal/General Medicine, Sengkang General Hospital, Singapore, Singapore; [2]Lee Kong Chian School of Medicine Nanyang Technological University, Singapore, Singapore; [3]Renal Medicine, Khoo Teck Puat Hospital, Singapore, Singapore; [4]Lee Kong Chian School of Medicine, Singapore, Singapore; [5]Renal Medicine, Singapore General Hospital, Singapore, Singapore; [6]Renal Medicine, Singapore General Hospital, Singapore, Singapore.*

Background: This study set out to understand how family members and renal care providers influence decisions around optimal initiation onto hemodialysis (access creation).

Methods: Indepth interviews were conducted with 69 participants including predialysis CKD 4 patients (n=31), newly initiated onto hemodialysis with (n=18) or without AVF/AVG (n=20). Data were inductively analysed using a thematic approach and deductively informed by the theory of relational autonomy.

Results: Patients' social relationships and vicarious experiences significantly shaped their behavioural activation regarding access creation. Unequal weightage to different relationships created boundaries around whom to include in the decision making process. Family had greatest influence, followed by friends then HCPs. Family involvement varied from active behaviours (verbalising preferences and sharing views), passive involvement (support with no explicit action to influence decision) to complete abstinence in the process. Patients who either chose not to involve others or had no input from others were least likely to prepare, or initiated HD without AVF/AVG. While most patients maintained that they have the final say indicating individualist autonomy in decision around modality and access, family considerations, vicarious experiences and hearsay were noted as being more important than clinical tests or information communicated by HCPs. Doctors' recommendations were described as influential only by those expressing trust in their clinician. Others expressed mistrust and apprehension to medical recommendations – these were closely linked to low symptomatic burden and lack of clarity and understanding of provided information. Patients perspectives on health care encounters were heterogeneous, fear of dialysis and exaggerated concerns related to access and dialysis (costs; lifestyle disruptions) were uniformly voiced – family and hearsay acted to either alleviate or intensify those concerns.

Conclusions: Social and relational factors influence how patients respond to dialysis counselling and preparation. The adequacy of pre-dialysis education as an individual approach needs review. Greater attention to relational forces and emotional concerns around dialysis is needed for effective decision making for optimal initiation onto dialysis.

Limited Options for the Measurement of Large Middle-Molecules in Routine Clinical Practice

Colin A. Hutchison,[1,2] Marc Dorval,[7] Angela Yee Moon Wang,[6] Sebastian Koball,[5] Mario Cozzolino,[3] Rathika Krishnasamy.[4] *[1]Nephrology, Hawke's Bay DHB, Hastings, New Zealand; [2]Medicine, University of Queensland, Brisbane, QLD, Australia; [3]Department of Health Sciences, University of Milan, Milan, Italy; [4]Nambour General Hospital, Nambour, QLD, Australia; [5]University of Rostock, Rostock, Germany; [6]University of Hong Kong, Queen Mary Hospital, Hong Kong, China; [7]Nephrology, Dr Georges-L Dumont Regional Hospital, Moncton, NB, Canada.*

Background: Large middle molecules (MM) have recently been described as a group of 28 uremic toxins with molecular weights between 15 and 60 kiloDalton. This group of large non-protein bound toxins are involved in chronic inflammation, atherosclerosis, structural heart disease and secondary immunodeficiency. New medium cut-off hemodialysis membranes (Theranova) provide efficient removal of these molecules for chronic hemodialysis patients. The purpose of this study was to determine which of these molecules could be measured as part of clinical practice in dialysis units around the world.

Methods: Laboratories associated with dialysis units in Australia, Canada, Germany, Hong Kong, Italy, New Zealand and the United Kingdom were asked to identify which of the large MM could be measured in routine clinical practice; the cost; time to process the sample and method of analysis. The molecules include 5 cytokines, 4 adipokines, 4 growth factors, 8 immune mediated proteins and 6 other molecules.

Results: The number of large MM which could be measured as part of routine clinical practice varied greatly from dialysis unit to unit: from 1 to 23 large MM available to clinicians with a median of 9 molecules. Three molecules (FGF-2, Complement factor D and AGEs) could not be measured in any of these units. In contrast, kappa and lambda free light chains, myoglobin and prolactin were available for assessment in more than 80% of laboratories. The cost (in USD) for measuring these molecules varied by molecule and between dialysis units. The median cost was $39 (range $3.5 to $351). The lowest cost was to measure myoglobin in Germany, the most expensive FGF-23 in Canada. Ten molecules could be reported within 24 hours but 6 had average reporting periods of greater than 10 days. Luminex and ELISA based methods were the most common forms of assessment. Of the 28 large middle-molecules 8 would require specific transport requirements to the laboratory (e.g. cooling) limiting their utility in clinical practice.

Conclusions: While interest in the removal of large MM by new dialysis technologies grows the capacity to measure these uremic toxins in clinical practice is currently limited. Of the molecules free light chains (kappa + lambda), prolactin and myoglobin are the most accessible in terms of stability, availability, cost and reporting times.

PUB233

Estimating Absolute Blood Volume During Hemodialysis Using Crit-Line

Hamed Samandari,[1] Yossi Chait,[2] Joseph Horowitz,[2] Christopher V. Hollot,[4] Daniel Schneditz.[3] *[1]Miami University, Mason, OH; [2]University of Massachusetts, Amherst, MA; [3]Medical University of Graz, Graz, Austria; [4]University of Massachusetts, Amherst, MA.*

Background: Knowledge of absolute blood volume (ABV) can inform dry weight estimation and design of ultrafiltration rate profiles. Our aim was to compare ABV estimates obtained from a recently published 2-compartment blood water concentration (BWC) model during a dialysate dilution test with estimates obtained using a model modified for hematocrit (HCT) measurements.

Methods: Four dilution tests (150 mL) were performed within a single HD treatment in 4 patients. Changes in BWC and HCT were simultaneously measured using blood volume monitor (0.1 sec sampling time) and Crit-Line sensor (20 sec sampling time). The 2-compartment BWC model was adapted to estimate ABV using HCT measurements. Separate ABV estimates were obtained from the new HCT model and the BWC model. Bland-Altman (BA) analysis was used to analyze agreement between the estimates. Nested one-way ANOVA was used to compute intra-treatment variability of estimates.

Results: The HCT model successfully estimated HCT dynamics during the dilution test (Fig. 1). Intra-treatment standard deviation (SD) of estimates of BWC and HCT models were 0.12 L and 0.32 L, respectively. BA limits of agreement (Fig. 2) between the two estimates were 0.13±0.71 L (bias±2SD).

Conclusions: Means of ABV estimates based on the new HCT model are in agreement with estimates derived from a validated BWC model, however, slow HCT sampling times increased the estimates' SD which could be improved by reducing sampling time. A protocol for estimating ABV can be readily integrated into current HD machine technology and potentially enable the development of personalized fluid volume management protocols.

PUB234

Using Standard Bicarbonate Bath for Hemodialysis of Critically Ill Patients with High Venous Oxygen Saturation (HVOS) Is Associated with Poor Outcomes

Nabadwip Pathak, Sreejith Parameswaran. *JIPMER, Puducherry, India.*

Background: Management of critically ill patients with HVOS requiring Renal Replacement Therapy (RRT) is challenging. HVOS (>75%) is known to increase mortality in critically-ill patients by 20-30%. The role of modifying dialysate bicarbonate (Dia-HCO3) concentration to avoid metabolic alkalosis in critically ill patients with HVOS requiring RRT remains unknown. We present observational data on the effects of using 30mEq/l Vs 35mEq/l of Dia-HCO3 in critically-ill patients requiring RRT.

Methods: Over a six week period in April – May 2018, we identified 6 critically ill patients with renal failure requiring RRT who had HVOS in our ICU. The Dia-HCO3 was reduced to 30mEq/L in 3 patients while the other 3 patients underwent RRT with standard Dia-HCO3 of 35mEq/L. Complications during and after RRT and patient outcomes were documented, along with VOS & VBG before and after RRT.

Results: RRT was uneventful in 3 patients who received Dia-HCO3 of 30 mEq/l. By comparison, RRT was stopped within 2 hours in 2 of the 3 patients receiving Dia-HCO3 of 35 mEq/l due to the development of severe hypotension. Both patients had refractory shock leading to cardiac arrest in next 2-3 hours. An increase in the post HD venous oxygen saturation was observed in three of 6 patients, other three patients postHD VBG could not be done.

Conclusions: To our knowledge, the effect of using lower Dia-HCO3 in critically-ill patients requiring RRT has not been studied. HVOS in the critically ill is indicative of mitochondrial dysfunction and poor peripheral utilization of O2. High Dia-HCO3 shifts the hemoglobin-oxygen dissociation curve to the left thereby further worsening tissue oxygenation by decreased release of oxygen. This effect in addition to anemia and HVOS could explain the clinical worsening and high mortality in this patient population. Further studies are needed to determine the clinical benefit of using low-moderate Dia-HCO3 among critically-ill patients requiring RRT.

Clinical characteristics

Patient Characteristics	Patient 1	Patient 2	Patient 3	Patient 4	Patient 5	Patient 6
Pre HD VBG pH	6.78	7.36	7.30	7.32	7.28	7.41
Pre HD Venous SpO2 (%)	82.7	88.6	77.3	84.8	86.2	83.7
Post HD VBG pH	7.08		7.41	7.43		
Post HD Venous SpO2 (%)	86		83.4	89.6		
Dia-HCO3 concentration (mEq/L)	35	35	35	30	30	30
Post HD Survival	No	No	yes	yes	yes	yes

Data Sonification: A Novel Way to Analyze "Big Data" from Kidney Patients

Carrie L. Reid-Knox,[1] Tommy C. Blanchard,[2] Len A. Usvyat,[2] Peter Kotanko.[1] *[1]Renal Research Institute, Somerville, MA; [2]Fresenius Medical Care North America, Waltham, MA.*

Background: Electronic health records allow the collection of unparalleled rich data sets. For exploratory analysis, data is usually presented graphically. However, data visualization is challenging with high-dimensional data. We explored transforming data into auditory sensory inputs (sonification) as a novel means to represent data.

Methods: We used routinely collected data from 35,146 dialysis patients followed during their terminal 100 weeks before death (Usvyat, Kidney Int, 2013). Each parameter (interdialytic weight gain (IDWG), systolic blood pressure (SBP), albumin and C-reactive protein (CRP)) had an instrument assigned to it for sonification. We developed algorithms that used tonal ambiguity and variations in pitch, octave, dynamic, and texture to represent parameter dynamics, and a strong beat to represent the passage of time. We disassociated emotional reactions by avoiding the use of major/minor, consonance/dissonance, familiar harmonic progressions, and tonal center.

Results: In sonification #1 (https://youtu.be/IarHnxPmHeE) parameters are represented by flute (IDWG), cello (SBP), guitar (albumin), and trombone (CRP). We chose the whole tone scale because of its perfect symmetry, its lack of tonal center/absence of a leading tone, and its lack of emotional associations of other musical modes. Pitch represents the changing parameter levels. In sonification #2 (https://youtu.be/IE4-1S9pwGE) instrumentation was the same as in #1, except for albumin (drum). We used chord alternation with two chords that are a whole step apart, which have no associations with cadence or familiar harmonic progressions that would imply suspense and/or relief to the listener. We used pitch and texture (expressed by number of instruments and instruments being played on the off-beats) to represent changes in parameters.

Conclusions: Our results show, for the first time, that longitudinal data from kidney patients can be represented as auditory signals, complementing graphic data representation. We avoided musical modes and patterns that carry emotional associations, allowing listeners to approach the sonification without bias. Multi-sensory data representation will become particularly important when applied to high-dimensional, "big" data. Future research needs to address questions of optimal data representation.

Trajectories of Health Markers in Dialysis Patients Before Death

Yue Jiao,[1] Andrew Long,[1] Tommy C. Blanchard,[1] Marta Reviriego-Mendoza,[1] John W. Larkin,[1] Jochen G. Raimann,[2] Len A. Usvyat,[1] Jeroen Kooman,[3] Frank van der Sande,[3] Peter Kotanko,[2,4] Franklin W. Maddux.[1] *[1]Fresenius Medical Care North America, Waltham, MA; [2]Renal Research Institute, New York, NY; [3]Maastricht University Medical Centre, Maastricht, Netherlands; [4]Icahn School of Medicine at Mount Sinai, New York, NY.*

Background: We characterized trajectories of health markers before death and compared them to patients who did not die during the same period.

Methods: Data from patients treated at a large dialysis provider who died during 2010 to 2017 was compared to data from patients who survived 12 months from a randomly selected index date. Using data from 12 months prior to death (or index date for survivors), we computed slopes from monthly averages for laboratories and treatment parameters via linear regression. For each variable, we calculated the percentage (%) of patients with significant increases, decreases, and stable slopes.

Results: We analyzed data from 182,481 patients who died and 140,999 patients who survived. We found significant differences in slopes between those who died and survived for cardiovascular, inflammatory, and nutritional markers (Figure 1). We found 28% of patients who died had decreases in predialysis systolic blood pressure (pre-SBP); 15% of survivors had decreases. Patients who died had decreases of 4% in neutrophils and 13% in lymphocytes versus 7% and 6% in those who survived. More patients who died (28%) had decreases in albumin (Alb) versus those who survived (13%). We also revealed additional distinct findings in the % of patients with increases in parameters for those who died versus survived.

Conclusions: Patients appear to have distinct patterns of changes in health markers before death compared to patients who survived. For example, nearly twice as many patients who died exhibited decreases in pre-SBP and Alb during the 12 months before death compared to survivors. Identifying combinations of changes in different parameters could be useful for construction of artificial intelligence-based prediction models.

Funding: Commercial Support - Fresenius Medical Care North America

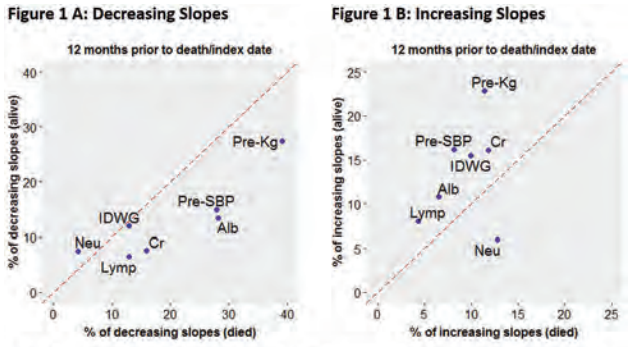

Figure 1. Percent of significant decreases (A) or increases (B) in slopes of health markers 12 months prior to the death on the x-axis, or the concurrent changes for those who survived on the y-axis for parameters related to: 1) cardiovascular diseases (Pre-SBP: predialysis SBP; IDWG: interdialytic weight gain; Pre-Kg: predialysis weight), 2) Inflammation (Lymp: lymphocytes; Neu: neutrophils), 3) nutrition (Alb: albumin; Cr: creatinine).

PUB237

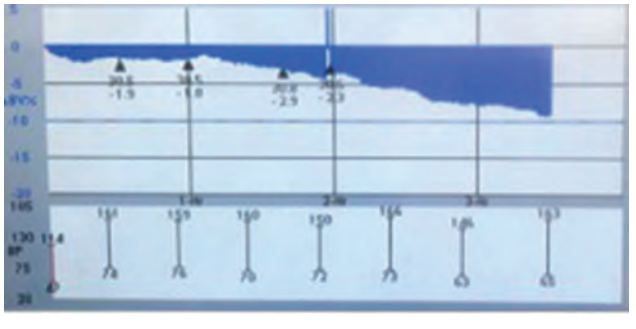
Optimizing Fluid Management with Crit-Line® in HD

Darryl Martin,[1] Dixie-Ann Sawin,[1] Rainer Himmele,[3,1] Robert J. Kossmann,[2,1] Allison Comerford.[2] *[1]Fresenius Medical Care Renal Therapies Group, Charlotte, NC; [2]Fresenius Medical Care North America, Waltham, MA; [3]Fresenius Medical Care NA, Charlotte, NC.*

Introduction: Unigue patient cases presented here discuss use of Crit-Line technology in HD.

Case Description: Case 1: Case 1: A 72-yr-old female (dry weight/DW 51kg) has a predialysis weight (wt) of 52.6kg and initial ultrafiltration goal (UF) of 1.6L. During the first hr, the Crit-Line slope was initially slightly negative then trended upwards (relative change in blood volume/ΔBV% ≤ -3%/hr; A profile). UF goal was increased by 200mL at 0:35 and 1:45 and a saline bolus given at 1:55hrs (black triangles). At 3:30, her final ΔBV% was -9.3% (A profile), UF was 2175mL and she had no intradialytic events (IDEs). Although she achieved postdialysis wt (~50.7kg), profile suggested opportunity to remove more fluid and dry weight adjusted to 50.6kg for next session. Case 2: A 56-yr-old, hypotensive-prone male (DW: 110Kg) with a predialysis wt of 117.1kg was never able to achieve >4.5L UF due to IDEs prior to Crit-Line use. Systolic BPs in the 90s (mmHg) was clinically acceptable for this patient and initial UF goal was 6L. His ΔBV% decreased rapidly (-7.9% at 1:05; C profile). His UF goal was then decreased by 200 mL at 1:05, 2:40 (ΔBV% -16%) and 3:20 (ΔBV% -18.0%) with no IDEs. At 3:30, ΔBV% was -18.2% (C profile), his BP dropped to 79/44 and he had a mild hand cramp (yellow diamond). His UF goal was reduced by 200 mL and symptoms dissipated. His final ΔBV% was -16.9% with ~5.2L of UF and his postdialysis wt was 112.1kg. His DW was adjusted up to 111.5kg for later treatments.

Discussion: Cases show safe, effective, real-time use of Crit-Line technology, where clinicians can accurately assess and adjust fluid removal as needed, while reducing potential for IDEs and fluid overload.



PUB238

Environmental Sustainability of Dialysis Facilities

Matthew D. Jose,[1,2] Natasha N. Abeysekera.[2] *[1]Royal Hobart Hospital, Hobart, TAS, Australia; [2]School of Medicine, University of Tasmania, Hobart, TAS, Australia.*

Background: Haemodialysis is responsible for high resource consumption, resulting in a high economic burden and cost to the environment. Our aim was to assess the current environmental sustainability of haemodialysis facilities in regional Australia.

Methods: Nurse unit managers of all Tasmanian public dialysis facilities received an online survey, which asked 23 questions relevant to the environmental sustainability of dialysis services. The survey used was a modified version of the survey used to assess UK dialysis facilities.

Results: Responses were received from all dialysis units in Tasmania (n=6, 100%). Energy saving initiatives included the use of fluorescent lighting (n=6, 100%), motion sensor lights (n=1, 17%), thermostat controlled heating (n=6, 100%) and automatic hibernation settings of fax machines and computers (n=6, 100%). Five units (83%) were supplied with energy by Aurora and one unit (17%) from TasNetworks. Water saving initiatives included motion sensor taps (n=3, 50%) but no units harvested rainwater nor recycled reverse osmosis water. Recycling initiatives included waste segregation in all units and four recycled PVC plastic. Sustainable transport initiatives included active and public transport (n=3, 50%). Three units (50%) also provided bicycle parking with access to shower and changing facilities. None of the units used virgin paper and all had double-sided printing as an automatic setting. All units used a combination of paper and digital medical records. All units used paper towels and food sourcing was unknown. All units supported green initiatives, but no unit had an environmental sustainability policy nor had performed an audit of their environmental sustainability.

Conclusions: Sustainable initiatives were evident in all haemodialysis units, but significant opportunity exists to improve the environmental impact of dialysis in Australia.

PUB239

Life on the Bridge: A 40-Year Journey with Dialysis

Judy Weintraub. *Life On The Bridge, Los Angeles, CA.*

Introduction: Life On The Bridge is a 22-minute humanistic documentary by Judy Weintraub, that raises expectations about creating a good life while living with kidney dialysis. It raises awareness of the realities of kidney disease and the treatments available, highlighting what is possible. This theme is ultimately a universal one: though we may not control all the circumstances of our lives, we always have a choice in our attitudes

Case Description: As the story unfolds, Judy, after years of waiting, is called in for a third kidney transplant. She had previously received two transplants, both of which failed within a few short months. Judy had begun kidney dialysis treatments as a teenager and has been on some form of dialysis ever since. Over the decades, she did both in-center hemodialysis and more than a decade of peritoneal dialysis and nocturnal HHD. The documentary follows what happens from the first hopeful days and weeks to several months later, as Judy and her doctors fight to keep this new transplant. Throughout, we also hear the personal dstories and experiences of people of different ethnicities and backgrounds who are living with dialysis or transplantation. Family members share what it's like to be with loved ones who live with this disease. Professionals speak out - doctors, nurses, technicians, and social workers share their view of the field.

Discussion: Several themes arise from the film: Education of professionals, patients, family members and the general public as to the possibilites of living well with the various modalities of kidney dialysis; The role of physicians as champions in their patient's care; Maintenance of positive expectations in living life, especially with a chronic illness; The crucial role that encouragement plays in optimizing outcomes; The importance of ongoing evaluation and the willingness to think outside-the-box to individualize care. This film's ultimate mission is to help patients and the professionals who care for them move toward the optimal health outcomes that we know are achievable. Judy Weintrub M.S. Ed., holds degrees in Special Education from USC and Psychology from UCLA. She holds credentials in the areas of Education, Communication Handicapped and Early Intervention. She also served on the boards of *Nephrology News & Issues, the Southern California Renal Disease Patient Advisory Council (Network 18) and the Southern California Chapter of the National Kidney Foundation.*

PUB240

Inflammatory and Nutritional Markers Prior to Death in Chronic Hemodialysis Patients: Results from the Global MONDO Initiative

Dalia E. Yousif,[1] Xiaoling Ye,[1] Jochen G. Raimann,[1] Yuedong Wang,[6] Jeroen Kooman,[2] Frank van der Sande,[2] Stefano Stuard,[3] Bernard J. Canaud,[4] Adrian M. Guinsburg,[3] Len A. Usvyat,[5] Peter Kotanko.[1] The MONDO Initiative *[1]Renal Research Institute, New York, NY; [2]Maastricht University Medical Centre, Maastricht, Netherlands; [3]Fresenius Medical Care, Bad Homburg, Germany; [4]FMC Deutschland GmbH, Bad Homburg, Germany; [5]Fresenius Medical Care North America, Melrose, MA; [6]University of California - Santa Barbara, Santa Barbara, CA.*

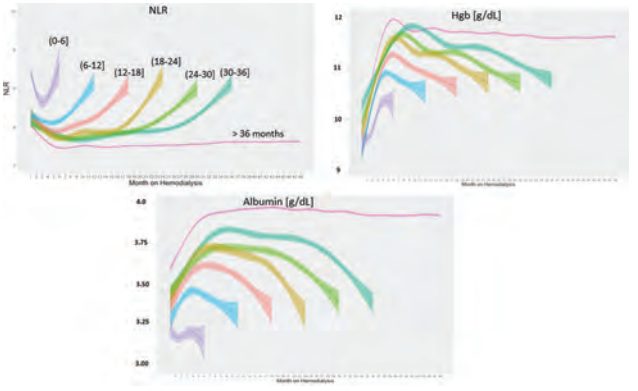
Background: Malnutrition, inflammation, and oxidative damage are highly prevalent in dialysis patients (pts) and each condition is associated with an increased risk of death. Hemodialysis pts with larger hemoglobin level fluctuations have higher mortality.

Methods: All the adult pts who died within the first 36 months (mos) of HD were stratified into 6 sub-groups, pts who died from month 0 to 6, 6 to 12, 12 to 18, 18 to 24,

24 to 30 and 30 to 36 mos after HD initiation. For those who survived 36+ mos on HD were served as the reference group. Monthly average NLR, Hgb, Pre-HD SBP and serum albumin were obtained, cubic spline function were applied to access the trends and rate of changes for each of the parameters of interest for up to 48 months after HD initiation. In addition, subgroup analysis was performed to study the regional differences.

Results: Totally, 18,276 incident HD pts were included, 2,068 were died within 6 mos, 1,231 died within 6 to 12 mos, 971 died within 12 to 18 mos, 792 died within 18 to 24 mos, 721 died within 24 to 30 mos, 648 died within 30 to 36 mos, and 12,295 survived more than 36 mos. For pts who died sooner after HD, NLR observed to be higher at the initiation of the dialysis, while Hgb and serum albumin were tended to be lower. In addition, NLR reached the nadir from 3 to 10 months after start of dialysis while serum Hgb and albumin seem to reach the maximum 3 to 10 mos after HD initiation, depends on the survival time.

Conclusions: Inflammation can interact with malnutrition, resulting in the excessively high mortality in the dialysis population. There are several readily available indicators reflecting catabolic, protein intake and oxidative stress that change prior to death in incident HD pts. The awareness of valuable index predicting worse outcomes is central therapeutic efforts, and interventions at the individual and regional levels.



PUB241

Patient Peer Mentoring in Hemodialysis: A Single Center Experience

Paul N. Bennett,[1,2] Lashone Brown,[3] Sydney Urbina,[1] Shaun S. Collard,[1] Brigitte Schiller.[1] *[1]Satellite Healthcare, San Jose, CA; [2]Faculty of Health, Deakin University, Geelong, VIC, Australia; [3]Satellite Healthcare Inc., Stockton, CA.*

Background: Patients new to hemodialysis (HD) are educated by dialysis clinicians in order to improve their start to HD. Peer mentorship, from experienced dialysis patients, has been shown to enhance this transition increasing patient engagement and quality of life. The aim of this study was to measure the effect of a patient peer mentor program on self-efficacy, anxiety and depression.

Methods: Mixed methods study design. A patient to patient mentor program was introduced to one dialysis center consisting of: mentor identification, mentor training, mentor and mentee matching, and regular mentor/mentee meeting episodes over a 2-month period. The primary outcome was change in self-efficacy as measured by 6-Item Self-Efficacy for Managing Chronic Disease Scale. Secondary outcomes were change in anxiety and depression as measured by the 4 item Patient Health Questionnaire Scale (PHQ-4). Mentee and mentor evaluations through group interviews were performed.

Results: Thrirteen patients participated (7 mentors and 6 mentees) from a center of 100 patients. 100% of participants agreed that they would recommend other dialysis patients to talk with a mentor. 100% of pairs agreed to continue to meet after the study had completed. No statistically significant improvement in self-efficacy, anxiety and depression was found. A high level of engagement from key dialysis center champions including the social worker and the renal dietitian played a key role in the success of starting the mentor/mentee program.

Conclusions: A coordinated mentor program maintained by clinicians was identified by patient mentees and mentors as a positive strategy for dialysis centers. Commitment from the dialysis organization and center staff is pivotal to ensure the sustainability of mentor program. A larger randomized cluster study is required to demonstrate improvement in self-efficacy, anxiety and depression.

PUB242

Quality of Life Trends in Patients with ESRD Undergoing Hemodialysis

Salim Bou Slaiman,[1] Sarah G. Thappa,[3] Youssef Shammaa,[2] Suzanne E. El Sayegh.[4] staten island university hospital *[1]staten island university hospital, Staten Island, NY; [2]Staten island university hospital, Staten Island, NY; [3]Touro College of Osteopathic Medicine, Staten Island, NY; [4]Staten Island University Hospital, Staten Island, NY.*

Background: Health-related quality of life (HRQoL) has been the subject of a lot of recent studies involving many chronic diseases and conditions and guiding treatment modalities. In addition, HRQoL has been shown to be a strong predictor of morbidity and mortality in patients with end-stage renal disease (ESRD). We conducted this study to compare the quality of life score trends across the years for the patients and to look for the variables that affect these scores.

Methods: We recruited patients in an outpatient dialysis center on Staten Island, NY. KDQOL scores administered yearly were collected for each patient, along with demographic and lab data. each patient had at least 2 and up to 4 scores collected, and for each score, a set of lab data within a month from the score was noted. Our primary objective was to analyze the trend of the QOL scores along with the trend of the lab data for each patient. Data analysis was carried out in SAS software. We performed a mixed logistic regression to account for the repeated measures of the KDQOL scores. Least squared means were computed to identify inter- and intra-subject variability.

Results: 96 patients were recruited, with a mean age of 63.9 years; 69% were males and 54% were white. There was no observed difference between age and the various scores. On average, men had lower scores than women in all score subsets. There was also a significant difference among the ethnicities with scores in the black population having lower scores than other races. Ferritin had significantly a negative correlation with PCS score (p-value<0.045) as well as PTH levels that were positively correlated to the effect score. There was no significant correlation between the other laboratory markers and the QOL scores over time.

Conclusions: the difference found between genders and races cope with their disease burden may depend on how anxiety, depression, and loss of autonomy may vary between genders and cultures Laboratory tests that influenced the QOL scores were PTH and ferritin. This can be due to its effect on phosphorus and calcium, which links to acid-base disturbances and bone change related to kidney disease. Type of access could affect the score by limiting the patient's physical activity and association with infection and hospitalization which invariably have a negative correlation with KDQOL scores.

PUB243

Dialysis Disequilibrium Syndrome: Rare Serious Complication of Hemodialysis and Effective Management

Sreedhar R. Adapa, Harpreet S. Dhindsa, Hemant Dhingra, Amarinder Singh Garcha. *The Nephrology Group, Inc, Fresno, CA.*

Introduction: Dialysis Disequilibrium syndrome (DDS) is an extremely rare central nervous system complication that occurs in patients receiving hemodialysis and can be potentially fatal. The prognosis is poor when this manifests as serious neurological manifestation like seizures, obtundation and evidence on effective management is sparse. We present the case of a patient who developed altered mental status during hemodialysis. Patient successfully recovered with administration of mannitol and 3% saline without any long-term neurologic squealae.

Case Description: A 72 year-old male who had not had any dialysis for 2 weeks because of peritoneal dialysis catheter malfunction was admitted with dyspnea and fluid overload. He was hyperkalemic, bradycardic and emergent hemodialysis was arranged. Labs showed severe azotemia with BUN 141mg/dl, Creatinine 9.8 mg/dl and Potassium 8.3 meq/L. Chest x-ray showed pulmonary edema. Patient developed twitching and became confused about 2 hours into dialysis. Dialysis was immediately terminated, patient was given mannitol 125 mg and 3% saline was started at 30 ml/hr. Post dialysis labs revealed BUN 64 mg/dl (urea reduction ratio 54.6%), Creatinine 5.2 mg/dl and Potassium 3.2 meq/L. He was dialyzed again the next day with low blood and dialysis flow rates. Mannitol and 3% saline were administered during dialysis. EEG revealed no epileptiform abnormality. Patient made full neurological recovery after 4 days.

Discussion: DDS usually occurs during or immediately after patients receive their first hemodialysis, but can rarely happen in patients already on dialysis. Prognosis of severe DDS is poor and prevention is ideal. It is important to identify the patients who are at high risk of developing DDS and use low efficiency dialysis with gradual urea reduction. Our patient was at risk for DDS considering severe azotemia that is a surrogate for uremic milieu. There is not much guidance in literature as far as management of DDS with severe neurologic manifestations is concerned. Our patient did well with administration of hypertonic agents that have not been used much in our current clinical practice. These agents may have a role to play in management of patients requiring emergent renal replacement therapy who develop DDS despite use of preventative measures such as low efficiency short hemodialysis sessions.

PUB244

Association of 3mTUG and All-Cause Mortality in Dialysis Patients

Kun Zhang, Chen Yu. *Shanghai Tongji Hospital, Shanghai, China.*

Background: To evaluate the association between physical performance and all-causes mortality in maintenance dialysis patients,and identify whether physical activity could predict the mortality independendy.

Methods: In this study, we evaluated maintenance dialysis patients in Shanghai Tongji hospital from Dec 2014 to Mar 2018, collected clinical data and serum hemoglobin, albumin, calcium, phosphate and parathyroid hormone(PTH) levels. We measured physical activity including muscle strength and balance ability used by timed up and go (3mTUG).

Results: 121 patients were involved, average age (61.6 ± 13.0)years, 62 peritoneal dialysis patients and the other 59 hemodialysis, 76 men and 45 women, average dialysis duration 31.7(12.3, 69) months. During the median 36 months follow-up, 22 patients(17%) were died. Age, modality, DN, phosphates, PTH and 3mTUG were risk factors for all-cause mortality(P<0.05). After adjusting age, modality, DN, phosphates and PTH, 3mTUG was an independent risk factor of all-cause mortality(P<0.05).

Conclusions: 3mTUG can predict mortality of dialysis patients independently.

PUB245

Hypoglycemia in Hospitalized Patients Undergoing Hemodialysis

Jeffrey I. Silberzweig,[1,2] Uvannie Enriquez,[3] Eunice Yang,[3] Jane J. Seley,[5] Gulce Askin,[4] Susanna Slukhinsky,[6] Flannery M. Cuevas,[3] Hyo Sook Kim,[3] Robee G. Ravago,[3] Felicia A. Mendelsohn Curanaj,[5] Marifel Axalan.[3] *[1]The Rogosin Institute, New York, NY; [2]Medicine/Nephrology, Weill Cornell Medical College, New York, NY; [3]Nursing, New York Presbyterian Hospital, New York, NY; [4]Weill Cornell Medical College, New York, NY; [5]NewYork-Presbyterian/ Weill Cornell Medicine, New York, NY; [6]Nutrition, The New York-Presbyterian Hospital, New Y, NY.*

Background: Approximately 40% of patients treated by hemodialysis (HD) have diabetes mellitus (DM). Hospitalized patients with DM have greater risk of hypoglycemic episodes; HD may further increase risk as it is an energy consuming procedure and patients may have decreased appetite, hypotension, nausea and dizziness. Malnutrition is an important contributor to poor outcomes among hospitalized patients so we began offering meal trays during HD but nursing staff reported a high rate of symptomatic hypoglycemia among patients receiving insulin dosed by standard hospital protocol.

Methods: With IRB approval, we retrospectively reviewed charts of patients undergoing HD between January and August 2016 who had point-of-care blood glucose (BG) testing during HD. In May, a Certified Diabetes Educator (EY) taught nursing colleagues to estimate the carbohydrate (CHO) content of meals. Patients who anticipated consuming at least 30g of CHO received full prandial insulin dose. For patients who anticipated consuming less than 30g, the nurse contacted the MD to consider reducing the insulin dose. The population was divided into pre- (January to May) and post- (June to August) education time periods. Charts were reviewed for co-morbid medical conditions, concurrent medications and BG levels for the 24 hours surrounding HD.

Results: Using the international definition for hospitalized patients (BG > 70 or < 100 with symptoms of hypoglycemia), 14/60 (23%) had hypoglycemia. After the education, there was no significant change in the occurrence of hypoglycemia during HD (20 vs 22.5%; p = 1.000). There were no significant differences among clinical factors between the two groups: age, race, sex, dialysis vintage, acute vs chronic kidney disease, co-morbid conditions, concurrent medications.

Conclusions: There is a high incidence of hypoglycemia among hospitalized patients with DM undergoing HD. The lack of change in the incidence of hypoglycemia after education may relate to stricter adherence to prescribed insulin dosing. We plan to develop a protocol for insulin for dosing during HD adjusting for the CHO content of the meal to be consumed and the anticipated energy utilization during HD. We will observe its effect on the frequency of hypoglycemic episodes during and six hours post-HD.

PUB246

Rapid Bedside Assessment of Diastolic Function in Hemodialysis Patients

Proma Mazumder, Erik Yarmey, Cameron Baston, Nova Panebianco, Anthony J. Dean, Nathaniel C. Reisinger. *University of Pennsylvania, Philadelphia, PA.*

Background: The prevalence of diastolic dysfunction (DD) among hemodialysis (HD) patients is 75%. The presence of DD is often unknown to the treating nephrologist leading to complications from intradialytic hypotension due to high ultrafiltration rate. DD is traditionally assessed using spectral and tissue Doppler waveform analysis. These techniques are time consuming and may be beyond the training of many providers performing clinician-performed ultrasound (CPUS). We have previously demonstrated that physicians can identify DD using qualitative ultrasound findings. We aim to evaluate if 3 qualitative visual parameters obtained on real-time B-mode echocardiography can accurately detect DD in HD patients.

Methods: CPUS echocardiograms were prospectively obtained by residency and fellowship trained sonologists on a convenience sample of 49 HD patients presenting to the emergency department for any reason. Cases were deidentified and randomized with 11 cases of normal diastolic function to avoid potential spectrum bias due to case-mix. The images were reviewed by two fellowship-trained sonologists who scored the clips for presence or absence of DD based on three visual indicators: presence or absence of left atrial enlargement, impaired left ventricular relaxation, and impaired mitral valve descent. The images were then rated on the severity of DD on a 0 (absent) to 3 (severe) scale. The accuracy of these findings was evaluated against DD on final cardiologist interpretation of referral echocardiograms.

Results: 39 of the HD patients had a diagnostic echocardiogram with an assessment of diastolic dysfunction documented in the prior year. Combined with the 11 normal studies, this gave a total of 50 cardiac ultrasounds for review. The overall accuracy for determining presence or absence of DD was 95.0% (CI 88.7 – 98.3). The accuracy of assessing severity to within 1 category above or below the criterion standard was 92.0% (CI 84.8 – 96.4). Interobserver correlation measured by Cohen's kappa for assessment of presence or absence of DD was 0.75, and for specific diastolic grade was 0.54.

Conclusions: Qualitative visual echocardiographic parameters can be used by clinicians to determine DD accurately in HD patients. These techniques could be adapted for detection of DD at the point-of-care in the dialysis unit.

PUB247

Utilization of Emergency Department and Risk of Resuscitation Among Patients Receiving Maintenance Hemodialysis

Tai-Shuan Lai,[1] Yi-Chih Lin.[2] *[1]Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; [2]National Taiwan University Hospital, Taipei city, Taiwan.*

Background: The end-stage renal disease has to become a growing health problem globally with increased disease burden and high medical costs. The utilization of emergency department among dialyzed patients remains uncertained and risk factors of resuscitation at Emergency Department are deserved to explore.

Methods: This longitudinal cohort study was sampled from National Health Insurance Database in Taiwan. Patients aged 19 to 90 years old with maintenance hemodialysis between January 1 to December 31, 2010, were recruited. We matched non-dialytic individuals by age, sex and Charlson Comorbidity Index (CCI) as a control group from the same data source. The utilization of emergency department among enrolled individuals was identified in 2012. We used generalized estimating equations with multiple variables adjustment to explore risk factors associated with resuscitation in emergency department visits among all suffered patients.

Results: Between January 1 to December 31, 2012, 2,985 individuals with hemodialysis and 2,985 individuals without hemodialysis were enrolled. There were 4,803 patient-times emergency department visits in hemodialysis group and 1,744 patient-times emergency department visits in the non-dialysis group. The level of the visited hospital, diagnosis category, severity of triage, and the experience of resuscitation had a statistically significant difference between hemodialysis group and non-hemodialysis group (p<0.05) but no significant difference in death (p=0.76) between two groups. In an analysis of multivariable generalized estimating equations, individuals with maintenance hemodialysis had a higher risk of resuscitation in emergency department visits compared with individuals without hemodialysis (adjusted odds ratio [aOR], 1.30, 95% CI: 1.01 to 1.68). Other risk factors for resuscitation at emergency department included age between 55 and 69 years old (aOR 1.80, 95% CI: 1.25 to 2.59), age older than 70 years old, (aOR 2.30, 95% CI: 1.61 to 3.29), the experience of hospitalization prior in 1 year, (aOR 1.35, 95% CI: 1.09 to 1.65), and the first and second degree of triage (aOR 1.96, 95% CI: 1.60 to 2.41).

Conclusions: Patients with maintenance hemodialysis had increased utilization of emergency department and a higher risk of resuscitation at emergency department compared to patients without hemodialysis.

PUB248

Association Between Suicidal Phenomenon/Depression and Inflammatory Status in Patients with ESRD on Hemodialysis

Enrique Rojas-Campos, Rosalinda Valencia-Coronado, Alfonso M. Cueto-Manzano, Laura Cortes-Sanabria. *Instituto Mexicano Del Seguro Social, Guadalajara, Mexico.*

Background: Suicide is a worldwide public health problem and depression is the mental problem most closely related to suicide. Depression is highly prevalent in ESRD, inflammation is related to ESRD and to depression. Aim: To determine the presence and severity of depression and suicidal ideation in patients on HD and the association with inflammation.

Methods: Cross sectional study, performed in 45 prevalent HD patients (June 2017-March 2018), Depression, suicidal ideation and hopeless were evaluated using Beck scales, performed by a single Psichiatrist blinded to biochemical data; inflammation was evaluated using CRP (High sensitivity), fibrinogen and globular sedimentation rate, age, time and acces type to dialysis and lipids. Subjects were infection free (3 previous months), with no current Psiquiatric therapy and/or medication, and no anti inflammatory therapy.

Results: Prevalence of depression is 88% and 33% had suicidal ideation. As higher was depression higher were CRP, fibrinogen globular sedimentation rate and suicidal ideation. In Graph is shown the correlation between suicidal ideation and CRP.

Conclusions: Inflammation measured by CRP, GSR and fibrinogen significantly correlates with depression and suicidal ideation. It is necesary to colaborate with multidisciplinary team to provide psicological and anti inflamatory therapy in ESRD.

Variable	No Symptoms	Depression mild	Depression moderate	Depression severe
PCR (mg/L)	3.40 ± 0.32	3.70 ± 0.62*	7.70 ± 1.4*	13.90 ± 3.20*
VSG (mm/H)	32.0 ± 1.2	34.0 ± 2.5	47.0 ± 7.2*	65.0 ± 8.5*
Fibrinogen (mg/dL)	338.0 ± 66.4	272.2 ± 88.4	329 ± 86.2	587.5 ± 24.1*
Suicidal ideation (pts)	0.0	0.10 ± 0.45	3.2 ± 2.8*	12.0 ± 3.0*

The Total IV Iron Burden and Cognitive Impairment in Hemodialysis Patients

Monique E. Cho,[1,2] Iran Lavasani,[3] Jared Hansen.[2,1] *[1]University of Utah, Salt Lake City, UT; [2]Veterans Health Administration, Salt Lake City, UT; [3]University of Utah, Salt Lake City, UT.*

Background: Hemodialysis (HD) patients routinely receive IV iron, which includes non-transferrin-bound iron that can accumulate in neurons and cause oxidative injury. Despite the established role of excess brain iron in dementia, the association between total accumulative IV iron dose and cognitive impairment, a highly prevalent condition in ESRD, has never been explored in HD patients.

Methods: We performed an observational pilot study of prevalent HD patients at University of Utah (N=16). Patients with history of dementia, chronic hepatitis, steroid use, malignancy, hematologic disorders, hospitalization within one month of screening were excluded. Total accumulative dose of IV iron for the entire duration of dialysis was calculated for each participant. Montreal Cognitive Assessment (MoCA) test was used to screen for cognitive impairment. The total IV iron dose was log transformed to enable parametric analysis with Pearson correlation coefficient to evaluate its association with MoCA score.

Results: The study group was diverse (8 Hispanics, 4 Whites, 1 Asian, and 3 mixed), with 9 men and 7 women. Half of the group had diabetes. The mean±SD values for age, dialysis duration, systolic blood pressure, hemoglobin, and albumin were 52±14 years, 7.4±5.8 years, 142±28 mmHg, 10.6±1.9 g/dL, and 3.9±0.2 mg/dL, respectively. The median (IQR) transferrin saturation and ferritin were 28 (21, 39) % and 652 (300, 971) ng/mL. The median total IV iron dose was 10,825 mg (range of 2,400 to 29,748 mg). Two patients refused MoCA test. The mean±SD MoCA score was 23±4 (N=14). There was a trend for a negative correlation between the total IV iron dose and MoCA score (Figure 1).

Conclusions: This is the first study to evaluate the association between the accumulative IV iron burden and cognitive impairment. Larger studies are required to investigate if IV iron is associated with dementia risk in ESRD.

How Accurate Is the Dry Weight?

Mohammed Hamid, Sholabomi Oyewole-Eletu, Kathleen Speta, Gregory D. Gudleski, Shirley S. Chang. *Jacobs school of medicine at the state university of New York at Buffalo, Williamsville, NY.*

Background: Studies indicate volume overload in ESRD/CKD stage V patients are associated with worse outcomes. We observed in kidney transplant (tx) recipients usually diurese postoperatively & continues as outpatient, raising the question of the accuracy of estimated dry weight, since there is no accurate tool for ideal weight determination. We decided to investigate the weight difference on the day of tx, at 1-month & 3-months post-tx in kidney transplant recipients at Erie County Medical Center (ECMC).

Methods: Retrospective analysis of 244 kidney tx recipients at ECMC from 1/1/16-12/31/17. Demographics & clinical characteristics were collected. Exclusion criteria are age ≤18 years old, delayed graft function ≥ 1 month, & renal allograft failure within 3 months post-tx.

Results: There were 140 recipients on hemodialysis (HD) prior to tx, 48 patients on peritoneal dialysis (PD), 65 recipients received pre-emptive transplantation. Overall, age and gender and ethicity were not statatistically different among all three groups. Weight on the day of tx were statistically higher than weight at one-month & at three-months post-tx among all groups. The one-month & three-months post-tx weights were not statistically different among all groups.

Conclusions: Results showed there are weight losses after kidney transplantataion exceeding the volume administered peri-operatively. The weight loss (4-6 kg) post-transplantation mainly reflects volume loss. Fluid management poses challenging dilemma in dialysis patient since volume overload & too agressive volume removal can induce circulatory stress & multi-organ injury. Knowning that patient's ideal weight is actually 4-6 kg below their achievable dry weight on dialysis may help the clinicians to better manage patient's volume status on dialysis. Reducing dry weight even by relative small amonts has been showen to improve blood pressure & reduce left ventricular hypertrophy. Further studies are needed to better manage volume status in dialysis patients, with health, social, & economic implications.

Weight Changes Over Time (kg)

Type of Dialysis	Day of Tx Weight 1	1 Month Post-Tx Weight 2	3 Months Post-Tx Weight 2
Preemptive (N=56)	89.7±21.1	84.4±19.9	85.8±20.1
HD (N=140)	85.5±19.0	81.6±18.9	82.8±18.6
PD (N=48)	88.4±21.1	82.5±19.3	83.9±19.7

The Association of Gender with Avoidable Emergency Department Visits in Patients on Hemodialysis

Ladan Golestaneh. *Montefiore Medical Center, Bronx, NY.*

Background: In national samples drawn from the USRDS female patients and those younger than 44 years old utilize hospital ED and inpatients services at a higher rate than their counterparts. We set out to explore whether this association held with avoidable ED visits in a cohort of mostly minority patients in a single low socioeconomic burrough in New York City.

Methods: We use Montefiore's clinical database, "Looking Glass"™ To build a cohort of patients on hemodialysis with a first ED visit between 2013-2017 to any of 4 main EDs in the Bronx. All subsequent ED visits without a resultant admission for the duration of the observation period and the count of ED visits for 365 days prior to this index ED visit were recorded. We refer to these ED visits as avoidable because they did not result in an inpatient admission. We used bivariate analysis to test the association of demographic, socioeconomic and clinical variables with sex. We then built models using negative binomial regression adjusted for time in study, to test the association of gender with avoidable ED count alone, when adjusted for socioeconomic variables and clinical variables respectively.

Results: We identified 4,573 patients of which, 43.2% were female and 53.6% were black. The median avoidable ED visits were higher in females (4(25-75%IQR 2-9). Female patients were older, more commonly black, had lowere SES scores and were less commonly married than their male counterparts. Females less commonly had commercial insurance. Females a higher rate of avoidable ED visits when adjusting for clinical variables in the final model (1.07(95%CI:1.01-1.13)). Marital status and SES dichotomized at the NYS mean acted as confounders in the association between female gender and outcome.

Conclusions: Females had a higher rate of avoidable ED visits than males in a cohort of low SES, mostly minority patients on hemodialysis in the Bronx. Potential contributors to this association include marital status, SES and overall clinical status.

Association of gender and avoidable ED visits

Gender	Unadjusted IRR	95%CI	IRR adjusted for socio-economic variables	95%CI	IRR adjusted for clinic-anthropomorphic variables	95%CI	IRR adjusted for all variables	95% CI
Female	1.05	0.99-1.12	1.04	0.97-1.02	1.07	1.01-1.13	1.07	1.04-1.13

PUB252

Dry Weight and Intra-Dialytic Weight Gains Vary by Season, but Ultrafiltration Rates Remain Stable in Long-Term Hemodialysis Patients

Priyanka Wani, Andrew I. Chin. *University of California Davis, Sacramento, CA.*

Background: In long-term hemodialysis (HD) patients, ultrafiltration (UF) rate is a function of intra-dialytic fluid weight gain (IDWG), dry weight (DW) and dialysis duration. IDWG and DW are known to vary according to the season of the year. UF rate, a measure that is being considered as a quality measure by regulators, may also vary seasonally; this may affect its appropriateness as a reportable measure.

Methods: We looked at a stable cohort of HD patients located in an urban area in a temporate climate zone, all of whom dialyzed for a 12 month period. We examined all post-HD weights (assumed to be DW), dialysis times, IDWGs and UF rates (mL/min/kg) for each subject. Seasons were defined as the month of the HD: Autumn=Sept-Oct-Nov; Winter=Dec-Jan-Feb; Spring=Mar-Apr-May; Summer=Jun-Jul-Aug. Differences in DW, IDWG and UF rate amongst seasons were analyzed by paired T-testing.

Results: 239 patients with complete HD treatment information for 2014-2015 were used in the analysis. Dry weight rose through the autumn and winter seasons, peaked in the spring, and decreased in the summer season. IDWGs followed a very similar pattern through the seasons, almost mirroring the change in DW (See Figure 1). DW and IDWG were both statistically different between the autumn and winter seasons, as well as between the autumn and spring seasons. UF rate, calculated as IDWG ÷ treatment time ÷ DW, was not statistically different across the 4 seasons, not surprising given that the DW and IDWG varied in the same direction and to a similar degree.

Conclusions: In stable HD patients, even though IDWG increased in certain seasons of the year, UF rate did not change because DW increased as well. We found that the seasonal variation of DW and IDWG followed a very similar pattern and magnitude of change. Therefore, UF rate remains fairly stable over the seasons of the year. As a quality measure, UF rate may not be significantly affected by the time of year when it is reported. These findings may differ in different climate zones.

Accuracy of Resting Metabolic Rate Prediction Equations in Persons on Maintenance Haemodialysis in Trinidad and Tobago

Patrice R. Prout, Selby Nichols. Human Nutrition Group *The University of the West Indies, St, Augustine Trinidad, Port of Spain, Trinidad and Tobago.*

Background: Establishing energy requirements is crucial in estimating nutritional needs and preventing malnutrition among persons with chronic kidney disease on haemodialysis. The study evaluated the accuracy of four commonly used resting metabolic rate (RMR) prediction equations among persons on maintenance haemodialysis (MHD).

Methods: Following informed consent and enrolment, participants had anthropometry and RMR measured using standard procedures. RMR predicted prediction equations were compared to that measured by indirect calorimetry using the Med Gem® device (microlife, USA). Anthropometry was measured using recomended procedures. Participation was voluntary. The study was approved by the Ethics Committee, The University of The West Indies..

Results: Sixty-five persons 50 to 65 years (females = 33; males = 32) participated in the study. Mean measured RMR was significantly higher in males than females (1373 ± 288 vs. 1222 ± 228; p = 0.02). RMR computed from predictive equations were significantly higher in males compared to females. There were no significant differences in RMR per kg of body weight or fat free mass between males and females. Overall, mean measured RMR was 20.1±5.0 per kg of body weight. The mean accuracy of predictive equation was significantly lower in males than females (39.1% ± 2.7% vs. 45.0% ± 4.3%; p <0.001). The level of RMR prediction equations underestimation (51.6% ± 2.7% vs. 39.4% ± 8.1%; p <0.001) and overestimation (16.7% ± 4.4 vs. 9.4% ± 2.2%; p <0.001) was higher in males than females.

Conclusions: RMR predictive equations had low level of accuracy with measured RMR. The level of accuracy was different for males and females. There is a need to develop sex-specific RMR prediction equations that improve the accuracy of estimating RMR among persons on MHD in this population.

PUB254

Lung Ultrasound in Maintenance Hemodialysis Patients Close to Dry Weight

Jose S. Lopez Gil,[1] Gabriela Leal,[1] Octavio Garcia,[1] Hector A. Perez-grovas,[1] Luis A. Garcia.[3] National Heart Institute México [1]*Instituto Nacional de Cardiología, México, Mexico;* [3]*Universidad Nacional Autónoma de México, México, Mexico.*

Background: Fluid overload is associated with adverse cardiovascular events in hemodialysis patients. Lung ultrasound has been validated in patients with excessive fluid overload, nevertheless in patients close to dry weight has not been validated. The aim of our study is to evaluate the utility of this method in this type of patients

Methods: Eighty hemodialysis sessions were examined, we divided the total population into two groups according to fluid overload estimated with a cut point of 1.5 liters, we realized a lung ultrasound (scanning for B-lines in 28 quadrants), NT-proBNP determination and multifrequency total body and thoracic bioimpedance extracellular water/body water ratio. Blood pressure, heart failure symptoms (dyspnea, orthopnea), hemoglobin delta and relative blood volume were measured by blood volume monitoring in BVM module of 5008 Fresenius

Results: 63% (17) of the patients corresponded to the female and the rest to male 37% (10). Mean age of the population was 42 ± 16 years. The vintage time of patients with hemodialysis was 3.6 ± 2.9 years. 30% (8) of the patients presented symptoms before the hemodialysis session. Up to 67% (18) of the patients b lines were observed before hemodialysis. In the setting of bioimpedance, the mean difference both total body to thoracic shows statistical significance as well as hemoglobin delta and blood volume circulating

Conclusions: B lines determination in patients close to dry weight they did not show statistical significance, nevertheless it iss important to highlight in the without fluid overload group, 4/20 patients with history of pulmonary hypertension had 9±3 B lines, we concluded that in later studies these patients could be excluded.

X±SD	Without fluid overload	Fluid overload	P-value

Successful Pregnancy in an ESRD Patient Receiving Intensive Hemodialysis

Rachid Daoui,[1] Victoria J. Phillips,[1] Shenthuraan Tharmarajah.[2] [1]*Nephrology, Saratoga Hospital, Saratoga Springs, NY;* [2]*Albany Medical College, Albany, NY.*

Introduction: In women with end stage renal disease (ESRD), the chances of both conception and pregnancy maintenance are low and associated with high rates of adverse maternal and neonatal outcomes. Past studies have highlighted residual renal function, early diagnosis of conception, and intensive hemodialysis for improved pregnancy outcomes. The literature still questions the optimum management of pregnant women with severe renal impairment as well as effective incremental dialysis dosing in this group. We report here a case of a stable hemodialysis patient with two live births two years apart, the latter being successful due to intensive hemodialysis.

Case Description: A 35-year-old woman (gravida 4, para 0) with ESRD on chronic in-center hemodialysis since 2015 was found to be pregnant in December 2016. Her 3 previous pregnancies had spontaneously aborted in the first trimester. Despite being recommended intensive hemodialysis 6 days a week, 6 hours per session, the patient did not follow these recommendations, and her son was born at 30 weeks with complications of prematurity and died at 4 months of age. In August 2017, the patient had positive blood and urine hCG levels and began intensive hemodialysis 6 days a week, 6 hours per day. In March 2018, an emergent C-section at 34 weeks produced a healthy 2200-g baby girl requiring only initial CPAP and encouragement to feed. The patient's hemoglobin level remained stable, blood pressure was well controlled without medication, and potassium level remained within normal range. The patient's phosphorus level declined and required supplementation. To date, the baby is 2 months old and healthy.

Discussion: Our case demonstrates a successful pregnancy in a patient of advanced maternal age and minimal residual renal function on intensive in-center hemodialysis. This case is unique due to the patient's older age involving two pregnancies with different outcomes, illustrating the importance of intensive hemodialysis in optimizing the maternal milieu early in pregnancy. We thus recommend that intensive hemodialysis be considered as a viable option for dialysis patients considering pregnancy.

PUB256

Is Central Venous Oxygen Saturation Decline During Hemodialysis Always Associated with Ultrafiltration?

Diana Aguirre,[1] Armando Vazquez Avila,[1] Daniel E. Ayala,[1] Jesus Arellano,[1] Luis A. Mariscal,[2,1] Victor H. Gomez,[1] Israel Campos.[2,1] *[1]Hospital General "Dr. Miguel Silva", Morelia, Mexico; [2]NausLife Hemodialysis Clinics, Morelia, Michoacán, Mexico.*

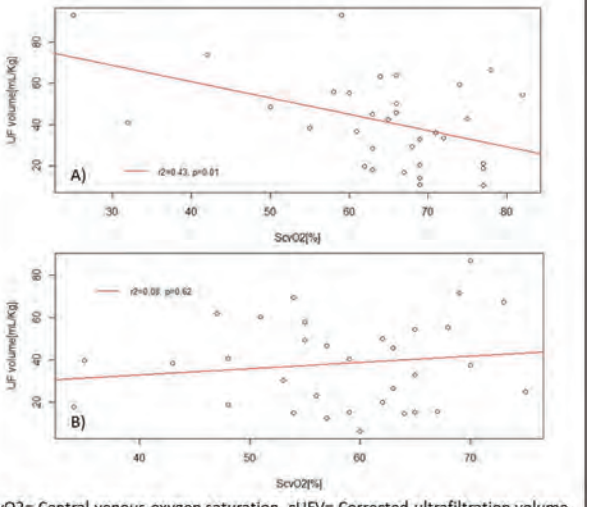
Background: Ultrafiltration volume inversely correlates with central venous oxygen saturation (ScvO2) during hemodialysis (HD). The effect of intra-dialytic exercise (IDE) on ScvO2 is unknown. The aim of this study was to explore the correlation between ScvO2 and corrected ultrafiltration volume (cUFV) during HD with and without intra-dialytic exercise.

Methods: Crossover study in maintenance adult HD patients. The cUFV (ultrafiltration volume/post dialysis body weight) reported in mL/Kg was computed through HD treatment at 60, 120 and 180 minutes, ScvO2 by gas analyzer was measured at the same time points, both were obtained during one HD treatment without IDE, then repeated in one HD treatment with IDE. The ScvO2 and cUFV correlation was estimated by Pearson's equation.

Results: 11 patients (22 HD treatments) were analyzed. The ScvO2 mean ±SD for all time points during HD treatment without and with IDE were 64 ±12.3% and 58.3 ±9.9%, p=0.04. The cUFV mean ±SD for all time points during HD treatment without and with IDE were 41.7 ±21.8 ml/kg and 38.2 ±20.6 ml/kg, p=0.57. Pearson's correlation moment between ScvO2 and cUFV during HD without and with IDE is reported in figure 1.

Conclusions: The mean value of ScvO2 during intra-dialytic exercise is lower compare to a non-exercise treatment. As expected, there is an inverse correlation between ScvO2 and corrected UF volume during a non-exercise HD treatment, this correlation is lost during intra-dialytic exercise. ScvO2 decline during intra-dialytic exercise is not associated with ultrafiltration volume.

Figure 1. ScvO2 and cUFV correlation during HD with and without intra-dialytic exercise.



ScvO2= Central venous oxygen saturation, cUFV= Corrected ultrafiltration volume

PUB257

Preoperative Systolic Blood Pressure Is an Independent Risk Factor for Aortic Valve Replacement in Hemodialysis Patients

Hidekazu Moriya, Rikako Oki, Yasuhiro Mochida, Kunihiro Ishioka, Sumi Hidaka, Takayasu Ohtake, Shuzo Kobayashi. *Shonan Kamakura General Hospital, Kamakura, Japan.*

Background: Calcified aortic stenosis is a common complication in hemodialysis (HD) patients and the progression speed of stenosis in HD patients is faster than that in non-dialysis patients. Prognosis of HD patients with aortic stenosis is poor and the choice of surgical aortic valve replacement (AVR) is subject to debate. However, there are few studies regarding prognosis and its risk factor for AVR.

Methods: We had a single center retrospective study. Thirty HD patients with aortic stenosis were performed by AVR from January 2009 to September 2013 in our hospital. We investigated blood pressure, serum albumin, cardiac echo findings (EF, AV pressure gradient, AV area) before AVR and intra-operating findings (bleeding volume, in-out balance, transfusion volume, operation time, aortic cut-off time, cardiopulmonary bypass time).

Results: Age of 30 patients (male 19, female 11) was 71.6±6.3 years old. Average duration of HD was 156 months. Diabetes mellitus was 10/30. AV area, AV pressure gradient and EF were 0.75±0.20cm^2, 67.3±35.0mmHg, 54.0±12.8%, respectively. 30-day mortality was 16.7% (5/30) and the causes of death were sepsis, gastrointestinal bleeding, pneumonia and cardiac failure. In-hospital mortality was 33.3% (10/30) and 1 year survival rate was 60%. Risk factors of in-hospital death from AVR were systolic blood pressure, cardiopulmonary bypass time and bleeding volume in univariate analysis. However, multivariate regression analysis showed that systolic blood pressure was an independent risk factor (hazard ratio [HR], 0.94; 95% CI, 0.91 to 0.98; p=0.043).

Conclusions: Low blood pressure is an independent risk factor of AVR in HD patients with aortic stenosis. AVR should be considered while HD patients maintain blood pressure.

PUB258

Low Serum Albumin and Hospitalization Among ESRD Patients on Dialysis

Abdulhadi T. Gelaidan,[1] Adil Ghaffar,[1] Robert Mark Black,[1] Orhan Efe,[2] Bharat S. Bhandari.[1] *[1]Saint Vincent Hospital, Worcester, MA; [2]St Vincent Hospital, Worcester, MA.*

Background: Patients on hemodialysis (HD) have disproportionately high hospitalization and readmission rates. Although several factors contribute to this relatively high hospitalization rate, albumin has been consistently seen as a marker and we looked at this association at our HD center.

Methods: A retrospective cohort study was conducted at Saint Vincent Hospital, Nephrology dialysis center, from March 1, 2017 to Febraury 28, 2018. Our sample was comprised of 72 patients. The inclusion criteria were; A) ESRD patients aged > 18 years old. B) On dialysis treatment for > 12 months. Exclusion criteria were; A) Deceased ESRD patients before February 28, 2018. B) Those transfered to other dialysis center. C) Post renal transplant. Hypoalbuminemia was defined as albumin < 3.9 g/dL. Hospitalization was defined as hospital admission at least once during study period. The mean of serum albumin was calculated in two different ways. First; the average of albumin for 12 months for each subject and second; the average of quartiles (each quartile include four consecutive months). We evaluated the association between serum albumin, history of diabetes mellitus and hospital admission by using Chi-square test with a significant p-value level of <0.05.

Results: Out of 72, 59 dialysis patients met the inclusion criteria. The rate of hospitalization was 55.9 %. The mean of serum albumin level during the study period among hospitalized and non-hospitalized dialysis patients were 3.62g/dL and 3.96g/dL, respectively. Dialysis patients with mean of serum albumin (average of 12 months) < 3.9 g/dL had a higher percentage of hospital admissions (66.7 %) (P-value=0.006). The mean of serum albumin (average of four quartiles of the study duration) < 3.9 g/dL had a higher percentage of hospital admissions (66.6%) compared to dialysis patients with mean albumin level equal or more than 3.9 g/dL (33.4 %) (P-value=0.003). The dialysis patients with a history of diabetes mellitus had a higher percentage of hospital admissions (60.6%) compared to dialysis patients without diabetes (39.4 %) (P value=0.01).

Conclusions: There is a statistically significant association between mean serum albumin less than 3.9 g/dL, diabetes mellitus and hospitalization among dialysis patients. Further studies should be considered to evaluate the possible causal relationship of these factors

PUB259

Dialysis Nurse Driven Bedside Assessment of Peripheral Vascular Disease in Indian Dialysis Patients: A Quality Improvement Project

Paras Dedhia,[1] Rachana H. Jasani,[1] Viswanath Billa,[2] Shrirang Bichu,[3] J. Kothari,[4] Rajesh B. Kumar.[1] *[1]Apex Kidney Care, Mumbai, India; [2]Bombay Hospital, Mumbai, India; [3]Bombay Hospital Near Liberty Theater New Marine Lines, Mumbai, India; [4]Hinduja Hospital,Healthcare & Apex Kidney Foundation, Mumbai, India.*

Background: Peripheral vascular disease (PVD) is highly prevalent in dialysis patients and associated with increased mortality and morbidity. Early identification and intervention may help to decrease morbidity and amputation in prevalent dialysis patients.

Methods: Peripheral vascular disease was screened by bedside ankle brachial index (ABI) using handheld Doppler by trained dialysis nurse. The ABI was calculated by the ratio of ankle systolic BP divided by arm systolic BP. Subjects were divided into 3 categories according to their ABI values; low (ABI < 0.9), normal (ABI 0.9-1.3), incompressible (ABI >1.4). Systolic BP in upper extremity was measured on brachial artery of the arm contralateral to vascular access and in lower extremities on posterior tibialis artery.

Results: Of the 281 subjects, 62 % were males. The average age was 53.5± 13.4 years. The average dialysis vintage was 3.3± 2.5 years. 31% had diabetes, 66 % had hypertension and 30 % had history of ischemic heart disease. 12 % reported history of smoking or tobacco use. Low ABI (<0.9, suggestive of atherosclerosis) was found in 12.5% subjects, normal ABI was found in 67.1% and incompressible ABI (suggestive of calcified vessels) was found in 20.3% subjects.

Conclusions: Peripheral vascular disease is fairly common in dialysis patients. Among dialysis patients, 1-in-3 had either low ABI or incompressible ABI. This calls for quality improvement initiative in each dialysis unit to screen and monitor for PVD by dialysis nurses and facilitate early referral for timely intervention.

PUB260

Diuretics: To Use or Not to Use? A Survey of Hemodialysis Patients' Willingness to Use Diuretics

Amanda A. Karasinski, Karthik M. Ranganna, Jesse M. Goldman. *Drexel University Hospital, Philadelphia, PA.*

Background: Chronic diuretics are empirically used to increase urine output (UO) in maintenance hemodialysis (HD) patients however conclusive evidence of benefit is lacking. Varied prescribing practices among nephrologists is evident from DOPPS data indicating that 0-84% of HD patients receive diuretics. DOPPS has reported a positive association

between residual renal function and diuretic use. Additionally, DOPPS showed improved survival in HD patients with greater daily urine output (UO) and lower interdialytic weight gain (IDWG).

Methods: An 8 item questionnaire was administered to HD patients at 3 dialysis centers in Philadelphia, PA. Demographic and patient characteristics collected included: age, gender, ethnicity, dialysis vintage, estimated daily UO, willingness to use diuretics and frequency. Data was analyzed using STATA v.13.

Results: Seventy four participants (42 male) were surveyed with mean age 59.4±12.6 years. Mean time on HD was 4±4.7 years with a mean UO of 196±288.6 cc daily. 65 were African Americans, 6 Hispanics, 2 Asians and 1 Caucasian. 15/74 (20%) surveyed were already receiving diuretics with a mean UO of 319±391.9 cc daily. The remaining 80% (59/74) not on diuretics had a mean UO of 164.5±250.7 cc daily. 31 patients surveyed, not on diuretics, reported a range UO of 0-60 cc daily. 9 patients on diuretics reported UO of 1L daily. A paired t test comparing UO among patients taking vs. not taking diuretics was statistically significant, $p<0.03$; if equal variance was assumed. Under an unequal variance assumption, the result was not statistically significant, $p<0.08$. See Table 1 for data on willingness of HD patients to take diuretics.

Conclusions: We discovered that the majority of HD patients surveyed are willing to use diuretics. We anticipate that patients with shorter dialysis vintage and residual renal function will benefit most from diuretic therapy. This survey is a pilot investigation for a large, prospective cohort study to determine the effects of loop diuretics on blood pressure, potassium, IDWG and quality of life in HD patients. We hope to define concrete parameters for predicting diuretic benefit in dialysis patients.

Table 1

	Willingness to use diuretics	Unwilling to use diuretics
n (%)	51 (69)	23 (31)
Female n (%)	20 (62.5)	12 (37.5)
Male n (%)	31 (73.8)	11 (26.3)

PUB261

7-Day iPTH Predicts Long-Term iPTH, Deserves as All-Cause Mortality Risk Factor in Secondary Hyperparathyroidism Patients After Parathyroidectomy

Weichen Zhang,[1] Qian Zhang,[1] Minmin Zhang,[2] Mengjing Wang,[1] Bihong Huang,[1] Jing Chen.[1] *[1]Nephrology, Huashan Hospital, Fudan University, Shanghai, China; [2]Huashan Hospital, Fudan Univerisy, Shanghai, China.*

Background: Parathyroidectomy(PTx) is an effective therapy to treat secondary hyperparathyroidism(SHPT). Though lots of studies have proved that PTx reduces mortality of SHPT patients, the effect of different postoperative PTH levels on long-term prognosis remains controversial. The aim of this research is to evaluate the appropriate PTH level after PTx and find out early predictors which can contribute to better prognosis.

Methods: We collected secondary hyperparathyroidism dialysis patients who underwent parathyroidectomy in Huashan Hospital in 2004-2017. Patients' data before and after PTx were collected including short-term (day 1 to day 7) and long-term (month 3, 6, 9 and 12) biochemical data. The primary endpoint is all-cause mortality and the secondary endpoint is surgery for recurrence.

Results: Ninety-one SHPT patients were enrolled in this research. Compared with preoperative parameters, serum calcium, phosphorous, iPTH and ALP of SHPT patients after PTx decreased significantly($P<0.001$). During follow-up vintage, 12 patients died and one patient had surgery because of recurrence. After PTx, postoperative iPTH rebounds within 3 months and then comes to a stable level. All patients were divided into three groups according to one-year average postoperative iPTH below 46 pg/ml or above 130 pg/ml. Of all parameters after PTx, all-cause mortality($P=0.046$) is significantly different among three groups. Kaplan-Meier curve shows that patients whose postoperative iPTH in the range of 46-130 pg/ml have the lowest all-cause mortality while those with postoperative iPTH<46 pg/ml have the highest mortality rate ($P=0.023$). Cox regression analysis also confirmed that low postoperative iPTH level is a risk factor of all-cause mortality in SHPT after PTx($P=0.036$, HR=0.086, 95%CI=0.009-0.848). In addition, patients in one-year iPTH<46pg/ml group have a lower 7-day iPTH levels comparing to those in one-year iPTH>46pg/ml group($P=0.001$). The ROC curve analysis results in 5 pg/ml of 7-day iPTH as a cut-off value (AUC=0.751, P=0.003).

Conclusions: SHPT patients with 7-day iPTH>5pg/ml have a higher rate to reach the proper iPTH level (one-year iPTH>46pg/ml). Low postoperative iPTH level is a risk factor of all-cause mortality in SHPT after PTx.

PUB262

Managing Severe Hypertension in a Patient on Hemodialysis – Combined Efforts of Physicians and Care Giver

Prof Narinder P. Singh, Swapan Deep Singh Nagpal, Anish Gupta. *Max Super Speciality Hospital, Ghaziabad, India.*

Introduction: Over 50% of CKD patients on hemodialysis have hypertension; more than half failing to achieve blood pressure goals. Despite optimum medications, patient may have uncontrolled hypertension. Non-pharmacologic methods and changes to dialytic approach may help in achieving the desired targets. The physician must remember four guiding principles: dietary sodium restriction, individualizing dialysate sodium, management of dry weight goals and adequate duration of dialysis. We present a chronic kidney disease patient on hemodialysis with severe uncontrolled hypertension. The combined efforts of the care-giver, treating physician and hypertension specialist resulted in better control of BP.

Case Description: A 68 year old male known hypertensive, diagnosed with ESRD, on hemodialysis for four years, presented with resistant hypertension and extreme intradialytic BP surges (SBP 240 mmHg). Various classes of antihypertensive medications at optimal doses had been tried, with dismal results. Many fruitful discussions took place among the care-giver, treating physician and hypertension specialist. Cumulative efforts led to changes in the treatment. The number of sessions of dialysis were increased from two to three per week; the duration of each dialysis increased from four hours to five hours. The dry weight goals were modified. Bio-electrical impedance analysis was used to detect over-hydration; daily fluid intake and ultrafiltration volume were modified. The dialysate sodium concentration was reduced from 135mEq/L to 134mEq/L. Anti-hypertensive medications were modified – intra-dialytic anti-hypertensive was switched from metoprolol to carvedilol(due to negligible intradialytic clearance of the latter); and pre-dialysis nifedipine was replaced with binedipine(a drug that shows prolonged depressor effect likely due to its high affinity for the dihydropyridine receptor). BP readings showed marked reduction and considerable drop in intradialytic surges.

Discussion: The case presents an insight into the perplexity of management of hypertension in patients with chronic kidney disease, more so in those on hemodialysis. Many such patients have resistant hypertension and are inadequately treated. A holistic approach, combining non-pharmacological means and inputs from the care giver, and treating physicians, may benefit such patients.

PUB263

Feasibility of Hemodilution Detection Following Extracorporeal Saline Bolus Injections Using Crit-Line® in a Clip (CLiC®)

Mirell Tapia, Xia Tao, Stephan Thijssen, Peter Kotanko. *Renal Research Institute, New York, NY.*

Background: Decreased cardiac output (CO) during hemodialysis increases the risk of sudden cardiac death, for this reason, CO monitoring is needed. The indicator dilution method used to measure CO with the Stewart-Hamilton equation is well established and currently in use. The aim of this pilot study is to demonstrate if CLiC® can detect a hemodilution signal induced by injections of saline boluses (SB) in the extracorporeal circuit. Data will support further exploration of the potential practical use of CLiC® to measure CO.

Methods: An ultrafiltration goal (UF) was prescribed, then, 120 mL were added to account for the SB. After a run-in period of 15 minutes, 3 SB in sequential volumes of 30 mL, 20 mL and 10 mL, each separated by 5 minutes, were infused into the arterial drip chamber, and 3 SB were infused in the same manner into the venous drip chamber. CLiC® data were recorded from the beginning of the session until 5 minutes after the last SB. Hemoglobin versus time data were plotted and further analyzed. Hemodilution curve was transferred into peak signal calculating the absolute change in hemoglobin with the baseline set to zero before the injection of saline.

Results: The above protocol was studied in 4 HD patients. CLiC ® was able to detect the hemodilution signal after SB injection and also the returning signal after cardiopulmonary recirculation. This was true for all three SB volumes studied.

Conclusions: The ability of the CLiC® to detect the hemodilution signal after the infusion of SB provides the opportunity to explore the applicability of this device in terms of attaining a more comprehensive hemodynamic monitoring during HD.

Funding: Commercial Support - Fresenius Medical Care. Renal Research Institute

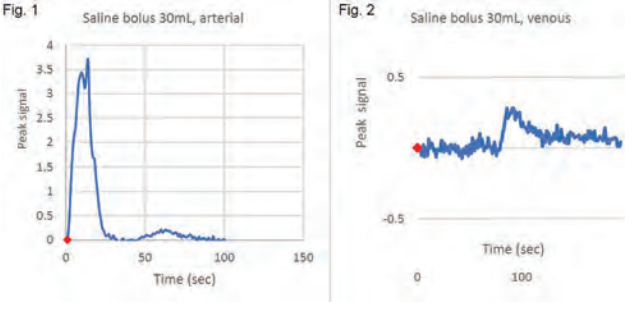

Fig. 1 Injection: arterial drip chamber. The first peak represents the hemodilution signal after the SB passes through the CLiC® for the first time, the second peak represents the return of the signal after cardiopulmonary recirculation.Fig. 2 Injection: venous drip chamber. The peak represents the hemodilution signal returning to the CLiC® after cardiopulmonary recirculation.

*Red marker indicates the time of injection of SB.

Nephrologists' Opinion Regarding Rationing Strategies in Hemodialysis Facilities During a Supply Crisis in Brazil Caused by a Truck Drivers' Strike

Jose A. Moura Neto,[1] Ana Flavia Moura,[4,2] Gustavo Moreira Tavares,[3] Constanca Cruz,[2] Jose Moura Jr..[4] *[1]Hemodialysis, CSB Group of Nephrology, Salvador, Brazil; [2]Bahiana School of Medicine and Public Health, Salvador, Brazil; [3]Brazilian School of Public and Business Administration - FGV, Rio de Janeiro, Brazil; [4]Grupo CSB, Salvador, Brazil.*

Background: Brazil has an internal transportation and supply system dependent on highways. Due to the rising price of diesel, a truck drivers' strike occurred in May 2018 affecting the entire country. Roadblocks occurred at more than 500 locations in 24 Brazilian states. With the interruption of distribution of healthcare supplies, a major concern emerged: how to avoid the lack of materials in dialysis facilities? Knowing that the discontinuation of dialysis would lead to the death of patients, dialysis facilities chose to adopt rationing strategies.

Methods: We conducted a survey with nephrologists in Brazil about their opinion regarding rationing strategies in dialysis facilities. First, we asked about their willingness to adopt rationing strategies and the timing of initiation of these strategies. Then, we asked which strategies would be first implemented and which would be the last strategy adopted.

Results: A total of 50 nephrologists answered our questionnaire. 44% of them were medical directors of dialysis facilities, and the majority (62%) were male. The mean age was 43.8 years (*SD* = 10.90). 50% would start rationing strategies immediately after the supply discontinuation, and 40% would adopt rationing strategies only when the internal inventory levels were considered low. No respondents disagreed about the need to adopt rationing strategies. Among the strategies to be adopted at the beginning, the reduction of the dialysate flow (chosen by 68% of respondents) and the reduction of the treatment time (chosen by 52%) were most common. The reduction of hemodialysis frequency from thrice- to twice-weekly was avoided and considered the last rationing strategy by 84% of nephrologists. Additional regression analyses revealed that female respondents adopted significantly fewer rationing strategies simultaneously than male (b = -.44, SE = 0.12, p < .01). This result is robust after controlling for respondent age and function.

Conclusions: All nephrologists considered adopting rationing strategies in the context of a supply crisis affecting the healthcare system. Among the strategies, the reduction of the dialysate flow and the reduction of the treatment time were the most common. Reduction of hemodialysis frequency was the last rationing strategy to be adopted.

PUB265

Relationship Between Ambulatory Blood Pressure Monitoring, Status Fluid, and Cardiac Function in Hemodialysis Patients

Soraya Abad,[1] Nicolás Macías,[3] Almudena Vega,[2] Esther Torres aguilera,[4] Ines Aragoncillo,[5] Jose Luno.[6] *[1]Hospital Gregorio Marañon, Madrid, Spain; [2]Hospital Gregorio Marañón., Madrid, Spain; [3]HGUGM, Madrid, Spain; [4]H.G.U. Gregorio Marañon, Madrid, Spain; [5]Hospital Gregorio Marañón, Madrid, Spain; [6]Hospital General Universitario Gregorio Marañón, Madrid, Spain.*

Background: Hypertension is a cardiovascular risk factor common in hemodialysis (HD) patients, correlates with left ventricular hypertrophy. Volume overload is the main cause of hypertension in this patients. Aim: Determine the relationship between ambulatory blood pressure monitoring (ABPM), status fluid and cardiac function in HD patients.

Methods: In a cross-sectional study, 24 chronic HD underwent ABMP 44hours. To assess cardiac function, an echocardiogram was performed. The hydration status was evaluated by bioimpedance spectroscopy (BIS) and the brain natriuretic peptide (BNP). Hypertension was defined according to the recommendations of JNC 8, with values higher than 140/90 mmHg, which correspond to values of 135/85 mmhg in ABPM according to ESH/ESC guidelines.

Results: The mean age was 59.5 ± 17.6 years, 62.5%. The mean daytime BP of 134 ± 25/77 ± 11 mmHg, daytime pulse pressure (PP) 56 ± 17 mmHg, mean nighttime BP 132 ± 25/73 ± 13, night PP 57 ± 17 mmHg. 22.7% of patients had a dipper pattern. 13 patients received antihipertensive drugs, the mean of antihipertensive drugs was 1.25 ± 1.11. Patients with mean BPS (44 h), daytime> 135 mmg and nocturnal BPS> 120 mmhg had a higher predialysis BPS (147 ± 20 vs125 ± 18 mmhg, 147 ± 19vs125 ± 18 mmhg and 145 ± 18 vs122 ± 20mmHg p < 0.05). Mean BPD (44h)> 85mmhg and nocturnal BPD> 70mmhg had a lower TAPSE in echocardiogram (16.8 ± 0.17vs22.2 ± 3.9 and 17.9 ± 2.5vs23.7 ± 2.7 p <0.005), which is related to dysfunction of right ventricle. Average PP (44h), daytime and nighttime levels> 50mmHg had higher fluid overload, expressed as overhydration (liters) (2.1 ± 1.1vs.1 ± 2.2, 2.1 ± 1.1vs-0.1 ± 2.2 and 1.9 ± 1.3 vs -0.1 ± 2.5 p <0.05), as adjusted for extracellular water (12.1 ± 5.6vs0.7 ± 13.7, 12.1 ± 5.6vs0.7 ± 13.7 and 11.14 ± 6.5 ± 0.6 ± 15.3) and higher BNP (ng / L) (922 ± 836vs114 ± 122, 922 ± 835vs114 ± 122 and 824 ± 835vs129 ± 130, p <0.05). The patients who received antihypertensive drug were younger (51 ± 19 vs 69 ± 11 years) had a higher mean TAD (80 ± 10 vs 69 ± 11 mmHg, p <0.05) and higher daytime BPD (83 ± 9 vs 70 ± 11mmhg, p <0.05).

Conclusions: Elevated values of PAD correlate with right ventricular dysfunction. Overhydrated patients present higher pulse pressure. The dry weight adjustment can help control PP, which is a cardiovascular risk factor.

PUB266

Safety and Adequacy of NxStage® Home Dialysis Machine Providing Acute Dialysis in a Rural Hospital

Mirjana Dimitrijevic, Keith A. Bellovich, Quresh T. Khairullah, Joel M. Topf, Heather L. Henderson. *St. John Hospital Medical Center, Detroit, MI.*

Background: The NxStage® home dialysis system is a simplified system designed for use by patients for home hemodialysis (HD). We evaluated the safety and adequacy of the NxStage® One S machine in a rural hospital. This hospital was unable to provide standard HD for patients in a low volume acute care setting, due to the cost of trained staff and the low volume of patients. By training registered nurses and technicians from the general care unit on the NxStage® machine, the hospital was able to continue to take care of dialysis patients rather than transfer them from their community.

Methods: In this observational, prospective study, patients who needed HD while hospitalized at Mid-Michigan Medical Center, Alpena, MI, were enrolled. Inclusion criteria: Patients with end stage renal disease (ESRD) or acute kidney injury (AKI) requiring dialysis. Exclusion criteria: Patients with drug overdose or poisoning. Data points collected included adverse events, dialysis flow sheets, hemoglobin, calcium, phosphorus, pre and post blood urea nitrogen, creatinine, and potassium. Prescribing guidelines were obtained from the dosing calculator NxStage.com. Adverse events (AE) were classified as mild or severe. Mild was defined as any intradialytic event that required intervention from the staff but did not require discontinuation of the treatment. Severe was defined as any intradialytic adverse event that required discontinuation of treatment.

Results: Twenty-seven patients were recruited and completed a total of 74 dialysis treatments over a 12-month period. The mean age was 66.2 years (STD +/- 15.7), 63 % were male, and 96 % Caucasian. Seventy three percent of patients had an AVF, 7 % AVG, and 10 % CVC. The average single treatment Kt/V achieved was 0.54 -1.07 per treatment. The average duration of treatment was 4.5 hrs. Admission diagnoses included: CHF, COPD, debility, hip fracture, ESRD, GI bleed, pneumonia, peritonitis, bacteremia, small bowel infarction. Mild AE's occurred in 18.5% of runs. There were no severe adverse events.

Conclusions: The NxStage® One S system provides safe and adequate acute dialysis. This system can be a viable alternative to a standard HD machine in a rural hospital.

PUB267

Characterization of Intradialytic and Interdialytic Cramping in Patients with ESRD

David Golod, Glenn F. Short, Brooke W. Hegarty, Donna Cabral-Lilly, William McVicar, Tom Wessel. *Flex Pharma, Boston, MA.*

Background: Muscle cramping is a common complication of hemodialysis that has been reported by 35-80% of End Stage Renal Disease (ESRD) patients as one of the leading reasons for interruption or early termination (approximately 18%). The cause of intradialytic cramping has not been established, but this painful complication often leads to interventions that may impact the adequacy of hemodialysis, such as reduction in ultrafiltration rate, administration of normal saline or hypertonic normal saline solution, use of pharmacologic agents, and premature termination of hemodialysis sessions. The incidence of cramping during dialysis and the interventions to treat these cramps are not commonly or consistently documented by treating centers. Because of this gap, there is a need to better understand the impact that this complication has on the quality of life for ESRD patients suffering from intra- and interdialytic cramps, and the correlation to hemodialysis session attendance and adequacy.

Methods: Flex Pharma is initiating an observational study at three hemodialysis centers in the USA to obtain information to characterize muscle cramping in adult ESRD patients. This study will document the overall patient cramping prevalence at these centers and capture the muscle cramping history prior to study start and during dialysis sessions in approximately 24 patients that have a history of intradialytic cramping. To obtain this information, questionnaires will be provided to the general patient population at these centers to determine cramping prevalence. Patients previously identified to have intradialytic cramping that enter the study will complete questionnaires before and during hemodialysis sessions for four consecutive weeks to capture cramping information and the impact to their quality of life. In addition, the adequacy of hemodialysis session goals will also be analyzed by comparing the planned goals and patient health status (target dry weight, planned ultrafiltration rate, and vital signs) against the success, deviations, or interventions responsible for whether these goals are met.

Results: The results of this study are expected by the end of the year.

Conclusions: The results of this study are expected by the end of the year.

Funding: Commercial Support - Flex Pharma

PUB268

Operationalizing Telemedicine for Home Dialysis Patients

Susie Q. Lew, Neal Sikka. *George Washington University, Washington, DC.*

Background: Starting in 2019, CMS will reimburse 2 out of every 3 monthly visits performed by telemedicine (TM) for home dialysis (D) patients (pts). The aim is to explore steps required to operationalize TM for home D pts

Methods: We analyze the regulatory requirements for a comprehensive monthly visit conducted by TM & offer recommendations on operationalizing monthly visits for the pt, practitioner, & D facility

Results: The regulatory requirements are: -Providers may use & bill for TM encounters with ESRD pts from their home or a dialysis facility when using 2 way interactive video conferencing (VC) -D pts must receive in-person assessments monthly for the 1st 3 months of home D & at least once every 3 months thereafter -If home is the originating

site, the facility may not bill for a facility fee Operational considerations for TM include: **-Licensing**: Practitioners must be licensed in the state where the pt is located (originating site) **-Credentialing**: If the pt is originating from a health facility, the practitioner must be credentialed & have privileges for the health facility **-Risk management**: Practitioners should check with the state regulatory agencies where the pt is located & one's own insurance policy to ensure coverage for TM visits **-Technology adoption & utilization**: Acquire & deploy encrypted platforms to ensure HIPAA compliance. Ensure availability of equipment required for VC in the originating & distant sites. Acquire equipment to conduct a physical exam (stethoscope). **-Documentation requirements**: Items needed to document a monthly visit via TM encounter **-Reimbursement**: Be familiar with appropriate billing and location codes to indicate the encounter was conducted via TM -Additionally, A) develop a plan that facilitates pts obtaining monthly labs near their home & for the labs results be downloaded to CROWNWeb. B) Develop practice based policies & procedures for providing home TM to ESRD pts. C) Pending language from CMS regarding examining a home HD pt's vascular access

Conclusions: Home D pts may elect to have the monthly visits conducted by TM under the provisions of CMS guidelines. These virtual visits may improve compliance with appointment attendance & care plans. The implementation of TM involves new procedures & technologies as well as workflows for pts, practitioners & D facilities. A step wise approach to meeting all regulatory & operational requirements may improve opportunities for successful implementation.

PUB269

Seamless PD (sm)

Vincent J. Carsillo. *Capital District Renal Physicians, Slingerlands, NY.*

Background: A new program designed to facilitate and grow peritoneal dialysis for nephrology practices. Our integrated approach increases opportunity for patients to choose peritoneal dialysis. A multifaceted approach was used to allow patients who urgently needed to begin dialysis. These patients could not wait for a traditional peritoneal dialysis catheter to heal. Many of these patients were not candidates for "urgent start PD' as they are uncomfortable lying flat in the outpatient setting and wanted to begin training right away. In this new program, patients were given an integrated approach including education, nephrology, and specialized surgical services to facilitate rapid entry into a home program. Specific surgical technique was used to create immediate use peritoneal access. Patients were able to begin training within 24-48 hours of catheter placement.

Methods: 20 patients who presented with an urgent need to begin dialysis for newly diagnosed ESRD were assesed by nephrology. If the patient was interested in peritoneal dialysis, they were entered into the program and received an integrated approach by multiple providers. The patients received specialized surgical technique and a catheter which could be used immediately if necessary. The patient was admitted to a home dialysis program within 24-48 hours. Patients began training immediately in an upright seated position with full volume exchanges.

Results: Over a 14 month period, 20 patients received specialized education, speed to catheter placement and specialized surgical technique. Patients ranged in age from 31-79 years. Male to female ratio was 10:10 BMI ranged from 23-47. All patients began training within 24-48 hours of catheter placement. At 14 months, there have been zero episodes of catheter failure, zero peritonitis episodes, and zero exit site leaks. There was one hospitalization within 90 days of catheter placement. All patients were able to participate in their care and began training within 24-48 hours of catheter placement. 100% of these patients finished training in the outpatient setting. One of the patients changed modality.

Conclusions: We believe this program to be a safe and effective way for patients to enter peritoneal dialysis programs. SEAMLESS PD (sm) has clear benefits over "urgent start PD" both for the patient and the medical team. This program increases patients' options and allows home dialysis programs to grow while delivering high quality care at a lower overall cost.

PUB270

Potential Use of PhotoVoice for Assessing Peritoneal Dialysis Patients' House Environment

Piyaporn Towannang, Pongpratch Puapatanakul, Krit Pongpirul, Talerngsak Kanjanabuch. *Chulalongkorn University, Bangkok, Thailand.*

Background: PhotoVoice is a qualitative research technique, in which a picture is used as a tool for explaining a phenomenon of interest. As this technique can potentially be useful for assessing the house environment of peritoneal dialysis (PD) patients, this study aims to assess its potential use for differentiating the house environment of PD patients.

Methods: In January 2018, 15% of PD patients at King Chulalongkorn Memorial Hospital were randomly selected and sorted by the PD duration and number of peritonitis episodes then categorized into 3 ordinal groups: Best (long duration with no peritonitis), Median, and Worst (short duration with some peritonitis). One patient randomly selected from each group received home visit by our PD nurse. Pictures of various locations that might associate with PD outcome were taken. Cross-case analysis of the pictures was performed.

Results: Eight out of 51 PD patients were included and sorted. Best patient was a 45-year-old male underwent PD for 84 months, Median patient was a 78-year-old male on PD for 28 months, and Worst patient, a 67-year-old male had received PD for 22 months but already had 3 peritonitis episodes. Twenty, 25, and 18 pictures were taken from their house, respectively. The cross-case analysis revealed that the pictures of hand-wash sink, PD fluid storage area, and PD fluid exchanging area obviously vary across the three cases and, therefore, could be useful for differentiating house environment of PD patients.

Conclusions: PhotoVoice is a useful and simple tool for assessing PD patient's house environment. At least three house locations should be the main focus of any home visit.

Peritoneal Dialysis: An Equal V in Calculating Kt/Vurea Underestimates the Dose for Women

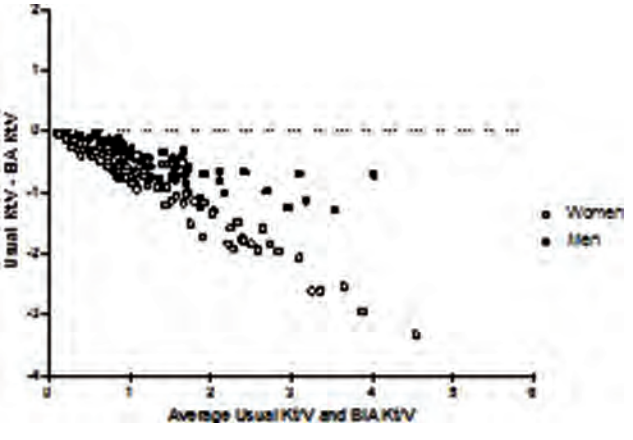
Gianella S. Lavanda,[1] Pablo A. Vale,[1] Luiz V. e Affonso,[1] Erica A. Guimarães,[1] Benedito J. Pereira,[2] Hugo Abensur,[3] Rosilene M. Elias,[3] Lilian Cordeiro.[1] *[1]Division of Nephrology, University school medicine of Sao Paulo, São Paulo, Brazil; [2]University of Sao Paulo School of Medicine, Sao Paulo, Brazil; [3]Universidade de Sao Paulo, Sao Paulo, Brazil.*

Background: Albeit PD technique and patient survival have been associated with residual renal function, the total amount of urea clearance (Kt/V) is recommended to be at least 1.7. The volume of distribution of urea (V) is based on total body water derived from anthropomorphic measurements, which certainly varies among patients.

Methods: To establish whether there is a difference in Kt/V, we compared V based on bioimpedance and V assuming 0.6 to all patients.

Results: A total of 170 Kt/V measurements were compared assuming V=0.6 x weight (usual Kt/V) and calculated using V obtained from the bioimpedance analysis (BIA Kt/V). We included incident patients on PD (50±18 years, 87 men); median diuresis was 440ml (from 100 to 1100ml). V from bioimpedance was 17.6±5.3 and 1.4±0.9L in women and men, respectively (p<0.0001), resulting in usual Kt/V and BIA Kt/V in the entire group of 0.93±0.62 and 1.63±1.12, respectively (p<0.0001). The usual Kt/V underestimated BIA Kt/V mainly in women, as shown in the Bland-Altman plot (Figure 1). We found no difference comparing BIA Kt/V between patients aging < or > 65 years old (p=0.736).

Conclusions: In PD patients, total body water calculated from bioimpedance allows a more reliable Kt/V calculation. Particularly for women, usual Kt/V underestimated the BIA Kt/V.



PUB272

Glycemic Control Before and After Starting Peritoneal Dialysis: A Single Center Case Series

Marc J. Kim,[1] Muhammad O. Hanif,[3] Ellie Kelepouris,[2] Suzanne Boyle,[2] Karthik M. Ranganna,[2] Sandeep Aggarwal.[2] *[1]Drexel College of Medicine, Ardmore, PA; [2]Drexel University College of Medicine, Philadelphia, PA; [3]Drexel University, PHILADELPHIA, PA.*

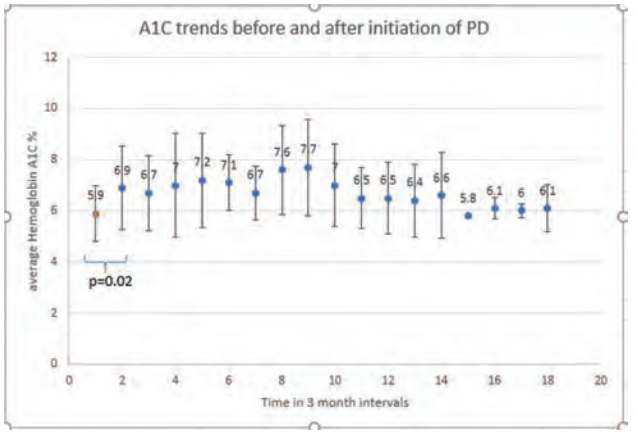
Background: Diabetes remains a leading cause of end stage renal disease in the US. Peritoneal dialysis because of glycemic load in the peritoneal dialysis fluid is often viewed as a potential risk factor for new onset or worsening diabetes. We present a case series

looking at hemoglobin A1c % pre and post initiation of peritoneal dialysis in our outpatient PD center and factors affecting it.

Methods: We collected data on nine PD patients, including demographics, medical history, BMI, pre-dialysis initation Hgb A1c and quarterly A1c levels after initiation of peritoneal dialysis. Average age was 51yrs, 7/9 patients were females. 3/9 patients had a diagnosis of T2DM before starting PD, 1 patient had a renal allograft failure as a cause of ESRD.

Results: There was a statistically significant difference in average pre-dialysis initiation Hgb A1c % vs post-dialysis Hgb A1c %, (5.9 +/- 1% vs. 6.8 +/- 1.5%, p = 0.02). The statistically significant increase in Hgb A1c level was noted only in the first quarter after which the Hgb A1c plateaued (figure 1). There was no statistically significant difference in BMI pre-dialysis initiation vs post-dialysis (29 +/- 10 vs. 30 +/- 9) or new diabetic medication use.

Conclusions: Our case series of 9 PD patients from a single outpatient PD center showed an initial increase in Hgb A1c after initation of PD, which plateaus immediately. Larger scale trials are required to look into the clinical and metabolic factors affecting glycemic control in peritoneal dialysis.



Hgb A1c % trends before and after initiation of peritoneal dialysis. Single center case series of nine patients. Orange circle represents average Hgb A1c% with SD vertical bars pre-dialysis. Blue circles represent average post-dialysis Hgb A1c% quarterly levels. Using Student's t-test there was a statistically significant difference in average pre-dialysis initiation Hgb A1c % vs post-dialysis Hgb A1c %, (5.9 +/- 1% vs. 6.8 +/- 1.5%, p = 0.02)

Ferritin Is a Predictive Factor for New Cardiovascular Event with Regards to a Therapeutic Strategy for Peritoneal Dialysis and Combined Therapy (PD+HD Hybrid) Patients

Hiroaki Io,[1] Yoshimi Sekiguchi,[1] Junichirou Nakata,[2] Masayuki Maiguma,[1] Masanori Ishizaka,[1] Hiroyuki Inoshita,[1] Takanori Nakano,[1] Yoko Matsuyama,[1] Yusuke Suzuki.[2] *[1]Juntendo University Nerima Hospital, Tokyo, Japan; [2]Juntendo University Faculty of Medicine, Tokyo, Japan.*

Background: Previous studies have reported that hypoalbuminemia showed definitely association with the degree of residual renal function (RRF) in peritoneal dialysis (PD) patients. The purpose of the present study was to analyze the predictive factors at the beginning of PD for a group that maintained RRF after 24 months, for PD persistence rate and cardio-vascular events (CVE).

Methods: The present study was retrospective and multicenter study with 132 PD patients. The predictive factors at the start of PD were analyzed between groups that maintained or lost RRF after 24 months. Furthermore, the predictive factors were also analyzed PD persistence rate and CVE.

Results: The group that lost RRF after 24 months had hypoalbuminemia and heavy proteinuria at the beginning of PD as compared to that of the group that maintained RRF. Patients with RRF had a better PD persistence rate when continuing not only PD therapy but also a combined HD with PD therapy than those without RRF (p<0.001) using a Kaplan-Meier method. The patients with past CVE (HR132.4, 95%CI3.420-5272.5) and high serum levels of ferritin (HR1.005,95%CI1.001-1.011) at the beginning of PD were independently associated with factors for new CVE after initiation of PD using a Cox regression analysis.

Conclusions: It is important to provide a strategy for PD indication in CKD patients with light proteinuria at the beginning of dialysis to maintain RRF and without past CVEs, low levels of ferritin to prevent CVEs after the initiation of PD.

PUB274

Peritoneal Ultrafiltration for Heart Failure - Experiences from a Randomised Controlled Trial

Hari Dukka,[1] Martin E. Wilkie,[4] Philip A. Kalra,[2] Christopher W. McIntyre,[3] Simon J. Davies,[6] Nicholas M. Selby,[5] Sunil Bhandari,[7] Maarten W. Taal.[5,1] *[1]Nephrology, Royal Derby teaching hospitals, Derby, United Kingdom; [2]Salford Royal Hospital NHS Trust, Salford, United Kingdom; [3]London Health Sciences Centre, London, ON, Canada; [4]Sheffield Teaching Hospitals, Sheffield, United Kingdom; [5]University of Nottingham, Derby, United Kingdom; [6]University Hospital of North Midlands, Stoke-on-Trent, United Kingdom; [7]Hull and East Yorkshire Hospitals NHS Trust and Hull York Medical School, East Yorkshire, United Kingdom.*

Background: Peritoneal ultrafiltration (PuF) is sometimes employed for advanced heart failure (HF) with intractable fluid overload, but evidence for its benefit is lacking. The Peritoneal Dialysis for Heart Failure (PD-HF) study was a multi-centre RCT that aimed to address this. However, the trial was stopped early due to inadequate recruitment. This abstract describes trial activity and reasons for the study's failure with the aim of informing future trial design.

Methods: The trial aimed to recruit 130 participants from six UK centres, who had severe HF (NYHA class 3 and 4) and CKD stage 3 and 4 on optimal medical treatment for ≥4 weeks defined as being on ACE inhibitor or ARB, beta blockers and screened for cardiac revascularization and /or resynchronization if appropriate. Participants who were diuretic resistant were randomised to conventional HF treatment or one overnight exchange of Icodextrin. Primary outcome was change in six minute walk test (6MWT), between baseline and 28 weeks (end of trial). Secondary outcomes were changes in cardiomyopathy questionnaire (Kansas city) results, SF 36 health survey results, hospitalisation and mortality.

Results: Over a two year period approximately 290 patients were screened, 20 were eligible for the trial of which 10 were recruited. Baseline characteristics of the recruited patients were: mean age 70.1±8.4, all had NYHA class 3 HF, mean 6 MWT of 181.3±49.6 m (one patient declined 6MWT), mean eGFR was 28.6±5.4ml/min/1.73m^2. Of the 10 patients who were eligible but did not participate, some felt PD was too difficult to cope with, some died before agreeing to participate or before being approached whilst others were too unwell. The reasons for the high number of ineligible patients was eGFR out of range (usually too high), frailty and not being on optimal HF treatment. The investigators identified reluctance of patients to consider invasive therapy and lack of coordination between cardiology and renal services as the main contributors to poor recruitment.

Conclusions: Lessons learnt from the PD-HF trial can be used in the planning of future studies in this area. It is clear that any future trial should plan to use a much larger number of sites to achieve recruitment targets and that coordination of cardiology and renal care is essential.

PUB275

High Transport State and Reduced Sodium Sieving in Cirrhotic Patients on Peritoneal Dialysis

Javier De Arteaga,[2] Edgard F. Ledesma,[1] Carlos Chiurchiu,[1] Walter Douthat,[2] Jorge de la Fuente.[1] *[1]Hospital Privado Universitario de Cordoba Argentina, Cordoba, Argentina; [2]Hospital Privado-Universitario de Cordoba, Cordoba, Argentina.*

Background: Peritoneal sodium sieving, an indirect measure of free water transport (FWT), is mainly the result of the osmotic conductance to glucose and the action of aquaporin channels. A high transport (HT) state and/or a plasma/ dialysate Na gradient > 5 mmol/lt, may counteract this sieving effect with sodium diffusion from plasma, and a diffusion correction applies. Upregulation of peritoneal aquaporins increases FWT in the kidney postransplant setting, related to steroid therapy (NDT 2011, vol 26) Cirrhotic pts are mostly HT with high UF and studies of FWT are not reported. **Objectives**: I) to evaluate results of sodium sieving (FWT) in 49 HT from 12/.2006 to 01/ 2017. Five patients are cirrhotic HT II) try to elucidate the possible causes of differences in sodium sieving between cirrhotics and other HTpts.

Methods: Patients : all consecutive high transport (HT) (4 hr D/P creat ≥0.81) pts in a single center since Dec.2006 till Jan.2017 (N =49 pts):.**Methods :** Minipets (lamilia2005) done yearly and when ultrafiltration changes.

Results: Results: GR1: HTcontrols: (N = 44): Gr 2: HTcirrhotic (N= 5). Table (1)

Conclusions: As compared to controls, NA sieving (FWT) is blunted and NA removal(NAR) is higher in cirrhotic patients. D0/D60min glucose is lower in cirrhotics P<0.006 pointing to a faster dissipation or more probably a dilution effect due to ascites generated " de novo".This effect could reduce the osmotic FWT. UF is higher in cirrhotics due to small pore water transport(UFSP)

Need Finding in Peritoneal Dialysis with Mobile Eye Tracking

Sandra B. Neumann. ETH Zürich (Federal Institut of Technology, Switzerland) *Peripal AG, Zurich, Switzerland.*

Background: In the German Code of Social Law V in §5 (7), paragraph a, the text states: "Only patients may be treated with "dialysis in a center", who need this type of dialysis due to their clinical picture. However, the reality looks quite different. This drawback was the motivation for a need finding study to find approaches to lower the access limitation to the peritoneal dialysis (PD) therapy, the most common home dialysis modality. The need finding study was conducted using mobile eye tracking with experienced and novice dialysis patients.

Methods: The dialysis patients were visited at home and accompanied in all therapy handling steps to gain insights of the user experience of PD from a first-person view. The data analysis was not limited to the single central therapy steps but included also the preparation phase and the therapy handling steps as a whole.

Results: In total, eight possibilities could be identified which promise to facilitate the access to home dialysis like a waste handling and managing system or a novel PD furniture. The most promising was a controller for PD which increases the safety against use errors and the comfort for the patient.

Conclusions: For many patients, the use of an auto-connect device could increase safety and ease of use for patients. In addition, it could enhance standardization of the therapy process. Based on the eye tracking results, feasibility was proven with a functional prototype and a start-up was initiated for the further development and market readiness of such a device, with the public launch targeted early 2018.

PUB277

Impact of Health Related Quality of Life Non-Renal Factors on the Life of Dialysis Patients: Should Mood Be the Focus?

Douglas rafanelle M. Motta,[1] Eduesley Santana-Santos,[2] Caio O. Bastos,[1] Andreia F. Menezes,[1] Kleyton A. Bastos.[1] *[1]Federal University of Sergipe, Lagarto, Brazil; [2]Nursing Department, Federal University of Sergipe, Aracaju, Brazil.*

Background: Chronic kidney disease patients often have compromised health related quality of life (HRQOL) while on dialysis. Mostly factors, either demographic, renal and non-renal associated with it, are not valued as they should in the management of such individuals.

Methods: We conducted a cross-sectional study between July and September 2013, with 215 patients on hemodialysis (HD) and 58 on peritoneal dialysis (PD) in order to evaluate HRQOL using the Kidney Disease Quality of Life- Short Form Instrument 1.3 (KDQOL-SF), and to identify factors associated with it, emphasizing the non-renal ones: mood, sleep disorders and sexual dysfunction.

Results: Patients had a mean age of 51 years, mostly men (62%), with low educational (72%) and socioeconomic levels (95%). The prevalence of depression (29%), anxiety (30%), poor sleep quality (56%), excessive daytime sleepiness (43%) and male (48%) and female (76%) sexual dysfunction was high. Models by confirmatory factor analysis showed that anxiety (p <0.01), depression (p <0.01) and lower education (p 0.01) were factors independently associated with lower HRQOL. It showed a higher prevalence of anxiety in HD patients (32%) and depression on those on PD (36%).

Conclusions: Ssearching for better HRQOL is complex and challenging and no variable should be neglected, especially in the most vulnerable groups such as those with less schooling. It is necessary for dialysis professionals to have a higher level of attention to the presence of anxiety, especially in HD patients, and depression, on those in DP, as mood disorders have a strong negative impact on HRQOL. Longitudinal and intervention studies are needed to confirm our findings and to assess whether the treatment of mood disorders can affect HRQOL of patients.

PUB278

PD PLUS Modeling with "Ideal" Dwell Times Predicts Adequate Kt/V and UF Without High Dextrose Solutions or Icodextrin

Corinne E. Zeller-Knuth, Rainer Himmele, Robert J. Kossmann, Dixie-Ann Sawin. *Fresenius Medical Care Renal Therapies Group, Charlotte, NC.*

Background: PD PLUS is an APD regimen with a mid- or late-day "PLUS" exchange with or without a last fill (LF). For high transporters, achieving UF goals can be challenging; for low transporters, achieving the Kt/V goal is a challenge. Using high dextrose (dex) or icodextrin dialysates can overcome this, but not without issues. This kinetic analysis modeled PD PLUS regimens that aimed to minimize total volume and dex exposure by utilizing a PLUS exchange (EX) with an "ideal" dwell time that targets max UF or Kt/V.

Methods: "Ideal" dwell times for maximum UF and Kt/V were determined for all PET transport categories with 1.5 and 2.5% dex dialysates using published data and algorithms derived from the PackPD® Program. Fifteen theoretical anuric patients were defined for modeling purposes by transport type (H, HA, A, LA, L) and patient size (S, M, L). The six modeled regimens (below) include overnight (ON) EXes with dwell times set at the predicted 1.5% UF Max time for each transport type with options for a dry day, LF, and PLUS EX. Dwell volumes for all EXes were set based on patient size; PLUS EX dwell times were set at "UF Max" or "Kt/V Max"; LF dwell time was set so total treatment time (TT) was 24 hrs. - 1.5% ON + 2.5% "UF Max" PLUS EX - 1.5% ON + 1.5% LF and 2.5% "UF Max" PLUS EX - 1.5% ON + 2.5% LF and 2.5% "UF Max" PLUS EX - 2.5% ON with dry day - 2.5% ON + 1.5% "Kt/V Max" PLUS EX - 2.5% ON + 1.5% LF and 1.5% "Kt/V Max" PLUS EX

Results: TTs for the overnight exchanges was 8-11 hrs, total volume was 6-18 L. At least 2 regimens for each patient achieved adequate clearance (weekly Kt/V ≥ 1.7) and UF (≥ 1 L/day). For some patients, a dry day was possible with 2.5% dex ON EX. Regimen 6 predicted adequate PD for all modeled patients.

Conclusions: This kinetic analysis demonstrates that adequate PD can be achieved without the use of high dextrose or icodextrin dialysates in most patients by using PD PLUS

in which the dwell time of the PLUS exchange is optimized for UF or Kt/V, as indicated. Data from clinical studies are needed to confirm the predictions of this modeling. Importantly, the accuracy of estimated ultrafiltration volumes using kinetic modeling is limited. Any PD prescription should be based on individual clinical needs and patient history.

PUB279

Treatment of Infection in Tunneled Double Lumen Catheter for Hemodialysis with Pulses of Ethanol 70%

Sergio Sloboda. *Renalduc, Rio de Janeiro, Brazil.*

Background: Catheter Related Bloodstream Infection (CRBSI) contributes to increased mortality rate in hemodialysis patient. Thus we must develop strategies to eradicate the catheter colonization. Lock with high-concentration antibiotics is a common practice and its continuous use related to the emergence of multidrug-resistant bacteria. In ethanol use in long-stay polyurethane catheters, the time is relevant in the relationship between security and elimination of biofilm. Continuous use will damage its components, the toxicity causes high liver enzyme and embolization by catheter fragments. The purpose of our work was to implement an effective protocol for use of ethanol at 70% in eliminating the biofilm without the emergence of adverse events.

Methods: We started a treatment protocol with lock of ethanol at 70% solution associated with 20 mg of enoxiparin for 6 hours in three consecutive days to replace the use of antibiotics locks, in the six patients that used Tunneled Double Lumen Catheter (TDLC) in last 12 months. Used heparin locking between dialysis. Performed blood cultures (venous and arterial branch) every two weeks. Repeating the treatment in the positive. We analyze, pre and post Protocol, the number of episodes of CRBSI per 1000 catheter day, values of transaminases (ALT), bacteriological profile analysis of blood cultures and the occurrence of adverse events. In the statistical analysis was used Wilcoxon test and median as a measure of central tendency.

Results: The CRBSI occurred in rate 8 *vs.* 0 episodes, pre *vs.* post protocol, $p<0.05$. There was no statistical significance between the values of ALT in two periods, being 10 and 11, $p>0.05$. In two times we observed DLCT low blood flow in ethanol use, being reinstated using intraluminal Alteplase 1mg/ml. In the pre protocol 60% of the microorganism remained in following blood cultures, this not observed during the use of ethanol. Re-infection in the ethanol use occurred after 34 days, being for different pathogen

Conclusions: The absence of CRBSI without the emergence of adverse events and toxicity shows the efficacy of therapy with ethanol on elimination of intraluminal biofilm in TDLC. Reinfection warned about the need to increase surveillance and training for handling of TDLC by the team of professionals involved in assisting and patient. The bacteriological control became critical to the prevention of new episodes of CRBSI

PUB280

A Fractured Dialysis Catheter or Calcified Fibrin Sheath? A Radiological Dilemma

Debajyoti M. Roy,[1] Sreekanth Koduri.[2] *[1]Changi General Hospital, Singapore, Singapore; [2]Changi General Hospital, Singapore, Singapore.*

Introduction: Whilst a-v fistula is an ideal dialysis access, yet up to 80% patients are initiated on dialysis with tunneled dialysis catheters (TDC). Long term TDC, as vascular access is often unavoidable, despite the associated risk of infections, thrombosis, central vein stenosis, catheter dysfunction and fibrin sheath formation.

Case Description: A 75-year-old woman with ESRF was admitted with fever and chills during her dialysis session. Her dialysis access was a tunneled catheter inserted 5 years prior. In the interim she did not have any episode of catheter malfunction or previous catheter related blood stream infection. She refused arterio-venous fistula creation in the past. The catheter was removed due to catheter related blood stream infection. A routine non-contrasted CT scan of the chest was performed 3 days later for follow up of a left pulmonary nodule. The radiology report was consistent with a retained central venous catheter fragment. Subsequent examination of the catheter tip sent for microbiology was examined and was consistent with complete removal of catheter.

Discussion: Fibrin sheaths commonly form on long-term central venous catheters. The process involves endothelial damage, thrombus formation, collagen deposition and sometimes calcification. A sleeve may form over the distal tip of the catheter. During removal of catheters these sheaths remain in the vein. Calcified venous fibrin sheaths have been misdiagnosed as retained catheter fragments. Calcified fibrin sheaths can be differentiated from retained catheter fragment if attention is given on CT scan to their irregular morphology, discontinuous areas of calcification often contiguous with noncalcified portions. **Take away Message: A retained calcified fibrous venous sheath may mimic a retained catheter fragment. This may trigger unnecessary radiological intervention or surgical exploration.**

CT scan: Coronal

PUB281

Serum Phosphorous Is the Independent Risk Factor for Vascular Access Dysfunction in Maintenance Hemodialysis Patients

Yubum Choi,[1] Mi Jung Lee,[1] Hyung Jong Kim,[1] So-young Lee,[1] Dong Ho Yang,[1] Hye yun Jeong.[2] *[1]CHA Bundang Medical Center, CHA university, Seongnam, GyeongGi-Do, Republic of Korea; [2]CHA Bundang Medical Center, Seongnam-si, Republic of Korea.*

Background: It is known that maintenance of function of arteriovenous fistula (AVF) is very important in the management of hemodialysis (HD) patients. Therefore, identifying a risk factor for decreased vascular access flow has a clinical relevance in real world practice. Although hyperphosphatemia plays a crucial role in the pathogenesis of vascular calcification, there is lack of studies evaluating the effect of hyperphosphatemia on AVF. This study investigated the impact of serum phosphorous (P) on vascular access flow in HD patients

Methods: Sixty-two maintenance HD patients who visited dialysis unit of Bundang CHA Medical Center from November 2016 to December 2017 were included in this study. Serum P levels were determined every month, and time-averaged serum P was calculated. All patients had left arm AVF (side to side anastomosis) and vascular access flow was assessed by Transonic HD 03. Decreased vascular access flow was defined as less than 600 mL/min.

Results: The mean age was 57.9 ± 12.1 years, 28 patients (50.9%) were men. The mean serum P levels were 5.1 ± 1.1 mg/dL and the vascular access flow was 1,071.4 ± 504.2 mL/min. Decreased vascular access flow was observed in 14 of 62 patients (22.6%). In univariate analysis, higher serum P was significantly associated with decreased vascular access flow (odds ratio [OR]=2.089, 95% confidence interval [CI]=1.159-3.766, P=0.014). But there was no significant association of dialysis blood flow rate, ejection fraction on echocardiography and serum calcium (Ca) levels with vascular access flow. Multivariable analysis indicated that higher serum P was independently associated with greater risk of decreased vascular access flow (OR=4.012, 95% CI=1.651-9.711, P=0.002). Old age, reduced EF, low dialysis blood flow rate and higher serum Ca was not associated with vascular access flow.

Conclusions: This study demonstrated that higher serum P was the independent risk factor for decreased vascular access flow in maintenance HD patients. Serial monitoring of serum P may be helpful to stratify the risk of vascular access dysfunction in these patients.

PUB282

Unused Mega Fistulas! A Case Series

Ali I. Gardezi, Fahad Aziz, Muhammad Sohaib Karim, Micah R. Chan. *Nephrology, University of Wisconsin School of Medicine and Public Health, Madison, WI.*

Introduction: A mega fistula forms due to aneurysmal dilatation of the whole outflow tract. It can lead to complications like high output cardiac failure and steal syndrome. We present a series of patients who developed mega fistulas due to lack of surveillance.

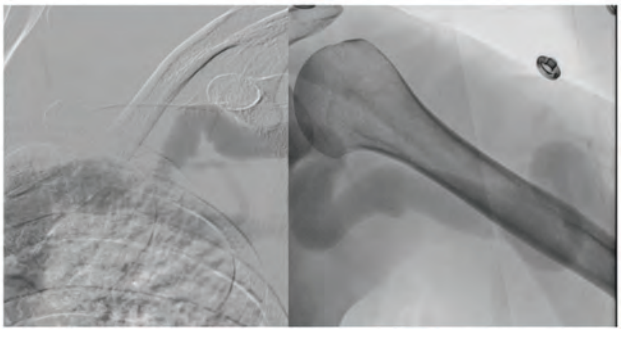
Case Description: Five post-transplant and one pre-dialysis patients were referred for evaluation of large aneurysmal fistulas. Angiogram was done in each case to define the anatomy. All the patients showed outflow stenosis. Details are shown in the table included.

Discussion: Undiagnosed venous outflow stenosis was the most likely reason of development of mega fistulas in this case series. Patients on dialysis undergo regular surveillance of their fistulas. Any abnormal sign usually prompts an evaluation in the form of angiogram with subsequent angioplasty of the outflow stenosis if found. Pre-dialysis

and post-transplant patients may not get surveillance of their fistulas which can cause a stenosis to go unrecognized. Outflow stenosis causes high pressure within the fistula which along with increased turbulence can lead to activation of pathophysiological mechanisms resulting in increased outward remodeling and overtime, increase in the size of the draining vein. Most of these mega fistulas require either ligation or surgical revision as the stenosis is usually chronic and difficult to intervene upon. Even if the stenosis is opened, it can lead to worsening of high output cardiac failure or steal syndrome. This case series highlights the importance of surveillance of the fistula even if it is not in use as it can prevent a complication like mega fistula by early diagnosis and treatment of outflow stenosis.

Findings and outcomes of patients with mega fistulas

Serial No.	Current Status of Renal Replacement Therapy	Type of AVF	Duration of Non Usage (Years)	Severity and Location of Stenosis	Outcomes
1	Post Transplant	Radiocephalic	12	100%, Cephalic vein at the elbow	Angioplasty not done. Referred for Ligation.
2	Post Transplant	Brachiocephalic	7	80%, Cephalic Arch-Subclavian vein junction	Stenosis resolved with successful angioplasty.
3	Post Transplant	Brachiocephalic	2	80% in Mid arm Cephalic vein. 70% at Cephalic arch	Angioplasty not done. Referred for Ligation
4	Post Transplant	Radiocephalic	14	100%, Cephalic vein at elbow	Angioplasty not done. Referred for Ligation.
5	Post Transplant	Radiocephalic	2	100%, Cephalic Arch-Subclavian vein junction	Angioplasty not done. Referred for Ligation.
6	Pre Dialysis	Brachiocephalic	4	100%, Cephalic Arch-Subclavian vein junction	Angioplasty unsuccessful. Referred for Ligation.



Mega Fistula with stenosis at the Cephalic arch-Subclavian vein junction.

PUB283

Pulmonary Embolism (PE) After Tunneled Catheter Removal in Dialysis Patients: An Underrated Complication?

Laura Nehrenheim, Dirk M. Hentschel, Adina S. Voiculescu. Interventional Nephrology *Brigham and Women's Hospital, Boston, MA.*

Introduction: Central venous catheters (CVC) cause complications and tunneled dialysis catheters (TDC) are associated with a higher mortality from infectious and cardiovascular causes. Asymptomatic catheter associated thrombosis has been described as frequent as in 25-40% of patients. Symptomatic thrombosis occurs in 1-5% of patient with CVC. The rate of PEs in patients with TDC is unknow. Removal of tunneled catheters is commonly perceived as low risk procedure and a PE as a complication has not been described. We want to present a dialysis patient with a PE after removal of his TDC.

Case Description: A 62 year-old man with ESRD on hemodialysis with a history of hypertension, diabetes mellitus, HCV, and bipolar disorder presented in the emergency department (ED) with chest pain and shortness of breath (SOB) one day after removal of right internal jugular vein TDC. The TCD was inserted to facilitate dialysis for a few weeks, while his left upper extremity autogenous access underwent surgical revision. The exit site appeared clean and intact without erythema. He had no signs of generalized infection and was hemodynamically stable with O2 saturation of 96%. Since the chest pain was localized over the exit site and his SOB was not severe, a chest X ray and a non-contrast chest CT were performed and were negative. The patient was discharged. Two days later, the patient reported continuing SOB with exertion and chest pain during inspiration while he was seen by his nephrologist on dialysis. He was sent to the ED, and ACS diagnostics as well as a CT-angiogram (CTA) were performed. CTA demonstrated a PE in the right upper lobe segmental artery. Echocardiogram showed no signs of right heart strain. The Patient was anticoaulated with warfarin with goal INR of 2-3 with heparin bridge. His symptoms improved and he was discharged home.

Discussion: Despite a reported high rate for catheter associated thrombosis, the rate of PE from line associated thrombus in patients with TDC is unknow. This case report demonstrates, that it is necessary to have a high rate of suspicion for PE in patients with indwelling dialysis catheters, especially if the TDC was manipulated. PE should be recognized as a possible complication of an otherwise low risk procedure as a TDC removal. Further studies are needed to clarify the amount of tunneled dialysis line associated PE.

PUB284

A Novel Collaborative Approach to Promote CKD Awareness in the State of Arkansas

Manisha Singh,[1] Nishank Jain,[2] Andrea K. Easom.[1] *[1]University of Arkansas For Medical Sciences, Little Rock, AR; [2]Little Rock VA Hospital, Little Rock, AR.*

Background: Over 400,000 Arkansans have CKD, about 1200 start dialysis annually and there are about a 100 Department of Health (ADH) tele-health sites at outreach clinics. Despite one of the highest incident rates of ESRD and poor access to pre-ESRD nephrology care, there were no educational tools promoting CKD awareness across the rural state. University of Arkansas for medical sciences (UAMS) developed such tools but lacked the outreach. UAMS and ADH collaborated with stakeholders to form a CKD Advisory Committee to address CKD awareness in AR.

Methods: UAMS and ADH collaborated with stakeholders (major insurance companies, non-profit-organizations like Arkansas foundation for medical care, local nephrologists,CKD patients) to form the Arkansas CKD advisory committee (ARCKDAC), with the mission to increase CKD awareness, detection and education of Arkansans using community engagement activities. The committee has 4 arms: 1. Data assessment and innovation. 2. Finance and cost assessment. 3. Quality initiatives. 4. Education and CKD. ARCKDAC directed attention to following 6 items-1. Comparing and contrasting ESRD incident data provided by ESRD Network 13 by AHD regions 2. Explore development of a statewide CKD registry; 3. Compile financial analysis of current health-care expense of CKD and potential cost-savings from changes in patient and provider behaviors resulting from these initiatives;4. Design and implement campaign "Know-Your-Kidney-Number" to promote CKD awareness; 5. Engage local nephrologists; 6. Use the "CKD: What You Need to Know" tools and results from a prior pilot project to educate committee and raise awareness. This project also established that tele-education was non-inferior to traditional face to face education for CKD patients. Provider-education tools include learn-on-demand videos with CME credits, resident teaching, and a "10-point plan" for primary-care physicians to address CKD.

Results: Anticipated improved CKD awareness in AR

Conclusions: We hope to address the barriers to CKD awareness through committee efforts. Advisory Committee members have the expertise, resources and commitment needed to improve local outcomes and explore a broad range of solutions. This can lead to positive change for Arkansans with CKD and the health care system.

PUB285

Bedside Renal Ultrasonography: A Key Tool in the Nephrology Resuscitation Crash Cart

Abhilash Koratala, Maryam Sattari, Amir Kazory. *University of Florida, Gainesville, FL.*

Background: Unstimulating nephrology elective experience during residency training has been identified as one of the reasons for the declining interest in nephrology as a career choice among internal medicine residents. Efforts have been made at redefining the scope of the specialty by incorporating novel educational approaches that not only enhance the learning experience but also portend salutary impact on patient care. Point-of-care ultrasonography (POCUS) is an inexpensive and relatively easy to learn tool that can be incorporated into day-to-day clinical practice and trainee curriculum.

Methods: We developed a focused renal POCUS curriculum for medicine residents at our institution. It is comprised of two 4-hour training sessions during the ambulatory rotation block. The first session includes an introductory lecture on ultrasound physics, instrumentation, and technique of performance of ultrasound, followed by hands-on training on normal subjects. The second session includes interpretation of various sonographic pathologies (using pre-defined images) and performance of renal ultrasound ± volume status assessment on pre-selected hospitalized patients. The images are saved and linked to electronic medical record of the patients, and are available for review as needed.

Results: Approximately 60 internal medicine residents with no prior renal ultrasound experience have completed the course over the past 12 months. By the end of the second session, all residents were able to adequately appraise the three most common sonographic pathologies namely, hydronephrosis, stone, and cyst. Moreover, they demonstrated better understanding of interpretation of renal size, cortical thickness and echogenicity in the clinical context. The feedback from the residents has been overwhelmingly positive leading to a constantly growing demand for participation.

Conclusions: Based on the success of the local process, we propose that more programs across US consider embracing this approach; POCUS has the potential to become an integral component of nephrology training after careful evaluation of resource utilization and cost benefit balance. In addition to helping generate more interest in nephrology as a career, it can have significant patient care implications and revive the declining rate of renal biopsy and hemodialysis catheter placement by nephrologists.

PUB286

Poor Awareness and Knowledge Among Internal Medicine House-Staff for Prescribing Cardiovascular Medications in Patients with CKD

Nfn Ranjeeta,[1] Joshua Fogel,[2] Sofia Rubinstein.[1] *[1]Nassau university Medical center, East Meadow, NY; [2]Brooklyn College, Brooklyn, NY.*

Background: Chronic Kidney Disease (CKD) alters pharmacokinetics of many cardiovascular medications resulting in increased risk of adverse drug events from their incorrect dose adjustment. The majority of cardiovascular medications in patients with

CKD are prescribed by primary care physicians. We study the awareness and knowledge of Internal Medicine (IM) house-staff for dose adjustment of commonly prescribed cardiovascular medications in patient with CKD.

Methods: We conducted a cross sectional survey among 341 IM house-staff. We studied the awareness whether a given medication needed dose adjustment ('medication dose needs adjustment' perception) and knowledge at what level of GFR a given medication needs to be adjusted ('medication dose adjustment at appropriate GFR level' perception) in CKD patients.

Results: Overall, there were high percentages for lack of awareness and knowledge in adjusting cardiovascular medications for CKD. Atenolol and Simvastatin had the highest percentages at 93.2% for incorrect 'medication dose needs adjustment' perceptions. Carvedilol and Amlodipine had the lowest percentages at 22.7% and 27.2% respectively for incorrect medication dose needs adjustment and incorrect medication dose adjustment at appropriate GFR level perceptions. PGY1 had greater odds for incorrect dose adjustment perception (OR: 5.56, 95% CI: 2.19, 14.12, p<0.001). Additional Nephrology exposure and training had lesser odds for incorrect dose adjustment perception (OR: 0.45, 95% CI: 0.21, 0.97, p<0.05).

Conclusions: IM house-staff have poor awareness and knowledge for cardiovascular medication dose adjustment in CKD patients. Medical schools and IM residency programs should place greater emphasis on Nephrology exposure and formal didactic Nephrology educational training. This can avoid incorrect dose prescribing and enhance patient safety.

PUB287

Principles and Strategies for Involving Patients and Caregivers in Research in CKD: Report of National Workshops

Talia M. Gutman,[4,1] Martin Howell,[4,1] Kathryn Dansie,[3] Carmel M. Hawley,[2,7] Jonathan C. Craig,[1,9] Allison Tong,[4,1] Shilpa Jesudason,[6,10] Jeremy R. Chapman,[5] David W. Johnson,[2,11] Lisa D. Murphy,[8] Donna M. Reidlinger,[7,11] Stephen P. McDonald.[6,10] Better Evidence and Translation - Chronic Kidney Disease (BEAT-CKD) *[1]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, NSW, Australia; [2]Nephrology, Princess Alexandra Hospital, Brisbane, QLD, Australia; [3]ANZDATA, Adelaide, SA, Australia; [4]School of Public Health, University of Sydney, Sydney, NSW, Australia; [5]Westmead Hospital, WESTMEAD, NSW, Australia; [6]CNARTS, Royal Adelaide Hospital, Adelaide, Adelaide, SA, Australia; [7]The University of Queensland, Woolloongabba, QLD, 4102, NSW, Australia; [8]Kidney Health Australia, South Melbourne, NSW, Australia; [9]College of Medicine and Public Health, Flinders University, Adelaide, SA, Australia; [10]Adelaide Medical School, University of Adelaide, Adelaide, SA, Australia; [11]Australasian Kidney Trials Network, Brisbane, QLD, Australia.*

Background: Patient involvement in research is widely advocated to ensure that their priorities are reflected in all phases of the research process, from setting the agenda through to implementation. However, there is limited evidence on how patients want to be engaged and involved in research. This study aims to identify strategies for consumer engagement and involvement in research in chronic kidney disease.

Methods: 105 patients and caregivers and 43 clinicians and researchers participated in three workshops in Sydney, Adelaide and Brisbane (Australia). In facilitated breakout groups, participants discussed principles and strategies for patient and caregiver involvement in research. Transcripts were analyzed thematically

Results: We identified five themes: fostering a consumer-centered culture (facilitating knowledge exchange and translation, providing an opportunity to give back, empowering health ownership, allaying skepticism and suspicion, building a community); respecting consumer expertise and commitment (clarifying expectations and responsibilities, equipping for meaningful involvement, valuing unique and diverse experiential knowledge, keeping 'in the loop' with results and impact); attuning to individual context (a preference based multipronged approach to engagement, reducing the burden of involvement, being sensitive to the patient journey); harnessing existing relationships and infrastructure (partnering with trusted clinicians, increasing exposure in clinical settings, mentoring patient-to-patient, extending reach through established networks); and developing a coordinated approach (power in the collective and united voice, systematic approach for equitable inclusion, streamlining access to opportunities and trustworthy information).

Conclusions: Patients want to be involved in research to take ownership of their health, yet are unaware and uncertain about potential opportunities for involvement. Establishing a supportive, respectful research culture, responding to their individual context, coordinating existing infrastructure and centralizing the flow of information may facilitate patient involvement as active partners in research

PUB288

Medication Adherence Analysis for CKD Patients

Min Zhang,[3] Suyuan Peng,[4,6] Zhang Dingjun,[5] Jiawei He,[7] Yifan Wu.[1,2] *[1]Guangdong Provincial Hospital of Chinese Medicine, Guang Zhou, China; [2]The Second Affiliated Hospital of Guangzhou University of Chinese Medicine, Guang Zhou, China; [3]Guangzhou University of Chinese Medicine, Guang Zhou, China; [4]Mayo Clinic, Rochester, MN; [5]Guangzhou University of Chinese Medicine, Guangzhou, China; [6]Health Sciences Research, Rochester, MN; [7]Guangzhou University of Chinese Medicine, Guang Zhou, China.*

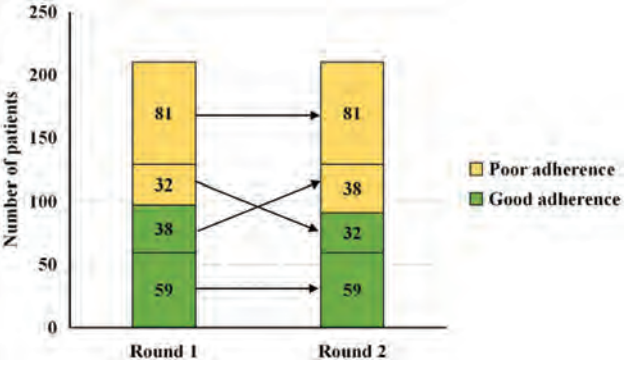
Background: According to the existing researches, the rate of medication adherence among chronic kidney disease patients was low. Improving patients'medication adherence might delay their disease progression.

Methods: Data were collected from CKD patients who had first visited the Chronic Disease Management Clinic at the Nephrology Department of the Guangdong Provincial Hospital of Chinese Medicine between March 2014 and April 2017. The collected data included the basic information of patients, the Morisky compliance scale, accompanying diseases, laboratory test results, what types of medication were being taken, and so on.

Results: 210 CKD patients were enrolled. Round 1: 97 patients were considered to have good adherence, 113 were considered to have poor adherence. Round 2: 91 patients were considered to have good adherence, 119 were considered to have poor adherence. 38 of the 97 good-adherence patients changed their medication adherence from good to poor, and 32 of the 113 poor-adherent patients changed their medication adherence from poor to good. Furthermore, Over 75% of the patients often forgot to take medication and or often did not pay attention to taking their medication. Additionally, the differences in the adherence between two groups were statistically significant including self-care or not, age, current residence and education level.

Conclusions: CKD patients had a high rate of poor medication adherence, accounting for 53.8% -56.7% of the total. Time had little impact on overall adherence, but had some effect on personal adherence. Younger age, higher education levels, living outside of Guangzhou city, and self-care or not, each led to worse medication compliance. Therefore, in actual clinical practice, we could improve patient compliance by taking corresponding measures.

Funding: Government Support - Non-U.S.



The trend map of medication adherence changes between two groups of patients within an interval of 1 year ± 3 months

PUB289

Predicting Success on Twitter: Nephrology Journals and Online Resources

Sarah Gleeson,[1] Swapnil Hiremath,[2] Silvi Shah,[3] Matthew A. Sparks,[4] Sinead Stoneman,[5] Joel M. Topf.[6] Nephrology Social Media Collective *[1]Nephrology, Auckland hospital, Auckland, New Zealand; [2]University of Ottawa, Ottawa, ON, Canada; [3]University of Cincinnati, Cincinnati, OH; [4]Duke University and Durham VA Medical Centers, Durham, NC; [5]University Hospital Waterford, Waterford, Ireland; [6]Oakland University William Beaumont School of Medicine, Rochester, MI.*

Background: Free open access medical education, often promoted and distributed through Twitter, is increasingly being used to supplement medical learning. An example is the Nephrology Twitter Journal Club (NephJC) which has hosted over 100 Twitter chats focusing on the medical literature impacting nephrology. Medical journals have also embraced Twitter with varying levels of enthusiasm. We hypothesise that on Twitter 1. Social media-based resources will have more followers than journals and 2 Amongst journals, those that commit to social media (through use of visual abstracts or social media editors) will have more followers

Methods: We evaluated the Twitter accounts of 18 nephrology journals and 4 nephrology social media-based resources for the number of followers and number of tweets to gauge their reach on Twitter. We report descriptive statistics, and comparisons between groups using non-parametric tests.

Results: Overall the median number of followers was 1947.5 (interquartile range, (IQR) 510.8-4179.3) and the median number of tweets was 966 (IQR 411.5-1730). We found little evidence that the subjects purchased 'fake followers' (< 5% of followers). The median number of tweets/day was 0.9 (IQR 0.4-1.8) and follower acquisition/day was 1.82 (IQR 1.1-3.3). Predictors of higher number of followers included Twitter vintage (p=0.005),

number of tweets (p=0.001), visual abstract usage (p=0.017) and journal impact factor (p=0.027). The social media-based accounts had more followers (median 3415, IQR 2031, 5172.8) than the journals (median 1579, IQR 510.8-3772.8)(p=0.27). They also had more tweets (Median 2396, IQR 783-7369.3) than the journals (median 872, IQR 411.5-327) (p=0.48).

Conclusions: This study shows that the number of followers a Twitter account has (and therefore its reach) is associated with both established (impact factor) and novel parameters (number of tweets, visual abstracts). Innovative social media centered initiatives such as NephJC had more followers than the journals, potentially due to their higher number of tweets and use of visual abstracts. The American Journal of Kidney Disease which has a social media editor and uses visual abstracts had the highest number of followers among the journals. Establishing a robust Twitter presence requires both consistent usage and adoption of new tools to disseminate information such as visual abstracts.

PUB290

Novel Technological Educational Tools for Patients with CKD

Geraldo B. Silva Junior,[1] Juliana G. Oliveira,[1] Marjan Askari,[2] Marilia Fahd,[1] Ronaldo A. Freitas filho,[1] Francisco aglalberto L. Silva,[1] José eurico Vasconcelos filho.[1] *[1]University of Fortaleza, Fortaleza, Brazil; [2]Erasmus University, Rotterdam, Netherlands.*

Background: Patients' adherence to treatment is far from ideal, and non-adherence impacts on outcomes. The aim of this study is to present novel technological educational tools to increase CKD patients adherence to treatment.

Methods: A multidisciplinary team (Health, Information Technology, Medical Informatics and Communication) discussed the technological possibilities based on CKD patients' needs. We have also interviewed patients in order to know their information needs and the main difficulties faced during treatment. We have them decided to create an application for smartphones, educational videos, a "smart medication box" and a shoe insole to monitor patients weight.

Results: The application was called "Renal Health", it included educational information for patients with CKD regarding the main aspects of the disease and its treatment, and provided tools for patients self-monitor their treatment, with alarms at the time of medications, dialysis, medical appointments etc. It also included information for the general population and for transplanted patients (mainly focused on immunosuppressants). The videos were intended to supply the necessities of illiterate patients who could not read the educational texts of the app. It was provided through a channel at youtube and would be incorporated in the application. The medication box was designed in a prototype version, in which a sensor is connected with the application. Whenever the patient open the box the app register the time and the name of the drug that was intended to be taken at that time. The shoe insole will be designed to monitor patients' weight, once interdialytic overweight is still a problem, which is associated with bad outcomes. Sensors will connect the information registered by the insole with the application, and alarms will be fired if a determined weight is overcome.

Conclusions: Patients' adherence to treatment is a challenge not only for CKD but for any disease. The Renal Health project evidence the countless possibilities that technology can provide to patients aiming to help them cope with a complex disease that requires a huge commitment to achieve good clinical outcomes, which is CKD. We intend to test these technologies in a large group of patients to assess its effects on clinical outcomes.

Funding: Government Support - Non-U.S.

PUB291

Establishment of a Telehealth Renal VA-ECHO Curriculum

Margaret E. Fleet,[1,2] Kathryn L. Todd,[3] Joleen A. Borgerding,[3] Bessie A. Young.[4,5] *[1]University of Washington, Seattle, WA; [2]VA Puget Sound Health Care System, Seattle, WA; [3]VA Puget Sound Health Care System, Seattle, WA; [4]University of Washington, Seattle, WA; [5]VA Puget Sound Health Care System, Seattle, WA.*

Background: Veterans Health Administration (VA) is the largest provider of health services in the nation for patients with chronic kidney disease (CKD). Many veterans with advanced CKD do not receive nephrology care before initiating dialysis. Veterans that do have access to this care do better. Reasons for this gap may include limited access due to geographical barriers, lack of local specialists and/or poor provider recognition of CKD. To bridge this access gap, the Seattle Renal VA-ECHO (Extension for Community Healthcare Outcomes) program developed a tele-mentoring program between nephrologists and underserved area primary care providers (PCPs). This program consists of didactic sessions with integrated case-based discussion via a Skype-meeting platform. To better facilitate learning, we developed a nationally delivered renal curriculum.

Methods: The goals of the curriculum are to: 1) Improve veteran access to renal specialty care; 2) Narrow PCP renal knowledge gaps; 3) Improve outcomes of veterans with kidney disease and other related complications. PCP knowledge gaps were identified via survey of VA PCPs and nephrologists and a review of electronic consultation (e-Consult) questions. A modular structure was chosen to develop common educational themes and allow for flexibility. Modules are logically sequenced to facilitate learning. Six modules with 3-16 didactic sessions were developed. Each session incorporates patient cases submitted by PCPs as e-consults. Learning objectives are integrated into each didactic topic. Nephrology and multidisciplinary content experts give didactics to create shared learning experiences. Curriculum development began in late 2016 and was in full use by 2017. Surveys were directed at frequent Renal VA-ECHO participants from 2016 and 2017 in an effort to capture learners pre and post-curriculum implementation.

Results: We surveyed 15 participants with a 47% response rate. The majority (57%) felt the curriculum was extremely helpful for learning focus, acquisition of knowledge, identification and filling of knowledge gaps and improvement in patient care. The remaining 43% found the curriculum to be quite helpful in these areas.

Conclusions: The development of a Telehealth Renal VA-ECHO Curriculum has helped to bridge knowledge gaps among rural PCPs and improve specialty care access and quality of care of veterans.

PUB292

A Kidney Biopsy Simulation Training Program: First Year's Results

Maria-Eleni Roumelioti, Jonathan G. Owen, Christos Argyropoulos, Yue-Harn Ng, Mark L. Unruh. *University of New Mexico, Albuquerque, NM.*

Background: Percutaneous kidney biopsy (PKB) is the most common procedure and should be adequately taught through simulation training according to ACGME requirements. We initiated a PKB simulation training program and we designed a two-year study to examine its effect on the confidence level, the procedural competence and the satisfaction with this training of Nephrology fellows compared to historical controls (fellows trained on PKBs before the initiation of the program).

Methods: All fellows were trained at UNM's simulation center (BATCAVE) with a PKB ultrasound training model (CAE Healthcare Blue Phantom™). Participants demographics and previous PKB experience was collected. Pre-assigned readings, online videos and hands-on practice on the simulation model were utilized. Performance of the trainee during each one-hour session was graded by the use of an evaluation form specifically designed for PKBs. Pre-and post-simulation surveys evaluated the participants' confidence level quantitatively (scale 0-5). All participants completed the satisfaction with PKB simulation experience scale (PKB-SSE).

Results: All three 1st and 2nd year current renal fellows completed the simulation training. The following table summarizes the basic information acquired from their training. Overall, the program enhanced the confidence level of fellows without previous experience on performing PKBs. All fellows expressed a high level of satisfaction (0-5) from their participation in this training.

Conclusions: PKB simulation training may improve trainees' confidence level especially for those without prior experience as well as their satisfaction with the training. The procedural competence of the trainees on PKBs will be evaluated during the second year of their fellowship and will be compared to the procedural competence of historical controls. Interventional Nephrology could re-foster interest in this subspecialty. Interventional Nephrology could re-foster interest in this subspecialty.

Promoting Shared Decision Making Practice for CKD Patients Through Patient Decision Aids and Nephrology Staff Education

Yasuhiro Komatsu,[1] Mari Ishida.[2] Japan Shared Decision Making Collaborative for Chronic Kidney Disease *[1]Gunma University, Graduate School of Medicine, Maebashi, Gunma, Japan; [2]Tokai Univercity Hachioji Hospital, Hachioji city, Japan.*

Background: Shared decision making (SDM) process is integral for promoting patient centered care and patient and family engagement, leading to higher Quality of Life, patient satisfaction, and treatment outcome. However, practice of shared decision making is not fully implemented in routine healthcare practice in Japan. We aim to develop a program which promotes shared decision making through education and creating decision aid material.

Methods: We outline the development process of Japan Shared Decision Making Collaborative for Chronic Kidney Disease, an organization and a program to promote the practice of SDM. We also present its key educational elements. We describe issues associated with the implementation of the education program.

Results: Japan SDM Collaborative for Chronic Kidney Disease has been launched in October 2017 to promote education and practice of SDM for end stage kidney disease. After review of the literature, panel of members created sixteen pages patient decision aid booklet, aiming to accelerate patient-provider conversation, encourage patient and family engagement, and patients' understanding of treatment options. Decision aid booklet is approved by key nephrology organizations in Japan, including Japanese Society of Nephrology, the Japanese Society for Dialysis Therapy, the Japan Society for Transplantation, Japanese Society for Peritoneal Dialysis, and Japanese Society for Clinical Renal Transplantation. The booklet contains questionnaires for patient lifestyle, preferences, and values. It also provides key information about hemodialysis, peritoneal dialysis and kidney transplantation. Training seminars for nephrologists and nurses were held, which include key lecture and group work to share understanding of SDM and address issues to promote SDM. Group work consists of simulated healthcare provider and patient encounter, discussion about treatment options using decision aid. From April to May 2018, five educatinal seminars with 250 participants from 90 institutes were successfully held.

Conclusions: Japan SDM Collaborative for Chronic Kidney Disease has been launched to promote SDM practice for end stage kidney disease patients in Japan.

PUB294

Investigation and Management of Inpatient Hyponatremia in a Teaching Hospital

Sandiya Bindroo,[1] Vikram S. Taware,[1] Divya Akella,[1] Tuhina Cornelius,[1] Kirankumar K. Patel,[1] Hannah R. Troutman.[2] *[1]Internal Medicine, Crozer Chester Medical Center, Upland, PA; [2]Crozer Chester Medical Center, Secane, PA.*

Background: Hyponatremia is not a disease but a pathophysiologic process accounting for approximately 15% of general hospital admissions, and it is associated with significant morbidity and mortality. The objective of this study is to evaluate the investigation and management of hyponatremia in a teaching hospital.

Methods: Retrospective, observational study was conducted at a large teaching hospital for a year period (1st-June-2016 to 30th-June-2017). A retrospective chart review was performed on general internal medicine hospitalized patients with the diagnosis of hyponatremia including those who were admitted with serum sodium (sNa) ≤135 Meq/l and those who developed hyponatremia during the hospital stay.

Results: Six hundred and ninety five patients (321 male/374 female) with a Mean±SD age of 62±19 years and nadir sNa of 127.37 ± 6.22 Meq/l were included. Only 450/695 (65%) were admitted with sNa ≤130Meq/l, and the rest 245/695 (35%) developed hyponatremia while during their hospital stay. The severity was 45.46%, 45% and 0.09% for mild (sNa ≥130 Meq/l), moderate (sNa ≥120Meq/l to 129Meq/l) and severe (sNa <120 Meq/l) hyponatremia. The documentation of acuity and volume status assessment was missing for 83% and 62% of patients respectively. Only 20% patients had measurements of paired serum and urine osmolality and sodium, while 12% and 34% had an assessment of adrenal reserve and thyroid status respectively. The mean length of hospital stay was 5.11±4.03 days with an inpatient mortality rate of 1%. At hospital discharge, 14% patients had persistent hyponatremia. Overall, 22% patients didn't have any treatment recorded for hyponatremia. Among 532/695 (76.54%) patients with recorded treatment, the most common modality was isotonic saline (97%) followed by fluid restriction (29%). Expert opinion was sought in 28% of cases, with significant discrepancies noted in management. Offending drugs continued in 33% of patients.

Conclusions: This study highlights the need to improve clinical practice and educate residents. By accurate documentation, appropriate expert opinion, and highlighting inpatient hyponatremia electronic alerts can prompt optimal investigation and treatment, preventing associated morbidity and mortality.

PUB295

Epidemiology of Sodium and Potassium Electrolyte Imbalance in Ambulatory Care in United Arab Emirates: A Single Centre Study

Chandra Mauli Jha,[1] Anand R. Chatterjee,[2] Hormaz D. Dastoor.[3] *[1]Nephrology & Dialysis Services, Gulf Diagnostic Center Hospital, Abu Dhabi, United Arab Emirates; [2]Gulf Diagnostic Center Hospital, Abu Dhabi, United Arab Emirates; [3]Rahba Hospital- Johns Hopkins International, ABU DHABI, United Arab Emirates.*

Background: Electrolyte imbalances are not common but important cause of morbidity, mortality and therapy outcome. The incidence of commonest Na^+ and K^+ abnormalities are ikely to rise due to increase in conditions like hypertension, diabetes mellitus, CKD & heart failure etc and due to drugs used for their management. There is lack of epidemiological data about these abnormalities in ambulatory care setup.. There was no study about Na^+ and K^+ imbalance in the arab world where the incidence of diabetes and cardiovascular disease is on rise in epidemic magnitude. It made us curious to assess about the incidence of these electrolyte abnormalities in ambulatory care setup.

Methods: Electronic record system of a Day Care Surgery Center serving all medical & surgical sub-specialities was acessed to retrieve retrospectively all the results of serum sodium and potassium tested during 1st January 2016 to 31st December 2017. The selection of center eliminated serious cases leading to a better presentation of ambulatory care patients. Age, sex, nationality, and value of electrolyte result but not the diseses were included in study. Excel 2016 was used for anlaysis.

Results: 73143 and 61480 patients utilized the facility in 2016 & 2017 respectively. 25872 & 17826 samples for K+, 24027 & 15090 samples for Na+ were analysed in 2016, 2017 respectively. 18272 patients in 2016 and 13520 patients were tested in 2016 & 2017 respectively. Age ranged from less than 1 year to 93 years in 2016 and 2 years to 89 years in 2017. The incidence of hyponatremia was 9.1% & 8.9% in 2016 & 2017 respectively while hyponatremia was les than 0.1%. incidence of Hypokalemia was 0.9 to 1% & hyperkalemia incidence was 0.32 to 0.35 %. Hypokalemia and hyponatremia was more common in younger age (no significant p) & among females (significant *p)* while hyperkalemia and hypernatremia was more common among males and older age (no significant p).

Conclusions: Incidence of Na+ & K+ abnormality in ambulatory care is low but its ablolute numbers may be significant. This is a single centre study with several limitations yet first of its kind in Arab world about epidemiology of sodium and potassium imbalance in ambulatory care setup A larger multicenter stuy ncluing relation to morbidity and drugs is to have better assessment of the problem is highly desirable and recommendable.

PUB296

Hypercarbia in a Patient with Acute Leukemia: Don't Be Tricked!

Abhilash Koratala,[1] Justin Lee Loy.[2] *[1]Nephrology, University of Florida, Gainesville, FL; [2]University of Florida Gainesville, Gainesville, FL.*

Introduction: Nephrologists are frequently consulted to assist with the management of acid-base and electrolyte disorders in the intensive care unit (ICU). As such, it is important to recognize the spurious causes of laboratory abnormalities in this context.

Case Description: A 58-year-old man was admitted for multifocal pneumonia. Laboratory studies demonstrated severe leukocytosis with a WBC count of 123 thou/mm^3 (Ref: 4-10), with peripheral blood smear suggestive of Acute Promyelocytic Leukemia. He was admitted to the ICU for treatment of pneumonia and possible Leukapheresis. Soon after that, he developed hypotension and worsening respiratory status requiring endotracheal intubation. Arterial blood gas (ABG) analysis was significant for a pH of 6.9, PaCO2 of 98 mmHg, PaO2 67 mmHg, on Fio2 of 100%. Pulse oximetry reading at that time was 92%. Serum chemistries demonstrated a potassium of 8.5 mmol/L with creatinine ~1.2 mg/dL. Nephrology was consulted for possible dialysis in the setting of severe systemic acidosis and hyperkalemia. Further investigations revealed no EKG changes suggestive of hyperkalemia and a serum lactate of 18.6 mmol/L. We suspected spurious hyperkalemia from cell lysis, which was confirmed by whole blood potassium of 4.3 mmol/L. While renal replacement therapy is a reasonable strategy to correct systemic acidosis, we were faced with the question whether this is primarily metabolic (lactic) or respiratory acidosis. In hypercapnic acidosis, correction of pH above 7.2 is not typically recommended as it may adversely affect the overall outcomes. A repeat ABG revealed similar PaCO2 but interestingly, point-of-care (bedside) blood gas analysis at the same time demonstrated a PaCO2 of only 20 mmHg, which indicates that the original high value of PaCO2 was spurious.

Discussion: Spurious hypoxemia can occur in cases of extreme leukocytosis and thrombocytosis due to in vitro oxygen consumption by these metabolically active cells, even when there is a few-minute delay between sample collection and analysis. However, spurious hypercarbia is not expected to occur owing to considerably higher CO2 buffering capacity of blood. However, our case shows this can occur, especially when there is concurrent metabolic acidosis.

PUB297

Validity of Urine Osmolality Measurement in Healthy Adults

Emad Al Jaber, Eric Judd. *University of Alabama at Birmingham, Birmingham, AL.*

Background: Hyponatremia, defined as a serum sodium level < 135 mEq/L, is the most common electrolyte disorder in clinical practice. Measurement of urine osmolality is critical part in the correct diagnose and management of patients with hyponatremia. The aim of this study is to quantify the changes in urine osmolality due to the presence of substances identified by urinalysis (UA), like glucosuria.

Methods: Albumin, ketones (e.g., acetoacetic acid and β-hydroxybutyrate), and glucose were added to the urine of healthy participants in amounts detected by dipstick urinalysis (Siemens multistix 10). For example, 0.2g of glucose per 10 mL of urine corresponded to 4+ glucose by dipstick. Urine osmolality was measured using freezing point depression (Model 2020, Advanced Instruments, Inc) at baseline and after adding fixed amounts of each substance. Change in urine osmolality was reported as median (range). Signed rank tests were performed to compare differences in osmolality from baseline; p-value < 0.05 considered statistically significant.

Results: The study population consisted of 10 participants (50% female, 40% African American, age ranging 27-62 years, and BMI ranging 25-34 kg/m2). Baseline urine osmolality ranged 74 – 874 mOsm/kg, and changes in urine osmolality were similar throughout the range of baseline values. Addition of acetoacidic acid at 160 mg/dL (e.g. 3+ketones by UA) raised the urine osmolality by 27.5 (20-29 mOsm/kg, p 0.004). β-hydroxybuterate at 160 mg/dL, which is not detected by urinalysis, raised the urine osmolality by 13.7 (3-20 mOsm/kg, p 0.016). Glucose at 2000 mg/dL (e.g., 4+ glucose by UA) raised the urine osmolality by 110 (97-116 mOsm/kg, p 0.004), and glucose at 500 mg/dL (e.g, 2+ glucose by UA) raised the urine osmolality by 24.7 (9-37 mOsm/kg, p 0.004). Albumin did not significantly change the urine osmolality with 4+ protein by urinalysis changing urine osmolality by -3 (-8-2 mOsm/kg, p 0.22).

Conclusions: The presence of ketones and glucose in the urine significantly increase urine osmolality measurements. When interpreting urine osmolality as an indicator of kidney water handling, one may need to correct for these substances, which can be detected by urinalysis. Importantly, the presence of albumin does not significantly alter urine osmolality.

PUB298

Acquired Renal Glucosuria in an Undifferentiated Connective Tissue Disease Patient with a SLC5A2 Heterozygous Mutation: An Unusual Case Report

Xiangchen Gu,[1] Yi Wang,[2] Min Chen.[2] *[1]Yueyang hospital of integrated Traditional Chinese and Western Medicine, Shanghai University of Traditional Chinese Medicine, Shanghai, China; [2]Yueyang hospital of Traditional Chinese and Western medicine, affiliated to Shanghai University of T.C.M., Shanghai, China.*

Introduction: Renal glucosuria is a renal tubular disorder characterized by persistent isolated glucosuria in the absence of hyperglycemia. The causes of renal glucosuria include a wide range of insults to proximal tubular cells including genetic conditions, drugs, and

poisons. Renal glucosuria caused by UCTD(undifferentiated connective tissue disease) is very rare.

Case Description: A 30-year-old woman was seen in the outpatient clinic for complaints of repeated frequency urination,odyuria. Laboratory tests showed urinary tract infection and renal glucosuria. After the antibiotic treatment, the UTI symptoms were relieved while renal glucosuria remained. Further laboratory test ruled out renal tubular acidosis, and immunologic tests showed a high antinuclear antibody titer (1:160), and elevated anti-Rho/SSA antibody. Schirmer's test, tear break-up time and lip biopsy were negative. The patient did not meet criteria for any known connective diseases. She was therefore diagnosed with UCTD. Genetic analysis showed SLC5A2 gene heterozygous mutation, and incubation of the patient's serum with normal mouse kidney tissue showed a pattern of SGLT2 in the epithelial tubules similar to that of incubation of normal mouse kidney tissue with the rabbit polyclonal anti-SGLT2 antibody. With the treatment of immune-suppression, the renal glucosuria doesn't exist.

Discussion: This case presents UCTD as a rare cause of renal glucosuria, and our findings suggest the presence of circulating autoantibodies to SGLT2.

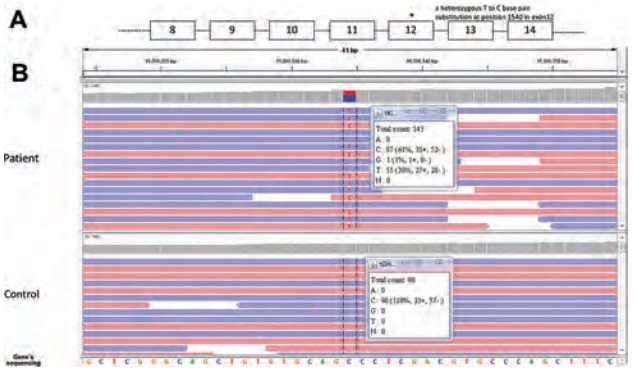

Fig1. Genome sequencing of all exon regions of SLC5A2

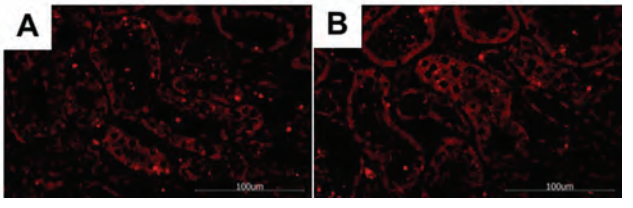

Fig2. Immunofluorescence staining of the frozen sections of normal mouse kidney with (A) the patient's serum and (B) rabbit polyclonal anti-SGLT2 antibody was performed.

PUB299

Changes in the Extracellular-to-Intracellular Water Ratio in a Sample of Japanese Adults Aged 15–88 Years Old: A Cross-Sectional Study to Develop a Formula for Quantifying Fluid Volume Overload

Yasushi Ohashi,[1] Nobuhiko Joki,[2] Keisuke Yamazaki,[1] Takeshi Kawamura,[1] Reibin Tai,[3] Hideyo Oguchi,[3] Rena Yuasa,[3] Ken Sakai.[3] *[1]Nephrology, Toho University Sakura Medical Center, Chiba, Japan; [2]Nephrology, Toho University Ohashi Medical Center, Tokyo, Japan; [3]Nephrology, Toho University Omori Medical Center, Tokyo, Japan.*

Background: Fluid volume overload is common and is associated with adverse outcomes in patients with chronic kidney disease (CKD). However, accurate assessment of fluid volume status remains a concern. The fluid volume balance between intracellular water (ICW) and extracellular water (ECW) gradually changes with age, which may be associated with a reserve capacity for volume overload. This study was designed to estimate the physiological fluid volume changes with age for assessing volume overload.

Methods: We performed using sample data obtained from InBody Japan Inc. (Kameido, koto-ku, Tokyo, Japan). A total of 1,992 individuals (753 men and 1,239 women) aged ≥15 years included in this study had their body composition measurements performed at training gyms in 2014. We developed a regression formula to assess the association of age with the ratio of ECW to ICW in these subjects.

Results: The mean ages of male and female subjects were 51.2 ± 15.2 and 57.4 ± 15.2 years, and their mean body mass indices were 23.4 ± 3.3 and 21.1 ± 2.8 kg/m^2, respectively. The total fluid volumes of male and female subjects were 39.6 ± 4.9 and 27.7 ± 3.0 L, whereas the percent body fat mass/kg of body weight were 19% and 26%, respectively. The ECW/ICW ratio increased with age due to the steeper decrease in the ICW content than in the ECW content, especially after the age of 70 years. The regression formulas used for calculating the age-adjusted ECW/ICW ratio were as follows: $[0.5857 + 7.4334 \times 10^{-6} \times (\text{age})^2]$ in men and $[0.6062 + 5.5775 \times 10^{-6} \times (\text{age})^2]$ in women. The standard errors of the quadratic least square regression coefficient in male and female subjects were 0.2825×10^{-6} and 0.2516×10^{-6}, respectively. The standard errors of the y-intercept in the formulas for male and female subjects were 0.000989 and 0.000974, respectively.

Conclusions: Fluid volume balance is universally influenced by decreased cell volume driven by aging and muscle attenuation, which disturbs the standard ICW/ECW ratio of 62:38. Our proposed formula for calculating the age-adjusted ECW/ICW ratio may be a useful calculation tool for the normalized fluid volume balance, and it can be applicable to the quantitative analysis of volume overload in patients with CKD.

PUB300

Research on the Relationship Between Urolithiasis and Metabolic Disease

Yuehong Li,[1] Qi Chen,[2] Xianglan Wu.[3] *[1]Department of Nephrology, Beijing Tsinghua Changgung Hospital, School of Clinical Medicine, Tsinghua University, Beijing, China; [2]Department of nephrology, Beijing Tsinghua Changgung Hospital, School of Clinical Medicine, Tsinghua University, Beijing, China; [3]Department of nephrology, Beijing Tsinghua Changgung Hospital, School of Clinical Medicine, Tsinghua University, Beijing, China.*

Background: Calcium oxalate (CaOx) is the most common urolithiasis, metabolic disease such as obesity, diabetic mellitus, dyslipidemia, hyperuricemia, and hypertension can influence the incidence and recurrence of urolithiasis via many mechanisms. This study aim to explore the relationship between CaOx stone and metabolic disease in Chinese urolithiasis patients.

Methods: Patients treated by surgery in Beijing Tsinghua Changgung Hospital from Oct. 2015 to Aug. 2017 were retrospectively study. Demographic characteristic and stone composition were analyzed. Patients of CaOx stones and non-CaOx stones'data were compared, including clinical material and examination. The prevalence of metabolic disease in CaOx patients were analyzed and Logistic regression were used to analyze the influence factors related to hyperlipidemia among CaOx patients.

Results: 1. Among 707 patients, there are 446 (63.1%) males and 261 (36.9%) females. 573 (81.0%) cases are CaOx stones. 2. Compared with non-CaOx patients, CaOx patients had significantly higher BMI (25.40kg/m2 vs. 24.54kg/m2, P=0.024) and urine gravity (1.012 vs. 1.011, P=0.024), lower blood chlorine (105.6mmol/L vs. 106.4mmol/L, P=0.007) and lower proportion of urinary infection (62.4% vs. 78.4%, P=0.001). 3. Compared with general population, CaOx patients had higher proportion of metabolic disease. 4. CaOx patients with hyperlipidemia had significantly higher level of uric acid (364.3umol/L vs. 331.9umol/L, P<0.001), serum calcium (2.23mmol/L vs. 2.19mmol/L, P=0.009), total protein (67.6g/L vs. 65.7g/L, P=0.001) and albumin (39.8g/L vs. 38.2g/L, P<0.001). They had lower level of iPTH (43.17ng/L vs. 51.95ng/L, P=0.003) and urine pH (6.13 vs. 6.36, P<0.001). 4. Multivariate Logistic regression analysis showed that hyperlipidemia in CaOx patients are related with hyperuricemia (OR 1.609, 95%CI 1.018-2.543, P=0.042), blood calcium≥2.3mmol/L (OR 1.953, 95%CI 1.092-3.491, P=0.024), iPTH≤40ng/L (OR 1.576, 95%CI 1.013-2.453, P=0.044) and urine pH≤6 (OR 1.820, 95%CI 1.164-2.848, P=0.009).

Conclusions: 1. Compared with non-CaOx, CaOx urolithiasis patients have higher BMI and urine gravity, lower proportion of urinary infection and blood chlorine. 2. Metabolic disease is common in CaOx urolithiasis patients, dyslipidemia is the most common one. 3. Hyperlipidemia in CaOx urolithiasis patients is associated with hyperuricemia, hypercalcemia, the decrease of iPTH and urine pH≤6.

PUB301

Metabolic Acidosis and Clinical Outcomes in CKD Patients – Multicenter Large Cohort Study Using Instrumental Variable Analysis

Jung Nam An,[1] Yong Chul Kim,[2] Kwon Wook Joo,[3] Yun Kyu Oh,[4] Chun Soo Lim,[1] Jung Pyo Lee.[1] *[1]Seoul National University Boramae Medical Center, Seoul, SEOUL, Republic of Korea; [2]SNUH, Seoul, Republic of Korea; [3]Seoul National University Hospital, Seoul, Seoul, Republic of Korea; [4]Department of Internal Medicine, Boramae Medical Center, Seoul, Republic of Korea.*

Background: Whether low serum total CO2 (TCO_2) concentrations, defined as metabolic acidosis, increase a risk for kidney function deterioration and mortality in chronic kidney disease (CKD) was controversial and not clear enough. Large-scale studies for the clinical impacts of metabolic acidosis in Asian CKD patients have been done, neither.

Methods: A multicenter cohort study of 42,270 adult nephrology outpatients, from 2001 to 2016, was conducted to investigate the association between serum TCO_2 concentrations measured at first outpatient visit and clinical outcomes. The patients diagnosed with end-stage renal disease (ESRD) from the first day of outpatient visit to 3 months were excluded. Instrumental variable was defined as the region divided to 4 groups based on the proportion of patients who have serum TCO_2 concentration lower than 22 mmol/L.

Results: The patients with initial TCO_2 < 22 mmol/L were 10.1%, hypertension and diabetes accounted for 29.3% and 20.9%, respectively. ESRD occurred at 8.5% patients and mortality rate was 12.2% during median 77.0 months follow-up period. Cox-proportional hazard regression model adjusted for initial estimated glomerular filtration rate demonstrated that low TCO_2 concentration increased a risk for progression to ESRD (hazard ratio [HR] 1.13; 95% confidence interval [95% CI] 1.04-1.23) and mortality (HR 1.47; 95% CI 1.37-1.59). Cox regression model using instrumental variable also verified a significant association between initial TCO_2 concentration and mortality (HR 0.58; 95% CI 0.51-0.66), however, there was no significant hazards of low TCO_2 concentration for progression to ESRD.

Conclusions: Metabolic acidosis was significantly associated with mortality, but not with progression to ESRD in this study using instrumental variable.

PUB302

Gitelman's Syndrome in a Patient with C1q Nephropathy: A Case Report

Sagar Gupta, Sudip M. Patil, Dinesh Khullar. *Nephrology, Max Super specialty Hospital, New Delhi, India.*

Introduction: Coexistence of C1q Nephropathy (C1qN) and Bartter–Gitelman syndromes (BGS) is exceedingly rare.Few case reports of patients with BGS subsequently developing nephrotic range proteinuria secondary to C1qN or FSGS have been described. We present here a case diagnosed as C1qN who later developed electrolyte abnormalities consistent with Gitelman Syndrome.

Case Description: A 17 year-old male from a middle eastern country was being evaluated for nephrotic range proteinuria of 14gms/d. At age 3, he had a kidney biopsy performed showing FSGS. He was treated with steroids, cyclosporine, mycophenolate and cyclophosphamide in various combinations till age 10 and had attained complete remission. Repeat renal biopsy was performed. It showed 20 glomeruli, 1/20 sclerosed, 6 glomeruli showed increased mesangial matrix and hypercellularity. No significant IFTA. IF showed IgA2+, C1q3+, [IgG,IgM,C3, κ & λ chains – all 1+]. EM showed electron dense deposits in mesangial and paramesangial regions and focal foot processes effacement (40%). ANA, extractable nuclear antigen panel, C3 & C4 were unremarkable. Pt was started on MMF & prednisolone. Proteinuria gradually improved to less than 300mg/d and all immunosuppressants were stopped by end of 2 years. BP always remained normal and S. Crt was 0.6 mg/dl. One year later, he developed electrolyte abnormalities consistent with BGS. He had recurrent severe hypokalemia with Sr. K as low as 1.3. Patient had 3 hospitalizations for severe weakness and inability to stand when S. potassium dropped below 2.0. Hypomagnesaemia (Sr.Mg range 0.8-1.4 mg/dl), metabolic alkalosis (pH 7.50-7.65) with bicarb 32-37 mEq/L, hypochloremia (S.Cl 85-95 mEq/L), hyperuricemia and hypercalcemia were also noted. Patient denied any intake of thiazide diuretics or herbal medications. Pt declined genetic testing for BGS due to financial reasons. He is maintained on KCl supplementation 320mEq/d, magnesium orotate, aldactone and febuxostat.

Discussion: This case report decribes a unique case of C1qN subsequently developing electrolyte abnormalities consistent with BGS. It is unclear how immune complex related C1qN may predispose to development of renal tubulopathy like BGS or vice versa but the two are probably linked. Development of proteinuria in such patients should prompt clinicians to think about this rare but possible differential of co-existent C1qN/FSGS and renal tubulopathy-BGS.

PUB303

Is This Mutation Associated with Lactic Acidosis?

Siddhartha Kakani. *Nephrology, University of Utah, Salt Lake City, UT.*

Introduction: Herein, we report a case of recurrent symptomatic lactic acidosis in which genetic evaluation revealed a mutation associated with cardiac disease; but, hitherto, not lactic acidosis. Further studies to explore possible associations between this mutation and lactic acidosis are warranted.

Case Description: A 39 year old obese male with obstructive sleep apnea (OSA) & chronic hypoxia on oxygen presented with history of multiple hospitalizations (50 in two years) for lactic acidosis. All episodes were associated with muscle weakness, fatigue and lactic acid levels of 6-10 mmol/L in the face of hemodynamic stability and a normal liver profile. Genetic evaluation revealed a normal acyl carnitine profile and no pathogenic variants of the PDH or Mitochondrial Respiratory Chain Complex. However, a heterozygous mutation of **PRKAG2, a gene coding for subunit of AMP activated protein kinase (AMPK),** was discovered. Supportive treatment, with emphasis on controlling factors that exacerbated the lactic acidosis, was provided.

Discussion: This patient had a heterozygous variant of PRKAG2- a gene that encodes the gamma-2 subunit of a heterotrimeric protein- **AMP activated protein kinase (AMPK).** AMPK is present in many tissues and functions as a "energy sensor" within cells. "Excessive energy expenditure" resulting in ATP breakdown with consequent increase in intracellular AMP activates AMPK. AMPK, in turn, downregulates energy expending processes like fatty acid oxidation. AMPK gene mutations are associated with hypertrophic cardiomyopathy and cardiac arrhythmias (like WPW syndrome). Given the role of AMPK in energy metabolism, it is conceivable that abnormalities of AMPK be associated with lactic acidosis. However, to our knowledge, no such association has yet been reported. It is pertinent to note that Metformin, a drug that increases hepatic AMPK activity, can cause lactic acidosis. It is possible that alterations in AMPK activity affect the intracellular energy balance and/or metabolism of lactate. This patient had chronic hypoxia, OSA and excessive caloric intake, all of which predisposed him to lactic acidosis. Although unproven, it is likely that a combination of predisposing clinical features and a genetic mutation such as this one resulted in lactic acidosis in this patient. There is no known treatment. Circumstances that facilitate lactic acid production like hypoxia, volume depletion & excessive glucose consumption should be avoided.

PUB304

Death Due to Refeeding Syndrome (RFS) Described in 1507 by Antonio Benivieni, the Father of Pathology and Narrative Medicine

Natale Gaspare De Santo,[1] Rosa M. De santo,[5] Carmela Bisaccia,[3] Malcolm E. Phillips,[4] Luca S. De santo.[2] *[1]Nephrology, University of Campania "L. Vanvitelli", Naples, Italy; [2]University of Foggia, Naples, Italy; [3]Mazzini Institute, Naples, Naples, Italy; [4]Hon. Consultant Nephrologist, Charing Cross Hospital, London, Naples, Italy; [5]School of Integrated Gestalt Therapy, Torre Annunziata, Naples, Italy.*

Background: RFS, a disease presenting assevere electrolyte disturbance - low serum concentration of sodium, magnesium and phosphate-causing death due to cardiac arrhythmias, cardiac failure and pulmonary edema - was described in 1981by Roland L. Weinsier and Carlos L. Krumdieck,butit is rootedin a more distant past.

Methods: We aim to report heretofore unknown deathscaused by RFS described by Antonio Benivieni (1443-1502)in*The hidden and remarkable causes of diseases and recovery*(Florence, 1507).The book narrated 111 clinical histories. For the first time diagnoses were disclosed by autopsy. Thus Benivieni became the Father of Pathology and his book - recently - recognized as the first example of Narrative Medicine (DeSanto RM, 2018).

Results: Report no. LVII reads: "[In 1496] extensive famine affected nearly the whole Italy, that many died in the public roads and city streets. Many also through bad and injurious foods, were attacked by various disorders. I noticed too that very many of those who had, after long fasting, obtained more abundant food, enjoyed their fuller nourishment for a few days and then died, so harmful and dangerous is satiety preceded by a long period of abstinence. I also saw women who in this way did harm to the children at their breast, and so brought death upon their children and themselves. But very many who were reduced to the invalid state were, by the care and diligence of physicians, restored to their former health in the hospitals".

Conclusions: Data illustrate (i) Death due starvation; (ii) Death due to ingestion of deteriorated/toxic foods(inevitable in times of famine being healthy food scarcely available); (iii) Death caused by excessive food ingestion after long lasting abstinence from food; (iiii) Death of breast fed children and of their starved mothers; (v) Healing of many diseased persons receiving hospital care. Deaths are similar to those caused byunrestricted feeding after starvation in Nazi camps, Japanese prisoners of war, *Dutch Famine* (1944-45), and *Great Bengal Famine* (1943) described by Nobel economist and philosopher Amartya Sen. For 507 years Benivieni'sweighty description of RFS was ignored.

PUB305

Normal Fractional Excretion of Urate to Diagnose Reset Osmostat in Children

Michael L. Moritz.[1,2] *[1]Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA; [2]University of Pittsburgh School of Medicine, Pittsburgh, PA.*

Introduction: Reset osmostat (RO) is a subtype of syndrome of inappropriate anti-diuretic hormone secretion (SIADH) that is rare in child. RO is characterized by refractory hyponatremia despite variations in sodium and water intake with a retained ability to dilute urine in response to a water challege. It has been suggested that a normal fractional excretion of urate (FEUrate) (< 11%) can distinguish reset osmostat from the other subtypes of SIADH in adults, which have an elevated FEurate (>11%).

Case Description: Reported are three children with euvolemic hyponatremia that was refractory to fluid restriction and sodium supplementation (Table). Hypothyroidism and adrenal insufficiency were excluded. Patients 1 and 2 were profoundly developmentally delayed and with a seizure disorder treated with Depakote and Trileptal, respectively. Hyponatremia was of prolonged duration. Patient 3 had a rickettsial infection with transient hyponatremia that resolved with treatment of the infection. Traditional serum and urinary biochemistries varied widely between the patients, and not in keeping with classic SIADH (Table). Water loading tests were not performed due to the risk of worsening hyponatremia. FEUrates were normal at around 6% in all patients, helping to confirm a diagnosis of RO. A normal FEUrate is helpful in establishing a diagnosis of RO in children with SIADH.

Discussion: A normal FEUrate is helpful in establishing a diagnosis of RO is children with SIADH

Syndrome of Inappropriate Anti-Diuretic Hormone (SIADH) Induced Just After Surgery for Non-Small Cell Lung Cancer

Masahiro Muto, Hitoshi Suzuki, Takashi Kobayashi, Masao Kihara, Yusuke Suzuki. *Department of Nephrology, Juntendo University Faculty of Medicine, Tokyo, Japan.*

Introduction: The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is a disorder of impaired water excretion caused by the inability to suppress secretion of antidiuretic hormone (ADH). It has been commonly associated with small cell carcinoma. However, the case with SIADH developed after pneumonectomy is rare and has different pathogenesis with paraneoplastic syndrome. We present a unique case of SIADH induced just after left upper lobectomy with hilar lymph node resection for non-small cell lung cancer (NSCLC). This case reviews possible alternative mechanism of SIADH in patients with NSCLC.

Case Description: 71-year-old woman was hospitalized in order to have a surgery for lung adenocarcinoma. Before three months of admission, the levels of carcinoembryonic antigen (CEA) increased (6.5ng/ml). Clinical examination resulted in the diagnosis as lung cancer (T2aN3M0, stage IIIB). After 2 days of left upper lobectomy, she exhibited disorientation. Although preoperative examinations indicated no electrolyte abnormalities, laboratory examinations revealed reduced serum sodium levels of 121mEq/L, increased sodium excretion (140mEq/L) with plasma hypoosmolarity (244mOsm/kg/H_2O) and urine hyperosmolarity (427mOsm/kg/H_2O). The levels of ADH remained more than detectivity despite hyponatremia. These data suggest that the hyponatremia in this case was caused by SIADH. She was treated with hypertonic saline infusion (NaCl 2%). After 3 days of initial treatment, the serum sodium concentration increased to 133mEq/L, and her disorientation was improved. Finally, the levels of ADH decreased undetectable on 9 days after the onset of SIADH. Hyponatremia did not recur without any therapy.

Discussion: There are possible alternative mechanisms of SIADH in this case. The surgical stress and aging have been shown to be a risk factor for the induction of SIADH. Another possibility is that decrease of left atrial pressure in response to reduction of pulmonary vascular residence stimulates volume receptors in the cardiopulmonary circulation resulting in the release of ADH. This case indicates the importance of considering SIADH as a possible complication in older patients undergoing lobectomy.

Pharmacodynamics and Safety of Sodium Zirconium Cyclosilicate in Healthy Chinese Subjects: Open-Label, Phase 1 Study

Tommy Cheung,[1] Fang Sun,[2] Yulin Qin,[3] Mats Någård,[3] Jenny Jonasson,[4] June Zhao.[3] *[1]Division of Clinical Pharmacology and Therapeutics, Department of Medicine, The University of Hong Kong, Hong Kong, China; [2]Global Medicines Development, AstraZeneca, Shanghai, China; [3]Global Medicines Development, AstraZeneca, Gaithersburg, MD; [4]Global Medicines Development, AstraZeneca, Gothenburg, Sweden.*

Background: Sodium zirconium cyclosilicate (SZC; formerly ZS-9) is a selective potassium (K)-binder that exchanges Na and H for K. It has been shown to rapidly restore normokalemia in Caucasian patients with hyperkalemia. Here we report the effects of SZC on urine K and Na, serum K, and safety in healthy Chinese subjects.

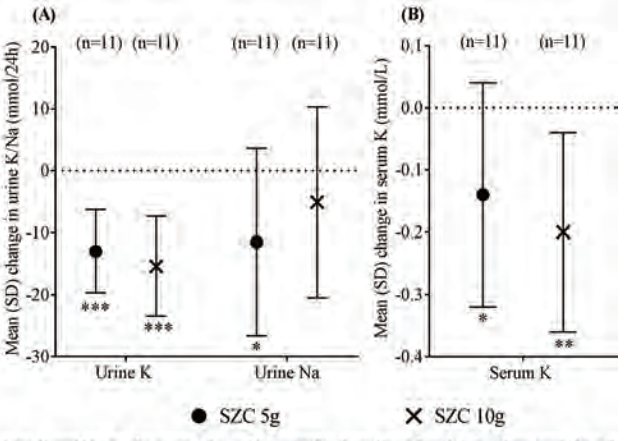
Methods: This open-label, phase 1 study randomized 22 healthy adults (18–55y) at a single center in Hong Kong. To control dietary Na and K intake, a standardized diet of 40 (±10%) mEq/d Na and 128(±10%) mEq/d K was given on Days 1–8. Oral SZC powder 5 or 10 g (n=11 each) was administered as a suspension in water once daily on Days 5–8. Urine K and Na was assessed from the mean of two 24-h samples at baseline (Days 3+4) and during SZC treatment (Days 7+8). Fasting serum K was measured daily. The primary endpoint was mean change from baseline in urine K; secondary endpoints included changes from baseline in urine Na, serum K, and other serum electrolytes, and adverse events (AEs).

Results: Subjects (59% male; mean age 33.5y) had a mean baseline serum K of 4.27 mmol/L. Urine and serum K significantly decreased from baseline with both SZC doses (Figure). Urine Na decreased; no clinically significant changes in other serum electrolytes, including Na, Ca, Mg, and PO_4, were reported. Overall, 16 subjects reported mild AEs during the study and 10 subjects reported mild AEs during SZC treatment. The most common AEs during the treatment period were gastrointestinal disorders but none were judged drug related. None developed hypokalemia or edema; no deaths, serious AEs, or discontinuation due to AEs were reported.

Conclusions: Oral SZC 5 and 10 g once daily significantly reduced urine and serum K in healthy Chinese subjects, and was well tolerated.

Funding: Commercial Support - AstraZeneca

Figure. Mean change from baseline in (A) urine K and Na, and (B) serum K in healthy Chinese subjects treated with SZC



Urine K and Na are the mean of two 24-h samples from Days 3 and 4 (baseline) and Days 7 and 8 (treatment); serum K values are the mean of values on Days 3–5 pre-dose (baseline), and Days 7 and 8 (treatment).
*P<0.05, **P<0.01, ***P<0.001 vs baseline.
K, potassium; Na, sodium; SD, standard deviation; SZC, sodium zirconium cyclosilicate.

PUB308

A Rare Case: Vitamin D Related Inappropriate ADH Syndrome

Sara Yavuz. *Nephrology, University of Yeditepe, Istanbul, Turkey.*

Introduction: The most important renal activity of ADH is to increase the water permeability of the distal and the collecting tubule. This helps to protect from dehydration. Inappropriate ADH syndrome is an clinic syndrome which there is more ADH concentration versus any osmotic or volume stimulus that normally affects ADH secretion. Among etiologic causes small cell bronchogenic carcinoma, pancreas and duodenal adenocarcinoma, leukemia, lymphoma, thymoma, cerebral trauma and tumors, meningitis, encephalitis, pneumonia, tuberculosis, lung abscess are listed. Vitamin D deficiency is a rare, irrational but quit important cause. In this case, unusual to the treatment of SIADH, vitamin D replacement was sufficient and Tolvaptan was stopped and not needed anymore.

Case Description: A 52-year-old male patient was admitted to the ER department with nausea, weakness, and blurred consciousness. In his labrotory findings, there were not any pathologic finding except low serum sodium level (121 mEq/L). 3% NaCl treatment was started first because of his emergency situation. Due to lack of effective response, the treatment was switched to Tolvaptan. But his vitamin D level was low (25 OH-cholecalciferol = 10 nmol/L). On admission day, measured ADH level was 10 pg/mL (N: 1-5 pg/mL), so etiology for inappropriate ADH syndrome was evaluated. No pathology was detected in endoscopy, colonoscopy, abdominal ultrasound examination and MRI. However, enlarged, 33x22 mm sized lymphadenopathies were detected in paratracheal, subcarinal region by CT scan. Mediastinoscopic lymph node biopsy was performed due to the suspicion malignancy because of very intense FDG absorption (SUV max: 11.20) But ancotic lymph node containing reactive changes was stated on pathology report. So the Vitamin D treatment with 300,000 units per month orally was started and tolvaptan treatment was stopped. 1 month after discharge, serum 25 OH-cholecalciferol level was 20 nmol/L and serum sodium level was 134 meq/L.

Discussion: Vitamin D deficiency is associated with musculoskeletal, cardiovascular and immunological disorders, malignancy and even with diabetes and hypertension. However, when we updated latest knowledges about vitamin D relation with hyponatremia, we obtained very limited information. In addition, this treatment was more cost effective and accesible than Tolvaptan. For these reasons, we would like to remind the vitamin D deficiency to the clinicians in case of hyponatremia.

PUB309

Heart Transplant Patient Presenting with Rare Cause of Hyponatremia After Carboplatin-Based Chemotherapy

Ravi K. Thimmisetty, Frank W. Braxton. *Nephrology Associates, Cape Girardeau, MO.*

Introduction: We are presenting a case of severe hyponatremia developed after carboplatin based chemotherapy requiring hypertonic saline and furosemide

Case Description: 81-year-old lady with h/o congenital heart disease s/p heart transplant 1995, hypertension, stage IV metastatic small cell cancer admitted for severe hyponatremia after 3rd day of first cycle of carboplatin etoposide. Home medications include cyclosporine, levothyroxine, pantoprazole, amlodipine, carvedilol, prednisone, lisinopril, and furosemide as needed basis only. She was complaining of new onset nausea, anorexia, mild abdominal discomfort, worsening fatigue and edema. Admission vitals were temperature of 97.7 f, blood pressure of 118/73 mm Hg, heart rate of 76 bpm, respiratory rate of 16 per minute and saturating 97 percent on room air. Examination shows tenderness at right quadrant and 2 + edema. Admission laboratory results showed serum sodium 119 meq/l, potassium 5.4 meq/l,

chloride 86 meq/l, bicarbonate 15, BUN 58 mg/dl, creatinine 1.71 mg/dl, ionized calcium 0.9 mmol/l, serum magnesium 1.4 mg/dl, white blood cells of 5.72 x 10^3 cells/ µL, Hemoglobin is 10.8 g/dl, Platelets 189 x 10^3 /L, total protein 5.3, albumin is 3.3 mgd/l. hyponatremia work up showed serum osmolarity 270 mosm/kg, TSH 6.9 IU/ml, random cortisol 4.5 µg/dL, serum uric acid 0.7 mg/dl, urine sodium <20 mmol/L, urine osmolarity 305 mosm/kg, random urine uric acid is 3 mg/dl, urine uric acid and creatinine ratio is 0.16 mg/mg, fractional excretion of Urea 26.7%, fractional excretion of uric acid is 16%. Antihypertensives were held and sodium polystyrene sulfonate was given on admission. Sodium was not improving after 1.4 liters of normal saline was given (119 > 120 > 119 meq/l). Immediately 2% hypertonic saline and furosemide was given. Within 36 hours, symptoms were resolved and patient was discharged in 4 days with sodium of 135 and creatinine of 1.1 mg/dl

Discussion: Literature was limited with carboplatin associated hyponatremia. Although multifactorial, two most important differentials to distinguish were SIADH and salt wasting nephropathy as treatment varies. Our case illustrates the difficulty of diagnosing salt wasting nephropathy from carboplatin, but treatable.

PUB310

Lymphocytic Hypophysitis: A Challenge to Diagnose Postpartum

Mala Sachdeva,[1] Nupur N. Uppal,[2] Alia Hasan,[1] Llene J. Miller.[3] *[1]Northwell Health, Great Neck, NY; [2]Hofstra Northwell School of Medicine, Great Neck, NY; [3]North Shore University Hospital, Great Neck, NY.*

Introduction: Hypernatremia during pregnancy is not commonly encountered. Additionally, differentiating between transient diabetes insipidus of pregnancy from central or nephrogenic diabetes insipidus during pregnancy poses additional dilemma. Moreover, lymphocytic hypophysitis as an etiologic disorder contributing to the hypernatremia is rare. Here, we report a complex case of lymphocytic hypophysis diagnosed postpartum.

Case Description: A 32 year old, 37 weeks pregnant female underwent emergent cesarean section due to concerns for fetal compromise and acute fatty liver of pregnancy. Preoperative labs were notable for acute kidney injury (creatinine 3.3mg/dL), elevated liver enzymes (AST 259 U/L, ALT 536 U/L, TB 5.1 mg/dL), significant coagulopathy, and hypoglycemia. Her presenting sodium was 141 mmol/L which progressively increased and peaked to 156 mmol/L post operatively with 5 to 7L urine output daily. Per patient, for approximately 1.5 weeks prior to presentation, she had been experiencing significant polyuria and polydipsia. Urine osmolality was 137 mosm/kg. At first, her hypernatremia was attributed to transient gestational diabetes insipidus associated with pregnancy amplified by acute fatty liver of pregnancy, however further workup changed the diagnosis to central diabetes insipidus secondary to hypophysitis due to ACTH <5pg/mL, A.M. cortisol 0.8 ug/dL, FSH 0.3IU/L, LH <0.1IU/L, TSH 0.28uL/mL, and FT4 0.6ng/dL. Furthermore, MRI of the brain revealed absence of the normal pituitary bright spot, and thickened pituitary stalk. She was started on prednisone, ddavp, and levothyroxine and did well. Six months postpartum her MRI brain revealed resolution of the thickened pituitary stalk, reappearance of the pituitary bright spot, as well as a smaller pituitary gland. She still remains on oral desmopressin as well as levothyroxine supplementation.

Discussion: Diagnosing lymphocytic hypophysitis in the postpartum period can be a challenge. Although rare, most cases occur in late pregnancy or in the postpartum period and one must keep this in the differential when evaluating a pregnant or postpartum woman with hypernatremia. Multidisciplinary team approach and expertise involving the endocrinologist, nephrologist, and obstetrician is important for quick diagnosis and for prompt treatment to avoid life threatening complications that could ensue.

PUB311

The Use of Serum Sodium–Chloride Difference in the Evaluation of Metabolic Acidosis in Hospitalized Patients

Kipyo Kim, Ho Jun Chin, Ki Young Na, Sejoong Kim. *Seoul National University Bundang Hospital, Gyeonggi-do, Republic of Korea.*

Background: Metabolic acidosis is generally defined by the presence of a low serum bicarbonate concentration. (It is hypothesized that metabolic acidosis would cause a compensatory decrease in the serum chloride (Cl) relative to sodium (Na) in order to preserve electroneutral balance.) Therefore, the purpose of our study was to investigate the use of Na-Cl difference or ratio as a bedside tool to evaluate the identifying metabolic acidosis in hospitalized patients as an alternative to measuring serum bicarbonate.

Methods: We retrospectively enrolled 17,320 adult patients who were admitted to the academic teaching hospital from January 2013 to December 2013. Serum Na, Cl, and bicarbonate were measured at admission and Na-Cl difference, Cl-Na ratio and corrected anion gap was calculated. Metabolic acidosis was defined as a bicarbonate below 23mEq/L.

Results: Metabolic acidosis occurred in 4488 (25.9%) of samples. Significant Spearman correlation coefficients were found between Na-Cl difference and corrected anion gap, and serum bicarbonate. Receiver operator characteristic curve showed that values revealing metabolic acidosis were less than 32.5 mEq/L for Na-Cl difference with sensitivities of 94.0% and specificity 90.0%. Additionaly, multivariate logistic regression analysis showed that Na-Cl difference levels at admission were independently associated with AKI and in-hospital mortality.

Conclusions: Na-Cl difference are simple and fast, and can be used as an alternative tool to identify metabolic acidosis in hospitalized patients.

PUB312

Edema Assessment of Dialysis Patients by Bioelectrical Impedance Analysis

Feixia Zhuo,[2] Jing Zheng,[1] Chen Chen,[1] Liming You.[1] *[1]Sun Yat-Sen university, Guangzhou, China; [2]The Fifth Affiliated Hospital of Sun Yat-sen Univeristy, Zhuhai, China.*

Background: Bioelectrical impedance analysis (BIA) is useful for assessment of body fluid status but it is rarely used in Chinese haemodialysis (HD) patients. So it is the first time to discuss the validity of BIA in Chinese HD patients. The aim of this study was to describe fluid status and volume overload in maintenance hemodialysis (MHD) patients with edema index (EI) by means of the bioelectrical impedance analysis (BIA) and to explore the associating factors of edema index (EI) in MHD patients.

Methods: Cross-sectional study design was used and 193 MHD patients in a hemodialysis center in China were enrolled. Body components were measured by using the body component analyzer MC-180 after dialysis. EI were calculated by using the ratio of extracellular water (ECW) to total body water (TBW). Age, urine volume, Kt/V, ultrafiltration volume, and nutritional biomarkers (albumin, feritin and creatinine) were collected. Descriptive statistics and multivariate logistic regression analysis were used to analyze the associating factors of the EI.

Results: There were 118 males and 75 females, with an average age of 50.22 ± 12.55 years and an average HD period of 60(3~216)months in this study. Sixty patients (69.77%) were indicated volume overload according to the standard of EI in neither diabetes nor hypoproteinemia group. Eighty-eight patients (92.63%) in diabetes or hypoproteinemia group and 12 patients (100%) in both diabetes and hypoproteinemia group were indicated volume overload respectively according to the EI in each group. Multivariable logistic regression analysis results were presented in figure 1.

Conclusions: The prevalence of volume overload is high in MHD patients especially in patients complicating with both diabetes and hypoproteinemia. Age, gender, dialysis age, Kt/v, muscle mass and body mass index are related with patients' fluid status. Edema index (EI) appears to be an easy and useful marker for the estimation of fluid status and volume overload in MHD patients with various clinical backgrounds.

The Relationship Between Liver Cyst Volume and QOL in Japanese ADPKD Patients

Satoru Muto,[1] Saori Nishio,[6] Ichiei Narita,[4] Toshio Mochizuki,[5] Ken Tsuchiya,[2] Kazuhiko Tsuruya,[3] Yoshifumi Ubara,[7] Shigeo Horie.[1] *[1]Juntendo University, Tokyo, Japan; [2]Tokyo Women's Medical University, Shinjuku-ku, Japan; [3]Nara Medical University, Kashihara, Japan; [4]Niigata University, Niigata, Japan; [5]Tokyo Woman's Medical University, Tokyo, Japan; [6]Hokkaido University, Sapporo, Japan; [7]Toranomon Hospital, Tokyo, Japan.*

Background: To clear the relationship between the size of liver cysts and QOL in ADPKD patients, we started the prospective longitudinal study to clear the impact of liver cysts on QOL during 3 years.

Methods: This multi-institutional, prospective, observational study was supported in part by a Grant-in-Aid for Progressive Renal Diseases Research, from the Ministry of Health, Labour and Welfare of Japan. We divided the included ADPKD patients into 4 groups (group A; control group < 25 %, group B; 25-49 %, group C; 50-75 %, group D; >75 %) according to liver cysts-parenchyma ratio (CPR). QOL was measured by FANLTC + FACT-Hep additional concerns for assessing general health-related QOL and liver-specific QOL, respectively. We compared QOL scores between groups during 3 years.

Results: We included 111 patients in this study. There are no significant differences between groups in eGFR ($p = 0.368$) and CKD stage ($p = 0.380$). At the time of enrollment, the FANLTC score ($p = 0.039$) and the FACT-Hep scores ($p < 0.001$) were significantly inversely correlated with liver CPR. With respect to the change of QOL score during study period 3 years, the larger liver CPR, the significantly decreased FANLTC score during 3 years ($p = 0.0011$, Figure 1). The trend test showed that FACT-Hep score also decreased significantly as the liver CPR became larger ($p = 0.0002$, Figure 2).

Conclusions: In this cross-sectional report, we could clear the long-term influence of the liver cyst volume on QOL in ADPKD patients.

Progression of Renal Function and Total Kidney Volume in Japanese ADPKD Patients: An Analysis of Data from Japanese Polycystic Kidney Disease Registry (J-PKD)

Satoru Muto,[1] Toshio Mochizuki,[2] Ken Tsuchiya,[3] Saori Nishio,[4] Kazushige Hanaoka,[9] Yoshifumi Ubara,[10] Kazuhiko Tsuruya,[5] Eiji Ishimura,[6] Tadashi Sofue,[8] Ichiei Narita,[11] Shoichi Maruyama,[7] Shigeo Horie.[1] *[1]Juntendo University, Tokyo, Japan; [2]Tokyo Woman's Medical University, Tokyo, Japan; [3]Tokyo Women's Medical University, Shinjuku-ku, Japan; [4]Hokkaido University, Sapporo, Japan; [5]Nara Medical University, Kashihara, Japan; [6]Meijibashi Hospital, Matsubara-shi, Japan; [7]Nagoya University Graduate School of Medicine, Nagoya, Japan; [8]Kagawa University, Kita-gun, Japan; [9]The Jikei Daisan Hospital, The Jikei University School of Medicine, Komae, Tokyo, Japan; [10]Toranomon Hospital, Tokyo, Japan; [11]Niigata University, Niigata, Japan.*

Background: The PKD Sectional Committee of a Grant-in-Aid for Progressive Renal Diseases Research, from the Ministry of Health, Labour and Welfare of Japan started the web-based, and prospective registry system, the Japan PKD Registry (J-PKD) in 2009, to record clinical, and laboratory data about PKD in Japan. Follow-up period of five years has been completed in all cases. We will report the final data of J-PKD registry.

Methods: Patient data including age, gender, family history, complication, medical history, laboratory data, and clinical diagnoses were electronically recorded at each institution and registered on the J-KDR webpage via the Internet Data and Information Center for Medical Research system, which is part of the University Hospital Medical Information Network.

Results: We included 339 patients in this study (215 female and 124 male). Median age was 51.0 years. The mean eGFR was 50.4 ml/min/1.73m^2 at the time of enrollment. The mean annual amount of eGFR change (ΔeGFR/Y) was -3.1 ml/min/1.73m^2. There are no significant differences in ΔeGFR/Y between CKD stage (P = 0.3393). The mean total kidney volume (TKV) was 1683.6 ml at the time of enrollment. The mean annual amount of TKV change (ΔTKV/Y) was 92.1 ml. There are significant differences in ΔTKV/Y between CKD stage (P = 0.0041, Figure). ΔTKV/Y was significantly inversely correlated with ΔeGFR/Y (P < 0.001). In cases with TKV ≥ 750ml, the annual decline rate of eGFR in patients with the rate of TKV growth ≥ 5 % was significantly faster compared with the patients with the rate of TKV growth < 5 % (< 5 %: -3.21 ± 3.66 ml/min/1.73m^2/Y, ≥ 5 %: -4.53 ± 4.26 ml/min/1.73m^2/Y, p = 0.0383).

Conclusions: In this cohort study, we will clear the natural course of renal function and TKV in Japanese ADPKD patients.

Funding: Government Support - Non-U.S.

PUB315

Rapidly Progressive Kidney Dysfunction Due to Tubulointerstitial AL Amyloidosis with Concurrent Apolipoprotein A-I/A-IV Amyloidosis in a Case of Autosomal Dominant Polycystic Kidney Disease

Atsuko Uehara,[2] Tomo Suzuki,[2] Daisuke Ichikawa,[2] Tsutomu Sakurada,[3] Akira Shimizu,[1] Junki Koike,[4] Yugo Shibagaki.[2] *[1]Nippion Medical School, Tokyo, Japan; [2]St Marianna University Hospital, Kawasaki, Japan; [3]St. Marianna University School of Medicine, Kawasaki, Japan; [4]St.Marianna University, Kawasaki, Japan.*

Introduction: AL or AHL amyloidosis usually cause paraprotein deposition mainly in glomerulus, whereas deposition of apolipoprotein A-I (ApoA1), and apolipoprotein A-IV (ApoA4) amyloidosis mainly occurs in renal tubulointerstitium (TI). Here, we describe a rare case of autosomal dominant polycystic kidney disease (ADPKD) who developed rapidly progressing non-proteinuric kidney disease which can be attributed to AL amyloidosis with concurrent apolipoprotein A-I/A-IV amyloidoses.

Case Description: A 54-year-old man was referred to our hospital for chronic kidney disease (CKD) with a serum creatinine (sCr) of 1.26 mg/dL. With multiple kidney cysts, and family history, we diagnosed as ADPKD. However, his kidney function declined too rapidly for ADPKD with sCr of 2.57 mg/dL in 1 year. Since his serum free kappa light chains were markedly elevated, with increased kappa-to-lambda light chain ratio, he underwent open renal biopsy, which revealed massive amorphous deposits confined to the TI, which stained positive for Congo red, sparing the glomeruli. Immunofluorescence showed dominant staining of the kappa light chain deposits. Electron microscopy revealed randomly arrayed straight 8- to 10-nm-thick fibrils. Bone marrow biopsy revealed amyloid deposits, and he was diagnosed as primary AL amyloidosis and underwent autologous hematopoietic stem cell transplantation. Unfortunately, he died of sepsis. Subsequently, mass spectrometry analysis revealed that extensive amount of ApoA1 and ApoA4 were also present in TI as well as kappa light chains. Hence, we conclude that our case was concurrent AL, ApoA1 and ApoA4 amyloidoses, with the latter being the main pathophysiology based on the mass spectrometry finding.

Discussion: Accurate diagnosis of amyloidosis is of paramount importance to avoid unnecessary treatment regimens. Even if renal biopsy suggests AL amyloidosis, mass spectrometry may unmask the complication of other type of amyloidosis, which can be useful to predict prognosis, and response to therapy. To our knowledge, this is the first report describing the case with ADPKD who suffered from several types of amyloidosis coexisting together.

PUB316

Continuously Evolving Phenotype of Fetal Presentation of HNF1B Gene Deletion

Roxana Cleper,[1,2] Dana Shapira,[1,2] Lewis Reisman,[1] Danith D. Blumenthal,[1,2] Adi Reches,[3,2] Shay Ben-Shachar.[3,2] *[1]Pediatric nephrology, Dana-Dwek Children's Hospital, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel; [2]Sackler Medical School, Tel Aviv University, Tel Aviv, Tel Aviv, Israel; [3]Genetic Institute, Tel Aviv Sourasky Medical Center, Tel Aviv, Israel.*

Introduction: *HNF1B* mutations, consisting usually of heterozygous microdeletions (1.4-1.5KB) at 17q12 with variable penetrance dominant inheritance in 30-40%, are the most common genetic cause for fetal hyperechogenic kidneys(20-30% detection rate) and of isolated CAKUT(Congenital Anomalies of Kidneys and Urinary Tract)(5-30% mutation identification). The evolution of these renal abnormalities, their impact on renal function and appearance of extrarenal features is unpredictable.

Case Description: We present our center's experience with 5 cases with *HNF1B* mutation: Presentation consisted of fetal hyperechogenic normal-/ enlarged kidneys in2/5,

polycystic small/enlarged kidneys in 2/5 and hypomagnesemia during seizures 1/5. Molecular diagnosis with HNF1B mutation detection was performed at: 34GW(gestation week) on amniocentesis 1/5, 2yrs- for polycystic kidneys 1/5, 2yrs- during evaluation for global develoopmental delay in 2/5, at 5.5yrs –for hypomagnesemia and seizures(this patient also had had hyperechogenic kidneys on fetal ultrasound with complete normalization at the age of 2yrs). TOP(termination of preganancy) was performed on the fetus diagnosed at 34weeks on parental request. Complete normalization of kidneys' hyperechogenicity by the ages of 2-3yrs in 3/4 living patients and normal GFR at 3-7yrs(despite intial Scr↑ during first 1.5-3mo) was seen in 4/4(inlcuding the patient with polycystic enlarged kidneys). Enterococcus UTI at 3.8yrs in the patient with persistently polycystic kdineys triggerred diagnosis of bilateral grade 3-4 VUR(vesicoureteral reflux) and bladder diverticles necessitating surgical intervention. Family history: maternal seizures and autistic-spectrum-disorder- maternal aunt 1/5, MODY small-size normal functioning kidneys father 1/5.

Discussion: Spontaneous resolution of fetal hyperechogenic kidneys in patients with HNF1B mutation with complete normalization of initially slightly depressed renal function might occur. Persistent parenchymal cystic changes in patients with HNF1B mutations do not exclude normal renal function. HNF1B mutation- associated parenchymal cystic changes might coexist with urological malfomations exposing the patient to urinary infections with further kidney damage. Continuous pursuit for later-onset HNF1B-associated metabolic, neurodevelopmental abnormalities is recommended

PUB317

Preventive Strategy for ADPKD in the Southern Spain: Economic Evaluation

Rafael josé Esteban de la rosa,[2,3] Jose luis Navarro_espigares,[1] Margarita Martinez atienza,[2,1] Elisa Hernandez-Torres,[1] Irene Argüelles toledo,[2,1] Juan antonio Bravo soto.[1,2] on behalf of the Grupo de Estudio de la Enfermedad Poliquística Autosómica Dominante (GEEPAD) and Asociación Amigos del Riñón. *[1]Servicio Andaluz De Salud, Granada, Spain; [2]Hospital Universitario Virgen de las Nieves, Granada, Spain; [3]Instituto de Investigación Biosanitaria de Granada (ibs.GRANADA), Granada, Spain*.

Background: Autosomal Dominant Polycystic Kidney Disease (ADPKD) is the hereditary kidney disease most frequently causes renal failure. Dialysis and transplantation are the therapeutic currently used. These renal replacement therapies (RRT) entail high health expenditures. Nowadays, there is still no curative treatment for ADPKD. We aim to analyse the cost-effectiveness of preventive strategy to stop ADPKD transmission based on assisted human reproduction such as preimplantation genetic testing (PGT) that includes "in vitro" fecundation (IVF) and intracytoplasmic sperm injection (ICSI).

Methods: A comparative analysis of the costs of IVF+ICSI+PGT versus RRT cost was carried out. The RRT cost was obtained from the specialised literature. The cost of the preventive strategy was calculated by adding the costs of an assisted reproduction procedure in a public hospital and the market price of the PGT in Spain. The average cost of a standard patient during the natural course of the disease has been calculated with patients' records from the ADPKD registry of Granada (Spain).

Results: The average costs of transplantation (47,136 and 6,477 euros/year, first year and successive years respectively), haemodialysis (44,778 euros/year), and peritoneal dialysis (34,554 euros/year) are notably higher than costs of preventing the transmission of the disease (5,520-6,020 euros). An incremental cost-effectiveness ratio in favour of the preventative strategy was obtained in a scenario with three single embryo transfers.

Conclusions: From the perspective of the cost-effectiveness analysis, the preventive strategy proved to be a superior alternative to the RRTs currently applied. Thus, it would be advisable to promote the strategy of preventing transmission of this disease through assisted human reproduction and genetic testing. Despite the positive contribution of this strategy to the economic sustainability of the public health system, a decided health policy action in its favour is needed.

PUB318

What Happens in Early Stage of Autosomal Dominant Polycystic Kidney Disease? Study in an Adolescent Population

Víctor Martínez jiménez. Grupo de Transición de Nefrología Del Hospital Virgen de La Arrixaca (Murcia, Spain) *Hospital Universitario Virgen de la Arrixaca, El Palmar (Murcia), Spain.*

Background: Autosomal Dominant Polycystic Kidney Disease (ADPKD) is a hereditary disease with progression to terminal Chronic Renal Disease, however the clinical findings begin in the 3rd decade of life: inability to concentrate urine, arterial hypertension and increased renal volume. There are few studies in children that analyze early markers of the disease. Objetive: to study and analyze the clinical characteristics in the initial phase of ADKPD in adolescents

Methods: -Adolescents of 12-22 years with a clinical or genetic diagnosis of ADPKD, followed in Nephrology or Pediatric consultations. -Analyzed variables: age, sex, mutation, glomerular filtration (CKD-EPI), urine osmolarity, proteinuria, hormones: Vasopressin, Aldosterone, Renin, Ambulatory blood pressure monitoring (ABPM):Dipper-No dipper pattern, kidney ultrasound:cysts and total renal volumen (TRV), health questionnaire

Results: -26 patients ADPKD: 43.5% men and 16.27±3.75 years. -46.2%PKD1, 15.4%PKD2, 38.5%without study -CKD-EPI 133,12±19,21 ml / min, Urinary osmolarity 650.8±278.08 -Cysts 12,58 ± 7,96 (0-28), TRV 343,47±129,46cc, TRV/height: 201,28±71,58 -Only 1 with previous HTA and 15.4% with low sodium diet. 61.5%Dipper Pattern. 1,42 ± 0,39 l/d of water -Dipper Pattern relationed with levels of Aldosterone (229.46±112.73 vs 97±11.31, p 0.001) and Renin (7.28±3.72 vs 3.05±1.03, p 0.036), without influencing of Vasopressin -CKD-EPI was related to: TRV (p 0.001) and TRV/height (p 0.009) -Vasopressin relationed with number of cysts (p 0.04), albuminuria (p = 0.004), proteinuria (p = 0.015) and Aldosterone (p 0.022). -In PKD1 the TRV is higher than in PKD2 (460.08±149.45 vs 228.18±14.59)

Conclusions: -Alterations urinary concentration, hypertension and deterioration of renal function are not early findings in this population. However, they have hyperfiltration, more cysts and TRV, and elevation of the renin-aldosterone, but normal vasopressin. -In patients with hyperfiltration there was an increase in TRV and Vasopressin in relation to cysts, proteinuria and aldosterone, so could be initial markers of progression. -PKD1 conditions higher TRV, but without alteration of the glomerular filtrate; so it would not be a bad prognostic factor in initial stages -We should explain to the patients general recommendations of drinking more water, low salt diet.

PUB319

CKD Patients with Autosomal Dominant Polycystic Kidney Disease or Other Inheritable Kidney Disease Have Distinct Characteristics and Higher Associated Healthcare Costs

Andrew J. Mallett,[1,2] Marcin Sowa,[4,3] Louise H. Wardrop,[2] Jianzhen Zhang,[3] Anne Cameron (Salisbury),[3] Helen G. Healy,[1,3] Wendy E. Hoy.[3] on behalf of the CKD.QLD consortium and the KidGen Collaborative *[1]Kidney Health Service, Royal Brisbane and Women's Hospital, Brisbane, QLD, Australia; [2]The KidGen Collaborative, Australian Genomics Health Alliance, Melbourne, VIC, Australia; [3]CKD.QLD and the NHMRC CKD.CRE, The University of Queensland, Brisbane, QLD, Australia; [4]Centre for the Business and Economics of Health, The University of Queensland, Brisbane, QLD, Australia*.

Background: Those with Autosomal Dominant Polycystic Kidney Disease (ADPKD) and Inherited Kidney Disease (IKD) are an identifiable minority of chronic kidney disease (CKD) patients. Their health service utilisation (HSU) in Australia is not defined. We aimed to identify characteristics and HSU amongst patients with CKD due to ADPKD, non-ADPKD Inherited Kidney Disease (IKD) and all-CKD causes in Queensland.

Methods: Patients with ADPKD and IKD were identified from the CKD.QLD Registry (n=7,311) and a regionally matched Queensland Health CKD cohort (n=21,773) based upon ICD-10 coding. Characteristics and HSU related to hospital presentations were analysed for 5years retrospective from June 2016 with dialysis admissions/appointments and admissions for reasons other than dialysis analysed separately.

Results: 309 (1.06%) ADPKD and 277 (0.95%) IKD patients were identified from the combined cohort (n=29,084). The median age at first admission of PKD, IKD and All-CKD patients were 53.7, 47.9 and 65.7years respectfully with mean eGFR at CKD.QLD consent being 34.1, 36.5 and 40.8ml/min/1.73m^2. PKD and IKD compared to All-CKD had lower frequency of diabetes (17% vs 21% vs 48%) and cardiovascular disease (CVD; 34% vs 32% vs 46%), but similar frequency of hypertension (79%vs80%vs81%) and mean body mass index (29.8 vs 29.2 vs 31.2). PKD and IKD were also associated with a higher incidence of dialysis than the All-CKD group within that 5year period (34% vs 24% vs 9%). Median hospital admissions for reasons other than dialysis were higher in those with PKD and IKD compared to All-CKD (7 vs 8 vs 4) with similar average length of stay (3.2 vs 4.4 vs 3.6days) per admission. Median 5year healthcare costs, excluding dialysis admissions/costs, were also higher in those with PKD and IKD compared to All-CKD ($42,088 vs $45,929 vs $16,403).

Conclusions: Those with PKD and IKD are younger, with earlier stage CKD and lower prevalence of diabetes and CVD compared to other CKD patients. Despite this, they are more likely to require dialysis within 5years and have increased hospital costs.

PUB320

Can Trehalose Intake Affect the Progression of Polycystic Kidney Diseases? Insight from a Murine Experimental Study

Li-Fang Chou,[1] Ya-Lien Cheng,[1] Ya-chung Tian,[1] Yung-Chang Chen,[2] Chih-Wei Yang,[1] Ming-Yang Chang.[1] *[1]Kidney Research Center, Chang Gung Memorial Hospital, Taoyuan, Taiwan; [2]Chang Gung Memorial Hospital, Keelung branch, Keelung, Taiwan*.

Background: Autophagy impairment has been recently proposed to play a central role in the pathogenesis of autosomal dominant polycystic kidney disease (ADPKD). Trehalose is a natural, non-reducing disaccharide that has been shown to enhance autophagy *in vitro*. In this study, we explored whether trehalose treatment protects the kidney against cyst formation in a *Pkd1*-hypomorphic mouse model.

Methods: *Pkd1* miRNA transgenic (*Pkd1* miR TG) mice were given 2% trehalose for drinking from day 35 for eight weeks. The control groups were fed with 2% sucrose or pure water. We then compared the body weights, the relative weights of the the kidneys, the histological cystic indices, and the renal function of mice receiving different treatments. Autophagy activation was investigated by RT-PCR analysis for the expression of autophagy-related genes *atg5*, *atg12*, and *beclin1* in the whole-kidney lysates, and western blotting was performed for the detection of LC3-I to LC3-II conversion.

Results: The results showed that *Pkd1* miR TG mice have a lower mRNA expression of autophagy-related genes compared to wild-type control mice, but the differences were not reversed after trehalose treatment. Trehalose also did not significantly affect the kidney weights, cystic indices, fibrosis scores and proliferative indices. The serm levels of glucose, blood urea nitrogen, and cystatin C were not significantly different between treatment and control groups.

Conclusions: These findings suggest that trehalose treatment alone does not seem to have a significant impact on the progression of polycystic kidney disease.

PUB321

Relationship Between Dietary Sodium and Protein Intake with Serum Copeptin in Autosomal Dominant Polycystic Kidney Disease

Jennifer Zhang,[1,2] Carly Mannix,[1,2] Anna M. Rangan,[3] Annette Wong,[1,2] Gopi Rangan.[1,2] PREVENT-ADPKD Investigators *[1]Centre for Transplant and Renal Research, Westmead Institute for Medical Research, The University of Sydney, Sydney, NSW, Australia; [2]Department of Renal Medicine, Westmead Hospital, Sydney, NSW, Australia; [3]School of Life and Environmental Sciences, The University of Sydney, Sydney, NSW, Australia*.

Background: Elevated levels of arginine vasopressin (AVP) are hypothesised to worsen the renal progression of autosomal dominant polycystic kidney disease (ADPKD). In addition to fluid intake, dietary solute intake can also influence AVP release. However, this association has not been specifically investigated in ADPKD. This aim of this study was to determine the relationship between dietary sodium and protein intakes with serum copeptin (a marker of AVP) in patients with early-stage ADPKD.

Methods: Patients with ADPKD (18-65 years, eGFR≥30 mL/min/1.73m^2) underwent a structured diet history interview to assess usual intake over the past 3 months during the Baseline Visit of the PREVENT-ADPKD study. Sodium and urea excretion were measured from 24hr urine collections to validate diet history-reported sodium and protein intakes, respectively. Serum copeptin was measured by a sandwich immunoassay (B.R.A.H.M.S).

Results: Sixty-nine participants (37 male, age 43±11 yrs, serum creatinine 97±36 μmol/L; mean±SD) were analysed, with a subset of 29 undertaking dietary assessment. When compared to 24hr urine urea excretion, the diet history was a valid method for estimating dietary protein, as reported intakes demonstrated a strong correlation with urine-derived estimates (r=0.658; P<0.001), and there was no evidence of systematic bias by the Bland-Altman method. The median serum copeptin concentration was 5.01 (IQR: 8.41) pmol/L. Multivariate analyses (adjusted for age, gender, 24hr urine volume and serum creatinine) revealed that serum copeptin was positively correlated with 24hr urine sodium (B=0.444; P=0.010) (the gold-standard for dietary sodium intake), but not with 24hr urine urea (B=0.663, P=0.197). No association was found between serum copeptin and diet history-reported sodium or protein intake.

Conclusions: These cross-sectional, observational data support the hypothesis that higher dietary sodium (but not protein) intake stimulates AVP release in ADPKD. The ongoing PREVENT-ADPKD study will determine the combined long-term effects of adequate hydration with lowering dietary solute intake on serum copeptin and renal cyst growth in ADPKD.

PUB322

Current Patterns of Practice of Autosomal Dominant Polycystic Kidney Disease in BC

Tae won Yi,[1] Mark Canney,[1] Adeera Levin,[2] Micheli U. Bevilacqua.[1] *[1]Department of Nephrology, University of British Columbia, Vancouver, BC, Canada; [2]St. Paul's Hospital and University of British Columbia, Vancouver, BC, Canada*.

Background: ADPKD is the most common inherited kidney disorder occurring in 1 of 400 to 1000 live births. Recently, novel biomarkers have shown promise in the literature for prediction of early disease progression such as total kidney volume (TKV). Landmark clinical trials have demonstrated the benefits of aggressive blood pressure (BP) control and specific medications such as Tolvaptan have been shown to slow disease progression. It is largely unknown if these recent breakthroughs have found their way into clinical practice. We sought to take a snapshot of 'real world' contemporary management of ADPKD, specifically assessing whether recent evidence is being incorporated into clinical practice.

Methods: This was a convenience sample of 54 patients under the care of 6 different nephrologists in 2 health authorities in British Columbia. For each patient, the dictated letter from the most recent out-patient clinical encounter was analyzed. All letters were assessed for the following quality indicators: documentation of date of renal imaging and plan for follow-up imaging, recording of TKV, consideration for Tolvaptan, BP, urine albumin:creatinine ratio (uACR), and frequency of follow-up visits.

Results: Mean (SD) age of the cohort was 51.2 (15.6) years and 48% were male. Median (IQR) eGFR was 66 (45-95) mL/min per 1.73m^2. The majority of patients (61%) had no documentation of renal imaging, and no patient had a measurement of TKV recorded. Two patients were receiving Tolvaptan and uACR was captured in 72% of cases. All patients had their medications listed and 65% were receiving antihypertensive therapy. The median BP was 123/80mmHg. The median follow-up time for patients with eGFR <60mL/min per 1.73m^2 was 6 months, compared to 11 months for patients with eGFR ≥60 mL/min per 1.73m^2.

Conclusions: Although these dictations were analyzed only at one point in time, the observed variability in care emphasizes the need for improved strategies to translate evidence-based interventions into clinical practice. This may include standardized care pathways for clinicians as well as strategies to maximize data capture such as an ADPKD registry.

PUB323

Empower PKD—What Do Patients Think?

Reem Mustafa,[1] Alan S. Yu,[2] Ronald D. Perrone,[3] Yeoung Jee Cho,[4] Allison Tong,[4] Katelyn Smelser,[5] Kim S. Kimminau,[2] David Baron,[6] Kevin J. Fowler.[7] The EMPOWER PKD team *[1]University of Kansas, Kansas City, KS; [2]University of Kansas Medical Center, Kansas City, KS; [3]Tufts Medical Center, Boston, MA; [4]The University of Sydney, Seven Hills, NSW, Australia; [5]University of Missouri-Kansas City, Kansas City, MO; [6]PKD Foundation, Kansas City, MO; [7]Kidney Health Initiative, Elmhurst, IL*.

Background: The Establishing Meaningful Patient-centered Outcomes With Relevance for patients with Polycystic Kidney Disease (EMPOWER PKD) initiative aims to engage PKD stakeholders and patients to learn about health priorities, insurance issues, and patient engagement.

Methods: We developed and pre-tested a guide to conduct semi-structured focus groups. Participants discussed impact of PKD on daily living and identified and ranked outcomes in PKD using a nominal, multi-vote technique. Other focus group topics included insurability and factors that influence a patient's active engagement with PKD. We conducted thematic analyses using Grounded Theory.

Results: Of 57 participants, 82% were PKD patients and 13% were caregivers. Mean age was 53 (range 19-80) years with 52% female. Participants included 91% white, 4% African American, 4% American Indian, and 2% Latino. Six focus groups yielded 70 outcomes classified into six categories: kidney health, lifestyle, comorbidities, psychological impact, family and awareness, and mortality. The highest ranked outcome was slowing the progression/symptoms of PKD followed by keeping kidneys healthy, and diet. Qualitative analysis identified six over-arching themes for the impact of PKD including: decision-making, daily impact, psychological impact, testing dilemmas, healthcare related issues, and family. Variability in patient engagement and misconceptions about the disease were common. While psychological impacts were not ranked highly as target outcomes in clinical studies this was a leading theme of discussions during the focus groups.

Conclusions: Patients with PKD and their families are unique. While early diagnosis and detection is an important focus for research in kidney disease in general, the effects of "labelling" with PKD on insurability decision is a main factor that hinder patients' active participation in care and research. With a treatment now approved for use in the US, it is important to be aware that patients' views and values have pivotal effects on care. Additional exploration should consider psychological impacts of disease, expanded race/ethnicity representation and consideration of socioeconomic differences. Additionally, perspectives in the context of newly available treatments should be assessed with a focus on how to activate PKD patients who are otherwise not engaged in their care or research.

PUB324

Reported Outcomes in ADPKD Studies: A Systematic Review

Reem Mustafa,[1] Kerri A. McGreal,[1] Ronald D. Perrone,[2] Alan S. Yu.[1] for the PKD Outcome Consortium (PKDOC) composite outcomes committee *[1]University of Kansas Medical Center, Kansas City, KS; [2]Tufts Medical Center, Boston, MA*.

Background: Studies for Autosomal Dominate Polycystic Kidney Disease (ADPKD) tend to have a wide variability in outcome measures. In this review we aim to identify different outcomes reported in ADPKD studies including composite outcomes.

Methods: We conducted a systematic review of published studies that included ADPKD patients as the main population or a main subgroup and measured renal outcomes. We searched the Cochrane Central Register (CENTRAL), OVID MEDLINE, EMBASE and Pubmed (from inception to December 2017). Our review included all studies regardless of design with ten or more participants. We excluded studies that only reported dialysis or transplant outcomes in ADPKD patients. We abstracted data in duplicate.

Results: We identified 391 records through database and grey literature searches. We included 146 records for full text screening and 87 published papers for data abstraction. Of these, we found 13 articles that reported composite outcomes. There is considerable inconsistency in the outcomes reported and how they are measured. We identified six different composite outcomes reported in these articles. These composite included: 1. 20% increase in Height adjusted Total Kidney Volume (HtTKV), Left ventricular mass index and Urinary albumin excretion, 2. time to 50% reduction of baseline estimated Glomerular Filtration Rate (GFR), end stage renal disease, or death, 3. Time to investigator-reported multiple ADPKD clinical progression events (e.g. onset or progression of hypertension, need for hypertensive treatment), severe kidney pain (requiring medical intervention), worsening albuminuria (by category), or 33% increase in serum creatinine (SCr), 4. onset/worsening of HTN, renal pain, proteinuria, 25% change from baseline renal function in reciprocal SCr levels, 5. doubling SCr, 50% reduction in GFR or need for renal replacement therapy, 6. 50% reduction in GFR, doubling of SCr, or initiation of dialysis, renal transplantation, or death.

Conclusions: There is a need to standardize outcomes in ADPKD studies. There is also a need for guidance about the appropriate components of composite outcomes in ADPKD studies. This will help comparison of results across studies especially if individual components are well defined.

PUB325

Epidemiology of Autosomal Dominant Polycystic Liver Disease (ADPLD) in Olmsted County

Tatsuya Suwabe,[1] Alanna Chamberlain,[1] Emilie Cornec-Le Gall,[2,1] Jill M. Killian,[1] Peter C. Harris,[1] Vicente E. Torres.[1] *[1]Mayo Clinic, Rochester, MN; [2]Centre Hospitalier Universitaire de Brest, BREST, France.*

Background: The incidence and prevalence of ADPLD are not known.

Methods: Mayo Clinic and Olmsted Medical Center (OMC) deliver most health care to Olmsted County residents. We searched diagnostic codes and the Mayo Clinic and OMC radiology databases to identify subjects and all medical records were reviewed to validate ADPKD diagnoses using the following criteria. A diagnosis of definite ADPLD was based on accepted radiographic findings plus a family history of ADPLD or genetic testing results; likely ADPLD, based on ≥20 liver cysts for any age; possible ADPLD, based on 5-19 liver cysts for any age; in all cases with no or only few kidney cysts. Incidence rates of ADPKD for the time period of 1980-2016 were calculated; point prevalences for the year 2010 were also calculated.

Results: We reviewed medical charts and abdominal images and/or radiology reports of 1,231 subjects with diagnostic codes of cystic liver during 1980-2016, and the medical charts and abdominal CT or MR scans of 2,765 subjects with multiple liver cysts from radiology databases during 1997-2016. In total, 134 patients with incident ADPLD (0 definite, 35 likely, 99 possible ADPLD) were identified during 1980-2016. Only 8 patients among 35 likely ADPLD and no patients with possible ADPLD had symptomatic hepatomegaly (total liver volume ≥ 2000 ml). Overall age- and sex-adjusted annual incidence rate of likely ADPLD was 1.01 (95%CI: 0.67 to 1.35) and that of likely or possible ADPLD was 4.01 per 100,000 person-years (3.32 to 4.69). The annual incidence rates of likely ADPLD increased gradually over time and those of possible ADPLD have increased markedly since 1997 when CT and MR scans became available electronically. Annual incidence rates of ADPLD were not different between females and males. On January 1, 2010, the overall age- and sex-adjusted prevalence of likely or possible ADPLD was 36.0 (25.3 to 46.6) and that for likely ADPLD alone was 9.5 (4.1 to 14.9) per 100,000 population.

Conclusions: The incidence rate of ADPLD with symptomatic hepatomegaly was very low. Incidence rates of likely or possible ADPLD have increased over time, possibly because milder cases of ADPLD have been increasingly detected with more frequent and better radiology imaging. Incidence and prevalence of ADPLD including mild cases of ADPLD may have been underestimated.

PUB326

Genetic Studies of Nephropathies with a Public Grant Funding in a Developing Country: A 3-Year Experience in an Academic Unit

Paola Krall, Claudio A. Flores, Leopoldo G. Ardiles, Sergio A. Mezzano. *Universidad Austral de Chile, Valdivia, Chile.*

Background: Implementation of genetic tests has diverse ongoing challenges that are even greater in developing countries. Since the human genome was published, many genes have been discovered by Sanger sequencing (SS) in association with diseases. Actually, next-generation sequencing (NGS) technology is displacing SS, but although costs have decreased, they remain high for developing countries and any NGS derived-variant should be validated by SS. Here we describe the 3-yr experience in the Nephrology Unit at a Chilean university that received a US$140.000 as a public grant to perform genetic studies of particular nephropathies.

Methods: Tests were implemented for 17 genes by SS technology (PKD1, PKD2, PKHD1, NPHS2, NPHS1, WT1, INF2, ACTN4, TRPC6, APOL1, WNK4, KANK1, ARHGEF17, CTNS) or NGS technology (COL4A3, COL4A4, COL4A5), associated with autosomal dominant and recessive polycystic kidney disease (ADPKD/ARPKD), steroid-resistant nephrotic syndrome (SRNS), focal and segmental glomerulosclerosis (FSGS), Alport syndrome (AS), Wilms tumor (WT) and nephropathic cystinosis (NC). The study was approved by the local Ethics Committees of Health Service and university to be offered to 120 cases with one of the diseases with a proven clinical utility.

Results: Until date, a genetic defect has been identified in 20/41 ADPKD, 1/1 ARPKD, 21/56 SRNS-FSGS, 7/17 AS, 2/4 WT1 and 1/1 NC cases, reaching a 43% (52/120) detection rate. In 92% (48/52) of these cases, the defect was located in a causative gene, mainly PKD1 and NPHS2, and at least one clinical utility was proposed, in terms of diagnosis, prognosis, management, genetic counseling or transplantation. The major challenges were genetic heterogeneity (SRNS-FSGS), sporadic unavailability of long-range PCR reactives (ADPKD) and elevated costs of NGS technology (AS).

Conclusions: We consider this experience valuable to design an NGS strategy targeting the almost 50 genes associated with the diseases of interest and consider the genetically resolved/unresolved cases as a validation/discovery cohorts, respectively. Nephrologists in Chile are aware of the utility of genetic tests and more efforts need to be done in order to make NGS more accessible and affordable or to be able to establish local cost-effective genetic test algorithms, in benefit of the patients and their families.

PUB327

Evaluation of Cost Drivers in the Management of Patients with Polycystic Kidney Disease Prior to the Development of ESKD in an Irish University Hospital

Eva B. Long,[1] Ayanfeoluwa Obilana,[2] Joe Eustace.[3] *[1]Nephrology, Cork University Hospital, Cork, Ireland; [2]Cork University Hospital, Cork, Ireland; [3]University College Cork, Cork, Ireland.*

Background: Economic evaluation of treatment in PCKD focuses on cost associated with ESKD. Considerable costs arise pre ESKD. We conducted the following retrospective study to define the clinical characteristics and main pre ESKD cost drivers of prevalent patients with ESKD as a result of PCKD at a single Irish University Hospital.

Methods: The medical record of all prevalent ESKD patients with PCKD was retrospectively reviewed to first referral. Prior ESKD followup was divided into 6 month bins and outpatient laboratory tests and clinical data closest to these was abstracted. eGFR was calculated using the MDRD formula.

Results: Of the 51 patients identified, 30 (59%) were female; the mean (sd) age was 56 (12) yrs. 33 (65%) had a reported family history of PCKD. Patients had first attended the renal outpatients a median (IQR) of 6 (3-11) yrs prior to developing ESKD and were treated for ESKD for a median (IQR) of 6 (3-12) yrs. 40 (78%) underwent renal transplantation, with a median (IQR) interval of 1 (0-3) yrs from the development of ESKD. During OPD follow up prior to commencing renal replacement therapy, the median (IQR) eGFR declined from 37.0 (26.5, 57.2) to 7.3 (5.1, 9.3) ml/min per 1.73m^2. The median (IQR) individualized rate of loss in eGFR pre ESKD was 4.7 (3.4, 6.0) ml/min per 1.73 m^2. 3 subjects had a rate of loss of eGFR of 10ml/min per 1.73m^2 per year or greater. The median (IQR) number of prescribed antihypertensive agents rose from 1 (0,2) to 2 (1,3) over per ESKD follow-up. At initial OPD visit the proportion of patients treated with an ACE inhibitor/ARB, Beta blocker or Calcium channel blocker were 30%, 20% and 24% respectively and pre dialysis was 61%, 31% and 55% respectively. At initial and end of pre ESKD OPD follow-up 28% and 23% reported persistent renal pain. 31 patients (61%) were treated with erythropoietin prior to developing ESKD, 20 for 1 year or less, 3 for 2 years and 8 for 3 or more years. 13 (26%) were treated pre ESKD with calcium free phosphate binder. Over follow-up 10 (20%)required a nephrectomy.

Conclusions: Patients with PCKD have substantial utilization of costly treatments pre-ESKD (erythopoetin, calcium free phosphate binders, nephrectomy). These costs and their minimization will substantially influence the relative cost effectiveness of primary therapy in PCKD.

PUB328

APOL1: A "Novel" Gene Underlying Kidney Disease in Chile?

Paola Krall, Anita Plaza, Marina Leiva gonzalez, Paula C. Lehmann, Daniela P. Nualart, Daniel Carpio, Claudio A. Flores, Leopoldo G. Ardiles, Sergio A. Mezzano. *Universidad Austral de Chile, Valdivia, Chile.*

Introduction: *APOL1* G1 risk allele is common among the African population since they confer resistance to *Trypansoma brucei*. Two G1 alleles are associated with kidney disease with focal and segmental glomerulosclerosis (FSGS). *APOL1* G1 allele is unevenly distributed and is very frequent in the African (American) population, but is considered very rare (<0.6%) in other populations. The genetic basis of FSGS Chilean patients has been associated mainly with *NPHS2*. Since 2014 Chile is experiencing an unprecedented 20-fold increase of Haitian immigrants, looking for better life quality. Haitians have 92% median African ancestry and the role of *APOL1* G1 allele in this population has been barely investigated. Here we describe 3 cases residing in Southern Chile who had proteinuria and resulted to be carriers of the G1 allele.

Case Description: Patient #1: 27yrs old man (APOL1 G1/G1) debuted with nephrotic syndrome when he was 20yrs. His renal biopsy was compatible with FSGS. He was unresponsive to prednisone and cyclosporine A and progressed to ESRD requiring hemodialysis. His younger sister presented hypertension, an FSGS-compatible biopsy and analysis confirmed the same genotype. **Patient #2**: 17yrs old man (APOL1 G1/G0) who had been nephrectomized as a newborn, debuted with nausea and vomits when he was 16yrs. His exams revealed an important persistent proteinuria and biopsy was compatible with FSGS. **Patient #3**: 30yrs old Haitian woman (APOL1 G1/G0) with a 28-wks old pregnancy was admitted at Hospital with moderate hypertension and proteinuria. Given that intrauterine growth restriction was observed, childbirth was induced with an extremely low birth weight (<1000gr).

Discussion: Chilean population has a 3% African ancestry that decreases from North to South, related to the historical Spanish conquest slavery. We confirmed two Chilean patients carrying the *APOL1* G1 allele and a third case of a Haitian pregnant woman, who developed kidney disease as adults. To our knowledge, these are the first cases in Chile, but studies with a more representative cohort are required. The clinical value of APOL1 risk alleles in kidney disease is still uncertain and second hits remain unknown. More evidence is needed before considering the *APOL1* status as an input to define a therapeutic option.

PUB329

NPHS2 Gene Mutations and Nephrotic Syndrome in Children and Adults in Kuwait

Salah K. Al-Waheeb,[1] Ahmad Al-Serri,[2] Ahmed A. Abou shall,[4] Effat A. Tony.[3] *[1]Pathology, Kuwait University, Jabriyah, Kuwait; [2]Kuwait university, Jabriya, Kuwait; [3]Internal Medicine, Assuit University, Assuit, Egypt; [4]Ministry of health - state of Kuwait, Kuwait, Kuwait.*

Background: Genetic testing in nephrotic syndrome (NS) has implications for clinical course, treatment response, risk for post-transplant proteinuria and prenatal diagnosis. The commonly studied rs61747728 NPHS2 gene polymorphism also known as p.R229Q has been reported to be associated with NS. Others failed to report an association, probably due to population differences. Genetics of NS havenot been studied in this part of the globe. We decided to start this journey by investigating the prevalence of the p.R229Q variant.

Methods: Inclusion criteria were: 1. Proteinuria (>3 g/24hrs) in children and >1g/24hrs in adults 2. Biopsy diagnosis of MCD or FSGS 3. No secondary causes of FSGS at the time of diagnosis. 2-5ml of blood were collected from patients. DNA was extracted following standard protocols. Genotyping was performed by Real-time TaqMan Allelic Discrimination Assay (Life technologies, CA, USA).

Results: A total of 51 patients and 4 controls were studied. 19/51 females and 32/52 males. 13/51 were Kuwaiti and the rest from diverse nationalities. 20/51 were > 40 years of age and 31/51 were < 40. 7/51 were < 20. 5/51 patients were heterozygotes for the R229Q gene polymorphism(9.8 %), with a broad age range 15-64. All were females from 3 different nationalities one of whom was Kuwaiti, 15 years of age. 3 had a tissue diagnosis of MCD and 2 were labelled as FSGS. 3 patients improved with steroids and continue to show stable renal function, whilst 2 showed no improvement with steroids or other immunosuppresants and continue to have a rise in serum creatinine. None are on dialysis or have a family history of kidney disease.

Conclusions: The data presented is the first attempt at studying genetic associations of NS in Kuwait. Mutations in NPHS2 in our population account for 9.8% of all our cases, similar to results reported by other groups. Although our sample is comparatively small, the plan is to obtain a total of 100-150 DNA samples by the end of 2018 and study mutations of other genes associated with NS eg INF2, WT-1 etc.. to uncover the genetic susceptibility in our population. Furthermore, we will attempt to sequence these genes to find out if susceptibility loci are similar to other authors. Ultimately we will perform whole exome sequencing to uncover other genes that might be unique to our population.

Uromodulin Mutation Is the Major Cause of Autosomal Dominant Tubulointerstitial Kidney Disease

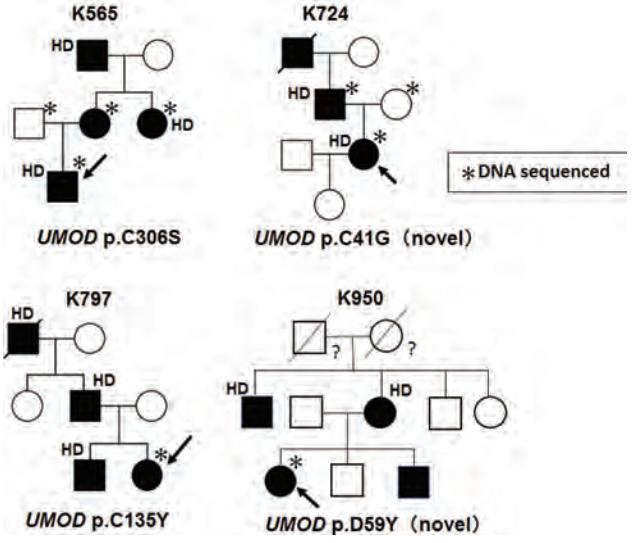
Azuma Nanamatsu,[1] Takayasu Mori,[1] Takuya Fujimaru,[1] Naohiro Nomura,[1] Motoko Chiga,[1] Atsushi Hesaka,[4] Masayuki Mizui,[4] Yoshitaka Isaka,[4] Hiroki Mizuno,[2] Akinari Sekine,[2] Junichi Hoshino,[2] Yoshifumi Ubara,[2] Tomomi Endo,[3] Tatsuo Tsukamoto,[3] Eisei Sohara,[1] Tatemitsu Rai,[1] Shinichi Uchida.[1] *[1]Tokyo Medical and Dental University, Tokyo, Japan; [2]Toranomon Hospital, Tokyo, Japan; [3]Kitano Hospital, The Tazuke Kofukai Medical Research Institute, Osaka, Japan; [4]Osaka University Graduate School of Medicine, Suita, Japan.*

Background: Autosomal dominant tubulointerstitial kidney disease (ADTKD) is a group of conditions characterized by autosomal dominant inheritance, pathologic changes of tubular and interstitial fibrosis, and progressive renal failure. Uromodulin (UMOD) is known as one of the causes of ADTKD (ADKTD-UMOD) that is also known as juvenile hyperuricemia. Precise diagnosis is difficult without genetic testing.

Methods: We previously developed a comprehensive genetic testing panel using next generation sequencing (NGS) covering 166 genes responsible for vast majority of inherited kidney diseases. Ten families suspected of ADTKD were genetically screened with the panel. Clinical and laboratory data were collected and analyzed.

Results: We identified causal mutations in *UMOD* in four ADTKD families (40%), and excluded simultaneously other candidate genes for ADTKD such as *MUC1*, *REN*, and *HNF1B*. One male and 3 females were included in the four probands (n=4). Age (±SD) at diagnosis was 33.7 (±10.3), and 2 had end-stage renal disease (ESRD). Mean serum urate concentration was 5.42 mg/dl (±1.08). The detail of the detected heterozygous mutations in *UMOD* were C41G, D59Y, C135Y, and C306S, which include two novel mutations (C41G and D59Y).

Conclusions: Four ADTKD-UMOD families including two with novel mutations were detected. We guess a great deal of ADTKD-UMOD cases may be overlooked or misjudged as nephrosclerosis or other kidney diseases because genetic testing on ADTKD is not necessarily conducted. Autosomal inheritance reminds us larger prevalence of ADTKD-UMOD. When we face to cases with familial renal failure with less abnormalities of urine tests, ADTKD should be considered.



PUB331

Alport Spectrum Disorders in Croatia – Preliminary Results of First Genetic Testing in Croatia

Danica G. Ljubanovic,[1] Tamara Nikuseva-Martic,[2] Marija Senjug Perica,[3] Petar Senjug,[4] Matija Horacek,[9] Danica Batinic,[5] Danko Milosevic,[6] Kresimir Galesic,[7] Marijan Saraga,[8] Dragan Klaric,[12] Maja Oroz,[10] Kristina Gotovac Jercic,[11] Matija Crnogorac.[13] *[1]University of Zagreb School of Medicine, Clinical Hospital Dubrava, Zagreb, Croatia; [2]School of Medicine University of Zagreb, Zagreb, Croatia; [3]Children's Hospital Srebrnjak, Zagreb, Croatia; [4]University Hospital Dubrava, Zagreb, Croatia; [5]Djecja bolnica Srebrnjak, Zagreb, Croatia; [6]Zagreb School of Medicine, Clinical Hospital Centre Zagreb, Zagreb, Croatia; [7]Dubrava University Hospital, Zagreb, Croatia; [8]University Hospital in Split, Split, Croatia; [9]School of medicine, University of Zagreb, Karlovac, Croatia; [10]Medical Faculty Zagreb, Zagreb, Croatia; [11]Clinical Hospital Center Zagreb, Zagreb, Croatia; [12]General Hospital Zadar, Zadar, Croatia; [13]Dubrava University clinical hospital, Zagreb, Croatia.*

Background: Alport syndrome (AS) and thin glomerular basement nephropathy (TBMN) are part of phenotypic and genotypic spectrum of COL4A3, COL4A4 and COL4A5 mutation disorders. Until beginning of our project "Genotype-Phenotype correlation in Alport's syndrome and Thin Glomerular Basement Membrane Nephropathy", founded by Croatian Science Foundation, genetic testing for Alport spectrum disorders (ASD) was not performed in Croatia and diagnosis of ASD relied solely on kidney biopsy analysis. Here we present preliminary results of first Croatian systematic genetic testing of ASD.

Methods: We are conducting multidisciplinary, nationwide, collaborative research in seven leading Croatian nephrology, pediatric nephrology and nephropathology institutions. We are collecting clinical data, about both renal and extra-renal symptoms, histological data (including staining for collagen IV α1, α3 and α5 chains), as well as, performing genetic counselling and family study data collection on Croatian AS and TBMN patients. The next generation sequencing (NGS) for COL4A5, COL4A4 and COL4A3 gene mutation screening are performed at molecular laboratory at Department of Pathology and Centre for Translational Research, University of Zagreb School of Medicine.

Results: We have identified 337 AS and TBMN patients (age range 2-80) by search of patients' records and data registries. From 337 patients, 158 have accepted to participate in genetic testing. Additionally 87 family members were enrolled in the study. Up to present day we have tested 90 index patients and 40 family members by NGS method. There was 25 (19.2%) patients and family members with mutations in COL4A3, 6 (4.6%) in COL4A4 and 33 (25.4%) in COL4A5. No mutation was found in 66 (50.8%) patients and family members.

Conclusions: Correct and early diagnosis, genetic counselling, and appropriate monitoring and management are essential for management of ASD patients. Our goal is to clarify Croatian Alport spectrum patients histologically, genetically and clinically and ultimately create ASD registry with clinical, histological and genetic and follow up information.

PUB332

Two Novel OCRL Gene Mutations in Chinese Patients with Lowe Syndrome and Literature Review

Jing Chen,[1] Hong Xu,[2] Qian Shen.[3] *[1]Children's Hospital of Fudan University, Shanghai, China, Shanghai, China; [2]Children's Hospital of Fudan university, Shanghai, China; [3]Children's Hospital of Fudan univeristiy, Shanghai, China.*

Background: To analyze the clinical and genetic features of Lowe syndrome carrying *OCRL* mutation.

Methods: The clinical findings and results of genetic studies were retrospectively reviewed for 2 male patients diagnosed with Lowe syndrome, and relevant literatures about *OCRL* mutation were reviewed in this article.

Results: Two male patients all presented with low molecular proteinuria, renal tubular acidosis, hypercalciuria and rickets. Patient 1 did not have obviously extra-renal symptoms, but was found to have mild cataract by a meticulous ophthalmological examination, MRI found cerebral hypoplasia. Patient 2 was found to have abnormal vision and congenital cataract soon after birth and treated by surgery. MRI showed the reduction of brain white matter and the slight dilation of lateral ventricle. Two novel *OCRL* gene mutations were detected. A homozygous missense mutation c.1514G>T(p.G505V) was found in exon 15 of *OCRL* gene in Patient 1, *OCRL* gene 13-24 exon deletion mutation was detected in Patient 2. Both mutations were never reported previously.

Conclusions: Lowe syndrome is characterized by the triad of congenital cataracts, severe intellectual impairment, and renal tubular dysfunction. *OCRL* gene analysis is helpful for the early diagnosis of the disease, as well as providing better genetic counseling and prenatal diagnosis for the proband families.

PUB333

Genetic Variants of Familial Hematuria Associated Genes in Families with Hematuria with Probands Diagnosed with IgA Nephropathy

Zihua Yu,[1,2] Liu Jiewei.[1] *[1]Dongfang Hospital, Fuzhou, China; [2]Department of Pediatrics, Xiamen University Affiliated Dongfang Hospital, Fuzhou, China.*

Background: Familial hematuria (FH) are genetic disorders characterized by persistent hematuria during childhood, including Alport syndrome (AS) caused by mutations in *COL4A3*/*COL4A4*/*COL4A5*, CFHR5 nephropathy caused by mutations in *CFHR5*, etc. Some FH patients with IgA deposits in the glomerular mesangium could be diagnosed with IgA nephropathy (IgAN) when they either lack examinations of renal ultrastructure or have normal renal ultrastructures. This study aims to examine genetic variants of FH associated genes in 3 families with hematuria with probands diagnosed with IgAN.

Methods: The probands diagnosed with IgAN and their family members from 3 families with hematuria were examined for genetic variants of FH associated genes by next generation sequencing. Genetic variants were verified by Sanger sequencing, and their pathogenicities were verified by bioinformatic analyses.

Results: A heterozygous mutation in *CFHR5*, 533A>G (Asn178Ser), was identified in Family one's proband and his father, but it wasn't found in his mother. A pathogenic mutation in *COL4A5*, 566G>T (Gly189Val), was detected in Family two' proband, and it was also found in his mother, sister and daughter, but it was detected in neither his father nor his nephew. Two heterozygous pathogenic mutations, *COL4A5* 539G>A (Gly180Glu) and *CFHR5* 508G>A (Val170Met), were identified in Family three's proband. *COL4A5* Gly180Glu was also detected in her sister, daughter and maternal nephew, but it was found in neither her oldest son nor youngest son. A heterozygous *CFHR5* Val170Met was found in her oldest son, sister and maternal nephew, but it was detected neither her daughter nor her the youngest son. *CFHR5* Asn178Ser is an uncertain significance. *COL4A5* Gly189Val, *COL4A5* Gly180Glu and *CFHR5* Val170Met were predicted as pathogenic mutations. So Family two' proband was diagnosed with XLAS, and Family three XLAS combined with *CFHR5* nephropathy.

Conclusions: It is necessary to examine genetic variants of FH associated genes in families with hematuria with probands diagnosed with IgAN.

PUB334

Opinions of African American Hypertensive Veterans and VA Primary Care Physicians Regarding APOL1 Genetic Testing

Farrukh M. Koraishy,[1,2] Carissa Van den berk clark,[1] Jeffrey B. Kopp.[3] *[1]Saint Louis University, Saint Louis, MO; [2]Veterans Administration, Saint Louis, MO; [3]NIDDK, NIH, Bethesda, MD.*

Background: A high-risk apolipoprotein (*APOL1)* genotype predisposes African-American (AA) individuals with hypertension to kidney disease. Although studies have shown that knowledge of genetic risk increases the likelihood of preventive health behaviors, *APOL1* genetic testing is not part of routine hypertension management among AA patients. In order to understand the feasibility of implementing genetic screening at the Veteran Administration (VA), we assessed perceptions of Veterans and VA primary care providers (PCP) about kidney disease, blood pressure (BP) management, race, and genetic testing.

Methods: Ten PCP and ten AA hypertensive Veterans were interviewed at the Saint Louis VA Medical Center. Interview transcripts were coded to identify themes and compared between patients and PCP using a phenomenological approach.

Results: AA subjects had significant awareness of kidney disease and hypertension. They did not have an awareness of the genetic link between race and risk for kidney disease. PCPs had more knowledge of genetic/ancestral risk of hypertension but mostly not of kidney disease. They often stated that they needed more information about the role of *APOL1* variants. PCP tended to believe that AA Veterans generally had poor BP management due to health care habits and compliance. AA patients varied in BP management and were more open to genetic screening while PCP had concerns about cost, insurance, organizational constraints and ethical issues. PCP were agreeable to *APOL1* testing, however, in most cases only if they had more information on how screening would change their practice. Many AA patients said that if they were found to have *APOL1* high-risk genotypes, that they would commit to new strategies to prevent kidney disease.

Conclusions: AA hypertensive Veterans had good knowledge about the pathway from hypertension to kidney disease. Veterans and PCP were mostly agreeable to *APOL1* genetic testing to learn about risk of kidney disease and engage in preventative behavior, but stated a need for more education. These results are preliminary, given the small sample size.

Myelin Bodies in LMX1B-Nephropathy

Gia J. Oh,[1] Neeraja Kambham.[2] *[1]Pediatrics, Stanford, Stanford, CA; [2]Stanford University, Stanford, CA.*

Introduction: Mutations in *LMX1B* have been found in families with isolated nephropathy without extrarenal abnormalities. We describe 2 families with autosomal dominant (AD) nephropathy due to heterozygous *LMX1B* c.737G>A, p.R246Q variant who unexpectedly had myelin figures in electron microscopy.

Case Description: Family A (1a). Patient IV:2's biopsy was notable for myelin bodies in podocytes (Figure 2). Her α-galactosidase A activity and *GLA* analyses were normal, thus excluding Fabry nephropathy. Family B (1b). Mother (Patient II:2) and son (Patient III:1) with nephropathy were found to have the p.R246Q variant, while the asymptomatic daughter (Patient III:2) did not have this variant.

Discussion: This is the first case series to report myelin figures in families with *LMX1B*-nephropathy. Consider *LMX1B*-nephropathy in AD glomerulopathy and in differential diagnosis for kidney biopsies with myelin bodies.

Patient	LMX1B Mutation	Age at Diagnosis (y)	Age at Last Follow-up (y)	Up/c at Last Follow-up (mg/mg)	eGFR at Last Follow-up (mL/min/1.73m.sq)	Kidney Histology	Myelin bodies on EM
Family A							
I:1	ND	40	60	ND	ESRD	ND	
III:2	ND	22	35	ND	ND	FSGS	None
IV:2	c.737G>A	3	11	4.2	169	Normal	2+, Podocytes

Genetic Variants of the COL4A5, COL4A4, and COL4A3 Genes in the Children with Familial Hematuria

Zihua Yu,[1,2] Zheng Li.[1] *[1]Dongfang Hospital, Fuzhou, China; [2]Department of Pediatrics, Xiamen University Affiliated Dongfang Hospital, Fuzhou, China*.

Background: The familial hematuric diseases are a genetically heterogeneous group of monogenic conditions, including Alport syndrome (AS) and thin basement membrane nephropathy (TBMN) caused by mutations in the *COL4A5*, *COL4A4* and *COL4A3* genes, etc. This study aims to examine genetic variants of the *COL4A5*, *COL4A4* and *COL4A3* genes in 48 children with familial hematuria (FH).

Methods: The clinical data and blood samples of 48 children with FH and their parents were collected. Genomic DNA was isolated from peripheral blood leucocytes. The 48 children and their parents were examined for genetic variants in all coding exons and exon-intron boundaries of genes by exome sequencing. Variants detected in the *COL4A5*, *COL4A4* and *COL4A3* genes by exome sequencing were further verified by Sanger sequencing. Pathogenicity of the identified variants was verified by bioinformatic analyses. The etiological diagnosis of some children with FH were made according to their genotypes and their phenotypes.

Results: Twenty-five mutations were identified in 29 children with FH by exome sequencing and Sanger sequencing. Among them, 20 nutations, such as *COL4A5* 539G>A, *COL4A5* 3985delC, *COL4A5* 566G>T, *COL4A5* 2822G>A, *COL4A5* EXON 29-30 deletions, *COL4A4* 4421C>T, *COL4A4* 4915G>C, *COL4A4* 2752G>A, *COL4A4* 1030-2A>C, *COL4A4* 2447G>A, *COL4A4* 4481delT, *COL4A4* 4288G>A, *COL4A4* 1567C>T, *COL4A3* 1496G>A, *COL4A3* 3619G>A, *COL4A3* 3627G>A, *COL4A3* 4700T>G, *COL4A3* 898G>A, *COL4A3* 2096T>C and *COL4A3* 4769G>A, were novel, and 5 mutations, such as *COL4A5* 2858G>T, *COL4A5* 530G>A, *COL4A4* 4599T>G, *COL4A4* 3499G>A and *COL4A3* 4235G>T, have already been reported. Muatations in the *COL4A5*, *COL4A4* and *COL4A3* gene were found in 60.4% (29/48) of 48 children with FH. An etiological diagnosis could be made in 56.3% (27/48) of 48 children with FH. Eleven children with FH were diagnosed with X-linked AS, and 1 child with FH was diagnosed with autosomal recessive AS, and 15 cases were diagnosed with either autosomal dominant AS or TBMN.

Conclusions: It is necessary for the children with FH to make an etiological diagnosis by examing genetic variants of the *COL4A5*, *COL4A4* and *COL4A3* genes.

PUB337

Complement-Mediated Glomerulonephritis – A Large Spectrum for a Rare Disease

Andrei Capitanescu,[1] Magda Zarojanu,[2] Lungu I. Adrian Catalin,[3] Nóra Veszeli,[4] Dorottya Csuka,[4] Nóra É. Garam,[4] Zoltan Prohaszka,[5] Sergiu Dumitrache.[6] *[1]Spitalul Clinic de Nefrologie Dr. Carol Davila, Bucharest, Romania; [2]Spitalul de Nefrologie Carol Davila, BUcharest, Romania; [3]Fundeni Clinical Institute, Bucharest, Romania; [4]Semmelweis University, Budapest, Hungary; [5]Semmelweis Univrestiy, Budapest, Hungary; [6]Dr. Carol Davila Clinical Hospital of Nephrology, Bucharest, Romania*.

Introduction: Membranoproliferative glomerulonephritis (MPGN) was recently reclassified as a complement alternative pathway-mediated C3 glomerulopathy (C3G) and immune complex-mediated membranoproliferative GN (IC-MPGN). The primary defect underlying complement-mediated glomerulonephritis is excessive activation of the alternative pathway as a result of either autoimmunity against regulatory components or abnormal genetic variants with a gain of function or loss of normal control of activating pathway.

Case Description: A 59 years old male was admitted to our clinic for anasarca, high blood pressure, oliguria, gross hematuria and worsening of serum creatinine from 2 to 6.2 mg/dl, for five days. A week before admission, he was evaluated in another hospital for a post-traumatic wound consisting in a cut on the left sole and was treated with antibiotics and NSAID. At admission, the biologic evaluation showed anemia, positive inflammatory tests, dyslipidemia, hypoalbuminemia, marked nitrogen retention (creatinine 10.19 mg/ dl, urea 170 mg/ dl), metabolic acidosis and hyperkaliemia, urinalysis with nephrotic proteinuria 9.5 g/ day and macroscopic dysmorphic hematuria. A kidney biopsy was performed, and the patient started RRT with intermittent hemodialysis. The kidney biopsy revealed MPGN with isolated segmental deposits of C3 and extracapillary proliferation. Complement analysis revealed decreased classical and alternative pathway activity. Sequencing of complement genes showed no mutations, but some CFH or CD46 risky variations were identified for both DDD and aHUS. MLPA results suggested that the CFHR1 gene may be present in three copies in the patient. Western blot analysis showed FHR1 bands with higher density than controls, consistent with the presence of an extra *CFHR1* copy. Monoclonal anti-FHR1 antibody did not detect any aberrant protein. He was given pulse therapy with Methylprednisolone and Cyclophosphamide followed by Prednisone with no improvement of renal function, and he remained dialysis dependent.

Discussion: This case demonstrates that C3G can also present with an abrupt loss of kidney function. It is unknown, how the extra *CFHR1* copy affects protein function, further in vitro tests are necessary to analyze its effect.

PUB338

Chronic and Sub-Chronic Hyponatremia and Risk of Serious Falls and Hip Fractures

Simran K. Bhandari,[1] John J. Sim,[1] Bonnie H. Li,[1] Connie Rhee,[2] Shirin Sundar,[6] Holly Krasa,[4] Kim Danforth,[5] Kamyar Kalantar-Zadeh,[3] Michael H. Kanter,[5] Steven J. Jacobsen,[5] Annette L. Adams.[5] *[1]Kaiser Permanente Los Angeles Medical Center, Los Angeles, CA; [2]University of California Irvine, Huntington Beach, CA; [3]University of California Irvine, School of Medicine, Orange, CA; [4]Otsuka, Washington, DC; [5]Kaiser Permanente Southern California, Pasadena, CA; [6]Otsuka America Pharmaceutical, Inc., Princeton, NJ*.

Background: Falls and fractures represent serious health concerns in the elderly. Addressing risk factors for falls which may ultimately reduce falls/fractures may help reduce morbidity and mortality. It remains unknown whether the duration of hyponatremia affects serious fall/fracture risk. We sought to evaluate the risk for serious falls and hip fractures among episodes of chronic (≥ 30 days) and subchronic hyponatremia (< 30 days) compared to normonatremia.

Methods: Retrospective cohort study within Kaiser Permanente Southern California (an integrated health system) between 1/1/1998 and 12/31/2016 among individuals ≥ 55 yrs with ≥ 2 outpatient serum sodium (Na) measurements. Hyponatremia defined as a serum Na of <135 mEq/L. Subchronic hyponatremia was defined as 1) a single serum Na measurement <135 mEq/L followed by a normal Na measurement (≥135 mEq/L) on a different day or 2) multiple serum Na values <135 mEq/L with less than 30 days between the first and second and/or last hyponatremia measurement. Chronic hyponatremia was defined as multiple serum Na measurements <135 mEq/L with 30 or more days between first and last serum hyponatremia measurement. Multivariable cox proportional hazards was used to estimate hazard ratios (HRs) for serious falls and/ or hip fractures in 1) subchronic hyponatremia versus normonatremia and 2) chronic hyponatremia versus normonatremia.

Results: Among 1,033,838 persons and 1,799,163 Na measurements, 73,883 (7.1%) serious fall and/or hip fracture events occurred among the cohort. Compared to normonatremia, subchronic hyponatremia and chronic hyponatremia had serious fall and/or hip fracture HRs (95% CI) of 5.77 (5.66 – 5.87) and 1.91 (1.86 – 1.96) respectively.

Conclusions: We observed an increased risk for serious falls and/or hip fractures in persons with chronic and subchronic hyponatremia. Early detection and management of outpatient hyponatremia may provide an opportunity to prevent adverse outcomes including serious falls and fractures.

A Pilot Study of the Serious Illness Care Program in a Dialysis Population

Ernest I. Mandel,[1,3] Francine Maloney,[3] Nathan J. Pertsch,[4,3] Jonathon D. Gass,[3] Justin J. Sanders,[2,3] Rachelle Bernacki,[2,3] Susan Block.[2,3] *[1]Brigham and Women's Hospital, Boston, MA; [2]Dana-Farber Cancer Institute, Boston, MA; [3]Ariadne Labs, Cambridge, MA; [4]Warren Alpert Medical School of Brown University, Providence, RI*.

Background: Clinician-led conversations about future care priorities are associated with enhanced goal consistent care for individuals with serious illness. However, such conversations occur infrequently with patients with end-stage renal disease (ESRD) on dialysis. The Serious Illness Care Program (SICP) is a multi-faceted, comprehensive initiative to promote serious illness conversations between clinicians and patients centered around a conversation guide. This study aimed to assess the acceptability and feasibility of the SICP conversation for dialysis patients in an outpatient dialysis unit.

Methods: Twelve individuals with end-stage renal disease on dialysis from a single outpatient dialysis unit participated in this study. Average age of participants was 68.8 years. Participants completed a demographics survey and baseline questionnaire on their life priorities and care preferences. Each participant then engaged in a clinician-led SICP structured serious illness conversation and completed an acceptability questionnaire. The conversations were recorded, transcribed and thematically analyzed.

Results: Conversations were an average of 20:53 minutes in length. Ten of twelve participants felt that the clinician had the conversation with them at the right time and only one participant did not feel it was worthwhile to have this conversation with the clinician. Two-thirds reported a neutral ("did not notice" or "neither liked or disliked") reaction to the clinician using a written guide during the conversation. Finally, only one participant noted an increase in anxiety about their illness, while 42% noted that the conversation increased their hopefulness about their quality of life in the future. Thematic analysis revealed common perspectives on dialysis including that it narrowed life experiences and opportunities, was chosen by default, and was expected to be temporary.

Conclusions: The results of this pilot study suggest that clinician-led SICP serious illness conversations may be acceptable and feasible for patients with ESRD on dialysis and support larger scale implementation of the SICP intervention in this population. The lessons

from our thematic analysis can inform future serious illness conversations with dialysis patients.

The Relationship Between Lab Parameters and Patient Reported Outcomes in Pre-ESRD and Dialysis Patients

Daniel A. Sturgill, Judith Maddatu, Naveet Bal, Sneha Nagavally, Dawn F. Wolfgram. *Medical College of Wisconsin, Wauwatosa, WI.*

Background: Management of pre-ESRD and dialysis patients places major emphasis on monitoring lab parameters. This population suffers from many symptoms, but it is unclear if routinely measured lab values correlate with patient reported outcomes (PROs). We evaluated the relationship between lab and hemodynamic measures and PROs in pre-ESRD and dialysis populations.

Methods: We conducted a cross-sectional study of pre-ESRD and dialysis cohorts. PROMIS surveys on cognitive function, physical function, and fatigue were administered via personal health record (PHR) or in clinic for the pre-ESRD cohort and at the dialysis center for the dialysis cohort. Linear regression analysis of the relationship between PROMIS T-scores (norm=50, SD=10) and labs including eGFR, BUN, hemoglobin (Hb), albumin for the pre-ESRD cohort, and Hb, albumin, Kt/V and intradialytic BP changes in the dialysis cohort. Models were adjusted for demographics and comorbidities.

Results: Our study included 76 pre-ESRD patients and 92 dialysis patients. The mean age (SD) was 61.0 (14.8) and 56.1 (14.8) years for the pre-ESRD and dialysis cohorts, respectively. Pre-ESRD patient mean eGFR (SD) was 18.4 ml/min (11.6). Overall, the pre-ESRD cohort reported no deficits in cognition (51.0 (9.2)) or fatigue (52.8 (10.4)), but did report moderately impaired physical function (39.8 (9.2)). Overall, the dialysis cohort reported no cognitive deficits (50.3 (10.9)), but did report moderately severe fatigue (55.0 (9.8)) and severely impaired physical function (37.9 (7.9)). In Pre-ESRD patients higher BUN and lower eGFR was associated with higher reported cognitive function, $p<0.01$ for both. In dialysis patients lower Hb was associated with greater reported fatigue, $p=0.01$, and higher albumin was marginally associated with higher physical function, $p=0.06$.

Conclusions: Patient reported impairment in physical function was identified in the pre-ESRD and dialysis cohorts. Hb and albumin were associated with increased reported fatigue and reduced physical function in the dialysis cohort. In the pre-ESRD cohort clearance parameters were associated with better reported cognition with unclear relevance. Our results suggest that further research is needed on how to improve PROs in pre-ESRD and dialysis patients.

PUB341

Hemoglobin Variability and Mortality Association in Elder Hemodialysis Patients

David Escamilla-Illescas, Michael E. Wasung, Luis R. Lopez y lopez, Mario A. Sebastian-Diaz. *Hospital Central del Sur de Alta Especialidad PEMEX, Mexico City, Mexico.*

Background: Anemia secondary to Chronic Kidney Disease requires treatment because its impact in mortality; this effects lies within a spectrum that can't be captured by an absolute level of isolated hemoglobin. Controversial results exist in the association between hemoglobin variability and mortality, so we decided to look for this association in elder population.

Methods: We performed a prospective cohort of patients over 60 years in hemodialysis conducted at the Hospital Central Sur de Alta Especialidad in the period from January 2017 to March 2018. Monthly measurement of hemoglobin was recorded and the variability calculated by linear regression model and absolute change model. We documented whether the patient reached the primary (mortality) or secondary outcomes (hospitalizations or visits to the Emergency Room). We performed Cox regression for both models of variability. Secondary outcomes were analyzed by ANOVA. At the end of the study we measured the Granov-Goor Index (GGI) with the NiCaS system, dividing into two groups where <10 is related to asymptomatic left ventricular systolic dysfunction (aLVSD) and compared change in cardiac index and total body water according to tertiles.

Results: Thirty-two patients met the inclusion criteria, 53.1% men with an average age of 72.2(±7.9) years old and a time in hemodialysis of 22(±25.6) months. During the follow-up period 25% of the patients died. The variability of hemoglobin was calculated and divided into tertiles. In the Cox regression there were no significant differences in survival for the linear regression model ($p=0.09$) and for the absolute change model ($p=0.1$). No significant differences were observed in secondary outcomes. At the end of the study, the IGG was measured and the group divided in those with aLVSD (13) and those with IGG>10 (7) without finding significant differences in the cardiac index or body water changes.

Conclusions: Elder patients on hemodialysis represent a vulnerable population exposed to many factors that contributes to fluctuation such as lack of erythropoietin administration or poor compliance of the treatment. In this study we don't observe differences in survival associated with greater variability maybe due to different pre-hemodialysis care, follow-up time or multiple comorbidities. We need to continue analyzing this vulnerable population.

PUB342

Mild Cognitive Impairment in Maintenance Hemodialysis Patients: A Cross-Section Survey and Cohort Study

Pei Xiaohua. *The First Affiliated Hospital of Nanjing Medical University, Nanjing, China.*

Background: Few studies focused on mild cognitive impairment (MCI) with maintenance hemodialysis (MHD) patients. This study was conducted to ascertain whether Mini-Mental State Examination (MMSE) or Montreal Cognitive Assessment (MoCA) was more accurate for MHD patients, then survey the prevalence, severity and risk factors of MCI with MHD patients, finally observe the progress of MCI with MHD patients in a period of six-months.

Methods: Referring with guidelines for cognitive impairment in China: the diagnosis and treatment of MCI (2010), MMSE and MoCA were used to assess the cognitive condition.

Results: 64 MHD and 54 non-HD subjects were included in this study. The mean age of the two groups was both beyond 60 years. The cut-off value of MoCA and MMSE were 26 and 27 to screen MCI, respectively. MoCA performed superior to MMSE in sensitivity, specificity and ^{AUC}ROC. The prevalence of MCI in MHD group was significantly higher than that in non-HD group (60.9% vs. 29.6%, MoCA) with OR 3.71. Spearman correlation test indicated that MCI was related with age, comorbidities, education years, uric acid, serum albumin, blood pressure. A multivariate stepwise regression analysis demonstrated that there was no relationship between MCI and the factors tested, except age. After an observation period of six months, MoCA indicated that MCI prevalence tended to augment and aggravate in the MHD group.

Conclusions: MoCA could be a more accurate assessment for screening MCI in both non-HD and MHD population. MHD patients might have a significantly higher prevalence of MCI. Age could be a vital important risk factor for MCI.

PUB343

Relationship Between TGF-β1, TGF-βR I, TGF-βR II, and Coagulation Fibrinolysis Factors and Their Effects on the Process of Renal Fibrosis

Zhang Y. Xia. *nephrology, first affilicated hospital of china medical university, Shenyang, China.*

Background: To explore the expressions of transforming growth factor β_1(TGF- β1), and its types I and II receptors (TGF- β Type I, II Receptors, TGF-βR I,II), and their roles and relationships in the mechanism of human glomerulonephritis, their correlation with blood coagulation fibrinolysis factors(FRA,FN, α_1-PI, PLG), and the accelerative effects on glomeruli cirrhosis, so as to identify the key factor that triggers and develops human glomerulonephritis.

Methods: Through immunohistochemistry, SABC, to assay the reflected changes in glomerular expressions of TGF-β_1 and TGF-βR I and II, and in selected biopsy samples of the following 41 disease cases. By applying direct immunofluorescence to assay FN and FRA, indirect immunofluorescence assays α_2-PI, and PLG, in 65 disease cases. Statistical analysis through Ridit and Spearman′s analysis.

Results: (1)Significant close correlations was noted between (TGF-ß1 and TGF-ßR I and II), and (FRA, FN, α_2-PI, PLG) in the sampling disease cases, and the expressions significantly increase in direct correlation to the increased severity of renal tissue inflammation and fibrosis. (2) The glomerular fibrosis is the combined effect of several factors. The key factors include (TGF-β_1 and TGF-βR I and II)and (FRA, FN).

Conclusions: The expressions and correlations within renal tissues of (TGF-β1 and TGF-βR I and II), and (ERA,FN,α_1-PI, PLG), indicate these are significant factors in the developments of renal tissue fibrosis or cirrhosis.

PUB344

Omega-3 Fatty Acid May Stabilize the Podocyte Cytoskeleton and Improve the Survival

Jiwon M. Lee,[1,3] Hyunsu Choi,[4] Jin young Jeong,[1] Yoon-Kyung Chang,[2] Dae Eun Choi,[1] Ki Ryang Na,[3] Kang Wook Lee,[3] Jwa-Jin Kim.[1] *[1]Chungnam National University, Seoul, Republic of Korea; [2]The Catholic University of Korea, Daejeon, Republic of Korea; [3]Chungnam National University Hospital, Daejeon, Republic of Korea; [4]Daejeon St. Mary's Hospital, Daejeon, Republic of Korea.*

Background: Cytoskeletal disruption is the main issue in podocytopathies. Previous studies reported that omega-3 improved podocyte survival via anti-apoptotic and anti-inflammatory effects. However, the role of omega-3 on the cytoskeleton of the podocyte is yet to be investigated. We studied on the effect of omega-3 on cytoskeleton in a puromycin aminonucleoside (PAN) induced podocyte injury model.

Methods: *In vitro* cultured mouse podocytes were divided into four groups: control, PAN treated, Omega-3 (EPA, DHA) treated, and PAN + EPA/DHA treated. PAN and EPA/DHA were treated by dose and time. Cytoskeletal components including F-actin, synaptopodin, α-actinin-4, and Jo-1 were evaluated. Oxidative stress and autophagic markers and cytoskeleton stains, such as Bax/Bcl2 ratio, caspase-3, phosphorylation (p)-mTOR, phosphorylation (p)-cofillin and RhoA were evaluated.

Results: Compared to control, the PAN-treated group showed decreased expression of f-actin and synaptopodin, α-actinin 4 and Jo-1; and increased (p)-mTOR, (p)-cofillin and RhoA. In the PAN group, treatment with EPA/DHA improved the expression of f-actin and synaptopodin, alpha actinin 4 and Jo-1. EPA/DHA also suppressed (p)-mTOR, (p)-cofillin, RhoA, and Bax/Bcl2 ratio, while activating capase-3.

Conclusions: EPA and DHA treatment improved cell survival and related markers in puromycin-treated mouse podocytes. The results inferred that Omega-3 may ameliorate the podocyte damage by anti-apoptotic and cytoskeleton-stabilizing effects.

Post Infectious Glomerulonephritis: A Cause of Pulmonary Renal Syndrome

Randa I. Farah,[2] Nadia M. Alqurini,[1] Ayman Wahbeh.[2] *[1]University of Arkansas for Medical Sciences, Little Rock, AR; [2]University of Jordan, Amman, Jordan.*

Introduction: The occurrence of diffuse alveolar hemorrhage (DAH) in association with post streptococcal glomerulonephritis (PSGN) is extremely rare. We present a case of acute kidney injury from PSGN that was initially treated with steroids. DAH developed shortly after stopping steroids. At that time the patient was recovering from the renal injury and was dialysis-independent.

Case Description: Our patient was a 25-year-old lady presented with a history of passing dark brown urine preceded by a vague history of a sore throat two weeks prior to that. He examination was normal. Serum creatinine was 2.4 mg/dl and hemoglobin was 11.6 mg/dl. Urinalysis showed +2 proteinuria, dysmorphic RBC's and several WBCs. Her spot urine protein to creatinine ratio (UPCR) was 1.9 grams/gram. Immunological workup was negative except a high serum anti-streptolysin-O titer (674.9 IU) and a low C3 (0.3 g/l). Kidney biopsy showed diffuse exudative glomerulonephritis. Two glomeruli out of ten showed cellular crescents. Immunoflourescence and electron microscopy were consistent with PSGN. She became anuric and serum creatinine rose to 4.5 mg/dl. Treatment was started with intravenous methylprednisolone 0.5 gram daily for 3 days. She went on to develop anasarca and uremic symptoms with a creatinine of 10.9 mg/dl then dialysis was initiated. Her urine output improved over few days and dialysis was held. During that period steroids were discontinued. Six days later she complained of dyspnea and hemoptysis. Hemoglobin dropped to 8 mg/dl and her oxygen saturation was 75%. Radiographic images were suggestive of DAH which was confirmed by bronchoscopy. The broncho-alveolar lavage was persistently bloody on sequential samples. IV methylprednisolone was restarted again for 3 days. She improved dramatically 2 days into treatment and was discharged on prednisone. Steroids were tapered slowly over 3 months and then stopped. Serum creatinine decreased to 0.4 mg/dl and UPCR improved to 0.32 at 1 year.

Discussion: Our patient had a picture of rapidly progressive glomerulonephritis and was started on high dose steroids. Shortly after stopping steroids she developed DAH which was promptly diagnosed and treated with steroids, raising the question about the role of immune suppression, specifically steroid use in adults with PSGN with DAH. Only five cases were reported in adults and no clear recommendations exist.

PUB346

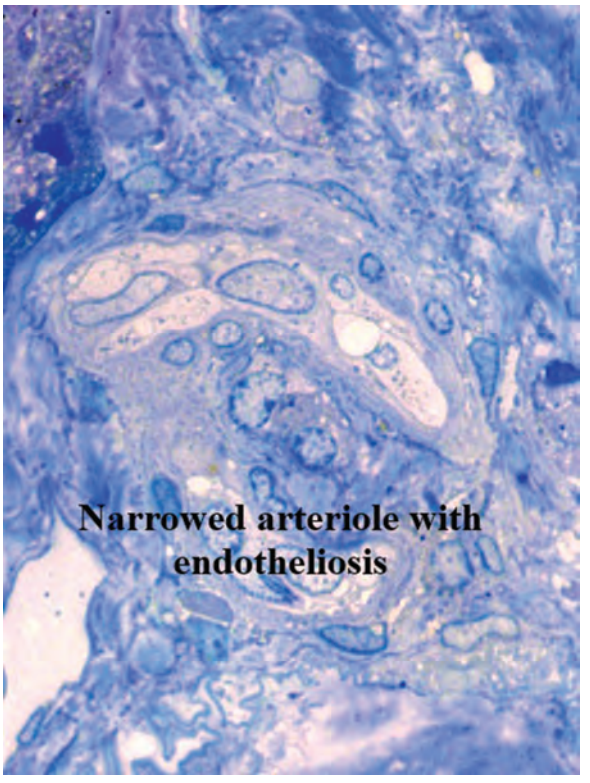
Catastrophic Antiphospholipid Syndrome Due to Systemic Lupus Erythematosus: The Beneficial Effect of Rituximab Treatment

Andreea Andronesi,[3,2] Ciprian Jurcut,[4] Cristina Cristache,[3] Bogdan M. Sorohan,[3] Bogdan Obrisca,[3] Danut Andronesi,[1] Gener Ismail.[3,2] *[1]General Surgery and Liver Transplant Department, Fundeni Clinical Institute, Bucharest, Romania; [2]Nephrology Department, UMF Carol Davila, Bucharest, Romania; [3]Fundeni Clinical Institute, Bucharest, Romania; [4]Central Emergency Military Hospital Dr Carol Davila, Bucharest, Romania.*

Introduction: Kidney involvement is a frequent complication of systemic lupus erythematosus (SLE). Kidney pathology is essential in differentiating lupus nephritis (LN) from thrombotic microangiopathy (TMA) secondary to antiphospholipid autoantibodies to choose proper treatment.

Case Description: A 61 years male patient with benign polyclonal gammopathy, overlap autoimmune hepatitis–primary biliary cirrhosis, acquired deficiency of factor VIII of clotting due to circulating inhibitors, aortic bioprosthesis for aortic stenosis and SLE with anticardiolipin (ACL) antibodies and lupus anticoagulant, is diagnosed one week before admission with raised serum creatinine (SCr 1.6 mg/dl) and short episodes of diplopia. At admittance he had proteinuria 800 mg/day, microangiopatic anemia, thrombocytopenia 79000/ml and hypofibrinogenemia 119 mg/dl. Kidney biopsy showed no LN but TMA (Image). MHC genotyping showed high risk for autoimmunity (DQB1*02,*05/DRB1*03,*14). For probable cAPS patient received low molecular weight heparin (LMWH), methyl-prednisolone, plasmapheresis, rituximab (two 500-mg infusions at 7-days interval) with resolution of acute kidney injury, diplopia and TMA and complete depletion of CD19+B-lymphocytes (Ly) after one month. Treatment was continued with LMWH and prednisone in tapering dosage. After 18 months we noticed reappearance of ACL and of CD19+B-Ly, followed after 5 months by increase of SCr to 1.4 mg/dl. 500 mg of iv rituximab was administered with SCr normalization.

Discussion: Targeted therapy was possible after kidney pathology exam, improving renal and general prognosis. CD19+B-Ly repopulation preceded biological relapse, so monitoring of CD19+B-Ly may be useful to predict relapses and guide rituximab therapy.



PUB347

New Assay with Enhanced Sensitivity for the Detection of Galactose-Deficient IgA1 Enables Mechanistic Studies Using Human Primary Cells

Colin Reily,[1] Dana Rizk,[1] Bruce A. Julian,[1] Jan Novak.[2,1] *[1]Medicine, University of Alabama at Birmingham, Birmingham, AL; [2]Microbiology, Univeristyi of Alabama at Birmingham, Birmingham, AL.*

Background: IgA nephropathy (IgAN), the most common primary glomerulonephritis in the world, is characterized by glomerular IgA1 immunodeposits enriched for galactose-deficient IgA1 (Gd-IgA1). These immunodeposits likely originate from the circulation. Patients with IgAN have elevated blood levels of Gd-IgA1, predominantly bound in circulating immune complexes. Current ELISA tests require a significant amount of IgA1 to properly assess IgA1 galactose deficiency. This requirement limits studies with cultured primary cells, such as peripheral blood lymphocytes (PBLs), due to low number of IgA1-producing cells in PBLs and, consequently, low IgA1 production. To circumvent the problem, immortalized IgA1-secreting cell lines were previously established from IgAN patients and controls. This approach enabled studies of O-glycosylation pathways associated with IgA1 galactose deficiency. Translating the finding from immortalized cells into primary cells has proven difficult due to limitations of the current assays. Thus, a more sensitive assay was needed for analysis of IgA1 glycosylation.

Methods: We developed a new chemiluminescent assay for Gd-IgA1 detection using a lectin from Helix pomatia (HPA; specific for terminal N-acetylgalactosamine) conjugated to acridinium ester. Cell-free media were collected post-incubation with PBLs or EBV-immortalized IgA1-producing cells. Galactose deficiency levels were assessed using HPA lectin conjugated to acridinium. Limits of detection were determined for the new assay and compared to that of previously established biotin-labeled HPA and colorimetric detection.

Results: The chemiluminescent assay showed a log-fold increase in sensitivity over the colorimetric assay as well as a two-fold improvement in the limit of detection. This improvement in sensitivity enabled assessment of galactose deficiency of IgA1 secreted by cultured primary PBLs.

Conclusions: We report a new method for analysis of Gd-IgA1 using a highly sensitive chemiluminescent assay. We show that this new assay can accurately assess the degree of galacrose deficiency in IgA1 secreted by cultured PBLs isolated from peripheral blood, a task not feasable with the traditional colorimetric lectin assay.

PUB348

Association of Atypical ANCA with Pauci-Immune Glomerulonephritis

Ali I. Gardezi,[1] Sana Waheed,[2] Tripti Singh.[2] *[1]Nephrology, University of Wisconsin School of Medicine and Public Health, Madison, WI; [2]University Of Wisconsin School Of Medicine and Public Health, Madison, WI.*

Background: ANCA are classified into three types based on the indirect immunofluorescence (IIF) pattern in ethanol fixed neutrophils. Whereas c-ANCA and p-ANCA have well established association with systemic vasculitis, atypical ANCA (a-ANCA) have mostly been associated with inflammatory bowel disease. We present the findings of our study to determine if there is any association of a-ANCA with pauciimmune GN.

Methods: This is a retrospective study of patients who had a pathological diagnosis of pauciimmune GN over a five years period. The patients were divided into three groups based on the presence of typical, atypical or no ANCA. Baseline characteristics, clinical presentation, pathological findings and outcomes were compared.

Results: 26 patients were found to have the required diagnosis and data. The results are shown in the table included.

Conclusions: To our, knowledge, this is the first study looking at the association of a-ANCA with pauciimmune GN. Almost a quarter of the patients had positive a-ANCA with negative PR3 and MPO by ELISA. Interestingly, there was only one patient with ANCA negative GN. It is possible that better IIF techniques were able to identify a-ANCA in those sera which would have been ANCA negative with older techniques. These antibodies may have formed against previously unrecognized antigens involved in the disease process. 4 out of 6 patients with a-ANCA had positive ANA which could give false positive ANCA results. But, ANA positivity could give rise to both atypical and perinuclear patterns, whereas, we only saw atypical pattern. Furthermore, the other 2 results with atypical ANCA cannot be explained by this phenomenon. A-ANCA might be associated with pauciimmune GN. In the presence of appropriate clinical presentation, presence of a-ANCA should prompt the clinicians and pathologists to consider the diagnosis of ANCA vasculitis.

Pauciimmune GN	Typical ANCA	Atypical ANCA	P-value
N	19/26 (76%)	6/26 (24%)	-
Age (years) mean±SEM	59.1±4.1	54.3±8.9	0.59
Male N, %	8, (42%)	4, (66.7%)	0.3
Extra renal manifestation N, %	7, (36.8%)	1, (16.7%)	0.36
ANA positive N, %	4, (21.1%)	4, (66.7%)	0.04
Serum creatinine (mg/dL) median (IQ range min and max)	2.7 (1.0, 18.8)	4.3 (1.1, 20.0)	0.34
Necrosis on biopsy N, %	17, (89.5%)	3, (50%)	0.04
HD on presentation N, %	5, (26.3%)	2, (33.3%)	0.74
Treatment with Cytoxan N, %	13, (68.4%)	3, (50%)	0.42

Pathology Patterns of Paraprotein-Induced Kidney Damage in 168 Patients from a Single Center

Elena Zakharova,[1,2] Ekaterina Stolyarevich.[2] *[1]Nephrology, Moscow City Hospital n.a. S.P. Botkin, Moscow, Russian Federation; [2]Nephrology, State University of Medicine and Dentistry, Moscow, Russian Federation.*

Background: Paraprotein-induced lesions in multiple myeloma (MM) include cast nephropathy (CN), AL amyloidosis, light chain deposition disease (LCDD), light chain proximal tubulopathy (LCPT), proliferative glomerulonephritis with monoclonal Ig deposits (PGMID) and several rarer variants. AL amyloidosis itself is mainly found in the absence of lymphoproliferative disease (LPD). LCDD, PGMID, LCPT and other lesions not related to MM or any LPD are merged under the umbrella of Monoclonal Gammopathy of Renal Significance (MGRS)

Methods: We evaluated 197 patients with LPD, AL amyloidosis and MGRS, who underwent kidney biopsy in 1997-2017. Pathology study included light microscopy and immune stainings with electron microscopy for selected cases. Patients without clear paraprotein deposition were excluded from analysis

Results: Study group included 86 males and 82 females, median age 61 [31; 81] years. Indication for biopsy was nephrotic syndrome in 124 (73.8%) cases, progressive decline of kidney function in 103 (61.3%) cases, or both in 65 (38.6%) cases. Pathology findings and clinical setting are shown in the Table

Conclusions: Most often type of paraprotien-induced renal desease is AL amyloidosis, including that complicates MM and Waldenstrom macroglobulinemia (WM). Patients with MM present also with CN, LCDD and variety of rare lesions, or with the combination of 2 or even 3 patterns. In turn, WM might be complicated by several types of lesions. MGRS and MM share patterns like LCDD and PGMID

Pathology pattern/clinical setting	Multiple myeloma	Waldenstrom macroglobulinemia	Franklin disease	Non-Hodgkin lymphoma	AL amyloidosis	MGRS	Total N (%)
AL amyloidosis	25	1	-	-	102	-	128 (76%)

PUB350

Normotensive Scleroderma Renal Crisis (SRC) with Urinary Findings of ATN

Jith Palacherla, Koba A. Lomashvili. *Emory University, Snellville, GA.*

Introduction: SRC can occur in 5-10% of SSc patients. Here we describe a case of normotensive SRC with severe AKI and unequivocal urinary finding of "muddy brown casts" consistent with ATN, presenting dilemma in using ACE inhibitor at initial presentation.

Case Description: A 76-year-old WF with newly diagnosed rapidly progressing diffuse SSC within past year, with failed multiple oral regimens, on prednisolone 12mg qd, and was admitted for Cytoxan infusion. She had recurrent L pleural effusion and pericardial effusion, s/p pericardial window and was normotensive on amlodipine 5 mg and lasix40 mg daily. She had poor po intake over last two weeks and diarrhea. On admission she had LE edemas, was in pain, BP was 172/93 and creatinine level 4.0, increased from baseline 0.8mg/dl two weeks ago. Platelets were 349. She was started on captopril 12.5mg tid for suspected SRC and analgesic doses readjusted with rapid normalization of BP in 120s/70s. Urine studies showed FeNA 1.5%, FeUrea 51.4%, no hemoglobin. Microscopy showed multiple muddy brown casts. She was oliguric but responded to Lasix. Her AKI worsened requiring hemodialysis (HD) over next few days. ACE was stopped after two days briefly when ATN casts were seen in urine and renin level obtained. BP remained in 110s and 120s/70s rest of her Hospital stay, (with or without ACE). ACE was restarted within few days since SRC could not be ruled out. To resolve therapeutic dilemma, we did kidney biopsy, showing thickening of intima in arterioles, thrombotic microangiopathy and mesangiolysis in ischemic glomeruli, consistent with SRC. Renin came back at 61ng/ml/h. Captopril dose was increased to 50 mg po tid as tolerated. She was discharged on HD.

Discussion: Granular casts and dysmorphic red cells can be found in urine in SRC, but sediment is usually bland. This case is unusual since urine sediment showed unequivocally ATN, and with briefly stopping captopril her BP remained within normal limits, despite having very high renin activity in combination with volume overload. Elevated blood pressure at presentation can be explained by uncontrolled pain and normalized within 4 h with pain control. This case demonstrates that when probability of SRC is high, finding ATN on urine microscopy should not preclude ACE/ARB use with or without pathological diagnosis.

PUB351

The Role of Complement in Primary Antiphospholipid Nephropathy

Sjoerd Timmermans,[1] Pieter V. Paassen.[2] Limburg Renal Registry *[1]Maastricht University Medical Center, Maastricht, Netherlands; [2]Maastricht University Medical Center/Nephrology and Clinical Immunology, Maastricht, Netherlands.*

Background: Renal involvement in the antiphospholipid syndrome has been linked to a spectrum of pathologies, including parenchymal disease known as antiphospholipid (aPL) nephropathy, and although the pathologic features are well-known, the natural history and mechanisms of primary aPL nephropathy have not been established. Recent studies linked thrombotic events to complement and moreover, complement blockade appears promising in severe aPL nephropathy. Here, we investigated primary aPL nephropathy and focused on complement.

Methods: Pathologic and clinical follow-up data were analyzed from adult patients with biopsy-proven aPL nephropathy with no evidence of secondary disease. Complement activation was studied on frozen kidney sections and in vitro after aPL binding to human endothelial cells.

Results: Twenty-one patients (13 female, 8 male) with persistent serum aPL reactivity presented with proteinuria (*n*=19), renal impairment (*n*=17), and/or hypertension (*n*=12). Glomerular disease was noted in 17 cases (thrombotic microangiopathy, *n*=14; focal segmental glomerulosclerosis, *n*=3); the extent of tubulointerstitial and vascular damage varied from mild (*n*=8), moderate (*n*=5), to severe (*n*=8). Electron dense deposits were found in 2 (10%) cases. Four biopsies had C3c co-located with C5b9 along capillaries and/or arteries, all of whom were scored as thrombotic microangiopathy. aPL binding (pooled IgG, *n*=4) to endothelial cells did neither induce C3c nor C5b9. Median follow-up was 5 (range, 1-24) years. Progression to the composite renal endpoint of doubling creatinine and end-stage renal disease occurred in 2 (10%) cases; both patients initially required dialysis. CKD stage 2 (*n*=5), 3 (*n*=12), and 4 (*n*=2) developed in the others. No differences were found regarding activity and chronicity indices on kidney biopsy. New thrombotic events occurred in 5 (24%) patients, one of whom received adequate anticoagulation.

Conclusions: In a large series of primary aPL nephropathy, the disease course appeared quite favorable. Complement activation could not be demonstrated and requires further evaluation.

PUB352

Cryoglobulinemic Membranoproliferative Glomerulonephritis (MPGN) in a Patient with Sjogren's Syndrome and IgM Monoclonal Paraproteinemia

Muhannad Alqudsi, Koba A. Lomashvili. *Renal Division, Emory University, Atlanta, GA.*

Introduction: Cryoglobulinemic GN is rare and usually occurs in type II cryoglobulinemia induced by hepatitis C. Here we present Hepatitis C negative patient with Sjogren's syndrome, cryoglobulinemic GN and monoclonal IgM Kappa paraproteinemia.

Case Description: 60 y/o AAF with PMH of dry mouth and eyes and recent increase in dental caries, was seen at Nephrology Clinic with severe LE edemas of 2 weeks duration and proteinuria 11gm/gm of creatinine (Cr). Her Cr increased from 1.1 to 4.5 mg/dl in one month, prompting renal biopsy showing MPGN Type I and extensive hyaline thrombi in glomerular capillaries suggesting cryoglobulinemic GN. Blood cryoglobulin was positive at 2.5% and serum and urine protein electrophoresis with Immunofixation detected two IgM Kappa monoclonal paraproteins. She had negative Hepatitis B DNA PCR, Hepatitis C and HIV tests. Autoimmune w/u showed ANA 1:230, SSA/RO Ab at 14, SSB/LA Ab > 320unit/ml, (normal < 7), low C3 46, low C4 <1mg/dl. Rheumatoid Factor (RF) was elevated at 423 IU/ml. Rheumatology consult confirmed diagnosis of Sjogren's syndrome. Bone marrow biopsy showed Plasma cells comprise less than 5% of the marrow cellularity, flow cytometry did not reveal plasma or B cell clone responsible for paraproteinemia. W/U for malignancies was negative. She was started on plasma exchange (PLEX) and plasma cell therapy, with Velcade, cytoxan and dexamethazone (VCD), discharged after six sessions of PLEX and continued on VCD for two months total of 4 cycles. Her Cr improved to 1.4-1.7mg/dl but kept having proteinuria with Immunofixation showing persistent IgM Kappa paraprotein. 40 days after last VCD she was given Rituximab, (two doses). At one-month F/U after rituximab, her creatinine improved to 0.8mg/dl, paraprotein concentration and proteinuria both decreased to half of pretreatment levels and cryoglobulin tested negative.

Discussion: The patient with Sjogren's syndrome is expected to have polyclonal RF, but she was tested positive on monoclonal IgM kappa. Since source cell clone was unknown, she was initially given plasma cell therapy, resulting in some improvement of kidney function and limited effect on her nephrotic syndrome (NS). She was given anti B cell therapy later on with further improvement in creatinine and proteinuria. If her NS fully resolves remains to be seen.

PUB353

Engineered Immune Complexes Containing Galactose-Deficient IgA1 and IgG Autoantibody, a Renewable Resource in IgA Nephropathy Research

Zhi qiang Huang,[1] Xianwen Zhang,[2] Joshua C. Anderson,[1] Stacy D. Hall,[1] Rhubell T. Brown,[1] Hitoshi Suzuki,[3] Bruce A. Julian,[1] Christopher D. Willey,[1] Jan Novak.[1] *[1]University of Alabama at Birmingham, Birmingham, AL; [2]Longhua Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, Shanghai, China; [3]Juntendo University Faculty of Medicine, Tokyo, Japan.*

Background: Circulating immune complexes (CIC) containing galactose-deficient IgA1 (Gd-IgA1) and Gd-IgA1-specific autoantibodies are considered a key pathogenetic factor in IgA nephropathy (IgAN). To enhance studies of IgAN, we generated engineered immune complexes (EIC) using Gd-IgA1 and a recombinant Gd-IgA1-specific IgG autoantibody derived from a patient with IgAN. The biological effects of EIC on human mesangial cells (hMC) were assessed and compared with those for CIC.

Methods: EIC were prepared from a recombinant IgG autoantibody specific for Gd-IgA1 from an IgAN patient and a Gd-IgA1 myeloma protein. EIC formed in human serum depleted of IgA and IgG and CIC from sera of IgAN patients were isolated by size-exclusion chromatography. hMC were stimulated with EIC or CIC and cellular proliferation and protein-tyrosine kinase (PTK) signaling were evaluated.

Results: EIC and CIC increased cellular proliferation of hMC by 2.88±0.69-fold and 3.97±2.18-fold, respectively. EIC and CIC induced signal transduction in hMC, resulting in enhanced phosphorylation of PDGFR-b, ERK1/2, and AKT1 detected by immunoblotting. Global protein-tyrosine kinome profiling revealed that EIC and CIC activated multiple PTKs. Among the ten kinases with highest phosphorylation indexes (KSTAT and specificity), eight kinases overlapped between EIC- and CIC-activated hMC: ROR1, LCK, LYN, KIT, YES1, BLK, TYK2, and CTK (MATK). Among other activated kinases (P<0.05 compared to negative control), 98% overlapped between EIC- and CIC-activated hMC. Among them, 17% belonged to Src family (a non-receptor protein kinases) and 25% to different growth-factor receptors, including PDGF/PDGFR, VEGFR, FGFR, EGFR, and INSR. Several activated kinases belonged to kinase families, such as Syk, Tec, Axl, and Eph.

Conclusions: EIC and CIC had similar capacity to activate hMC through phosphorylation of multiple kinases and activation of downstream pathways, ultimately resulting in cellular proliferation. EIC may thus serve as a convenient model of IC in the studies of pathogenesis of IgAN.

Circulating Antibodies Against M-Type Phospholipase A2 Receptor Can Predict Treatment Response and Outcome in Chinese patients with Primary Membranous Nephropathy

Zhen Qu,[1] Mufan Zhang,[1] Zhao Cui,[1] Minghui Zhao.[2] *[1]Peking University First Hospital, Beijing, China; [2]Peking University First Hospital, Peking University, Beijing, China.*

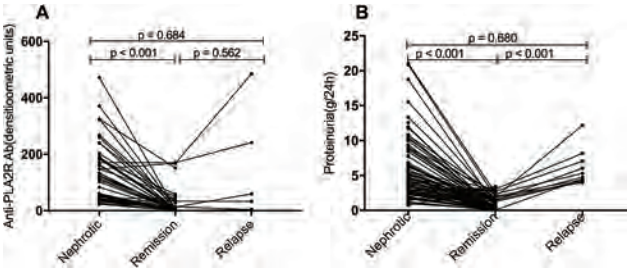
Background: Anti-phospholipase A2 receptor (PLA2R) antibodies are specific to the diagnosis of primary membranous nephropathy (pMN). The prevalence of positive antibodies varies among different cohorts. Discrepancy remains on the association between antibody levels and clinical courses, and the prognostic value of antibodies to treatment responses and kidney outcomes.

Methods: 359 consecutive kidney biopsy-proven pMN patients were enrolled. Anti-PLA2R antibodies were detected by immunofluorescence assay (IFA) and enzyme-linked immunosorbent assay (ELISA).

Results: The positive rate of anti-PLA2R antibodies in pMN were 65.2% (234/359) by IFA and 56.3% (202/359) by ELISA. Antibody level presented positive correlation with urinary protein excretion (r=0.164, P=0.002). The detectable antibodies (OR=2.99, P=0.007) and higher level of proteinuria (OR=1.11, P=0.009) were independent risk factors to no-remission after treatments. High level (>179U/mL) and moderate level (64-179U/mL) antibodies predicted higher risk to no-remission. Higher level of antibodies (HR=1.002, P=0.019) was the independent risk factor to kidney dysfunction during follow-up. High level (>179U/mL) of antibodies possessed higher risk to kidney dysfunction. The antibodies turned negative in 42/52 (80.8%) patients who achieved clinical remission, while remained positive in all patients of no response (P<0.001).

Conclusions: We documented a lower positivity rate of anti-PLA2R antibodies in this large Chinese pMN cohort and close correlations between antibody levels and clinical severity. The risk stratification of antibody levels could predict treatment responses and kidney outcomes of pMN.

Funding: Government Support - Non-U.S.



Anti-PLA$_2$R antibody levels and proteinuria in pMN patients at the time of kidney biopsy, remission and relapse. Patients who reach a remission had a decrement in the level of anti-PLA$_2$R antibodies and proteinuria. The proteinuria and the level of anti-PLA$_2$R antibodies were increased during relapse.

PUB355

Atypical Anti-GBM Glomerulonephritis with Crescents

Mohamad M. Alkadi, Mostafa F. Elshirbeny, Imaad B. Mujeeb, Omar Fituri. *Hamad Medical Corporation, Doha, Qatar.*

Introduction: Atypical anti-GBM disease is a rare variant characterized by an indolent course, no pulmonary involvement, undetectable circulating antibodies and absence of crescents in kidney biopsy. Here we present a case of rapidly progressive glomerulonephritis due to atypical anti-GBM.

Case Description: This is a 37 year-old man with no past medical history who presented in December, 2016 with bilateral lower extremity swelling and dark urine for 10 days. He denied fever, chills, shortness of breath, hemoptysis, vomiting, diarrhea, joint pain, skin rash or dysuria. Physical examination was remarkable for elevated blood pressure of 160/110 mm Hg and bilateral Lower extremity pitting edema. His labs showed elevated serum creatinine of 270 mmol/L, hypoalbuminemia, hyperlipidemia, microscopic hematuria and 15 g proteinuria. Virologic and immunologic workup was negative including hepatitis B, hepatitis C, HIV, ANA, ANCA, C3, C4 and Anti-GBM antibodies. kidney biopsy showed diffuse proliferation in glomeruli with increased mesangial cellularity and diffuse crescents involving > 50% of glomeruli. Direct Immunofluorescent studies showed diffuse linear GBM staining with IgG (3+) in glomeruli as shown in figure 1. Electron

microscopy showed similar proliferative features and severe foot process effacement, but no immune complex, fibrillary, or paraprotein-related deposits in GBM or mesangial regions. Patient was treated with IV pulse steroids, 8 sessions of plasmapheresis and 6-month of oral cyclophosphamide. He was also maintained on oral steroids. His serum creatinine and proteinuria 1 year post treatment were 117 mmol/l and 3.7 g, respectively.

Discussion: This case is unique because atypical anti-GBM glomerulonephritis is extremely rare and having diffuse crescentic phenotype in atypical anti-GBM hasn't been reported before. Despite high sensitivity of ELISA in detecting serum anti-GBM antibodies, anti-GBM cannot be ruled out completely without kidney biopsy.

Successful Therapeutic Procedure of Two Cases of Monoclonal Immunoglobulin Heavy Chain Deposition Disease (HCDD)

Minoru Hatano,[1] Yumiko Nakamura,[1] Takatsugu Iwashita,[1] Yuta Kogure,[1] Koki Ogawa,[1] Kensuke Joh,[2,1] Maiko Yamasaki,[1] Tomonari Ogawa,[1] Koichi Kanozawa,[1] Hajime Hasegawa.[1] *[1]Saitama Medical Center, Saitama Medical University, Saitama, Japan; [2]Tohoku University Graduate School of Medicine, Sendai-city, Japan.*

Introduction: Among monoclonal immunoglobulin deposition disease (<1.0% of biopsy cases), heavy chain deposition disease (HCDD) is considered to be very rare and therapy-resistant glomerular disorder. We recently experienced 2 cases of HCDD who successfully showed clinical remission by immunosuppressive agent and corticosteroid.

Case Description: First case was 37-years-old man, and pointed out sever proteinuria and hematuria on the regular health check at 2 months prior to the admission. Light microscopic (LM) biopsy observation showed membranoproliferative glomerulonephritis (MPGN), and immunostaining showed IgG (+), C1q (+), C3 (+) and IgG3 (+). Light chains were all negative. Electron microscopic (EM) study showed powder-like deposition in the basement membrane. Because CH1 staining was negative, he was final diagnosed as gamma 3-HCDD. He was not satisfied with the myeloma criteria, however, hematologists agreed with the administration of bortezomib+dexamethasone at day-55 and intermittently repeated 12-times. After finishing the 4th therapy, his hematuria was disappeared, and finally his proteinuria was disappeared at day-422. Second case was 30-years-old woman, and she recognized edema on the lower extremities at 2 months prior to the admission. She showed remarkable proteinuria, hematuria and renal dysfunction. Renal biopsy showed MPGN in LM study, and IgG (+), C1q (-), C3 (-), IgG1 (+) in the immunostaining. Light chain staining were both negative, and powder-like deposition was observed in EM study. IgG-Fab and Fc specific staining revealed Fab (-) and Fc (+), suggesting CH1 deficient HCDD. Because hematologists did not agree to use bortezomib, she was started PSL 30 mg/day alone at day-42, and both proteinuria and eGFR were getting to be restored at day-116.

Discussion: Both of our cases responded to the therapy, whereas HCDD is known to show therapy resistance. Bortezomib might show the better efficacy to this disease, however, we sometimes hesitate to use bortezomib in patients in earlier stage because they usually do not agree with the myeloma criteria. However, PSL alone might be sufficiently effective to cases in earlier stage.

PUB357

Anti-Complement Factor H Mediated Glomerulonephritis at a Tertiary Care Centre

Umesh L. *Institute of nephrourology, Bangalore, India.*

Background: Complement dyregulation has become an important etiology for glomerular diseases. Anti body against complement factor H which regulates the alternate complement pathway can cause atypicical HUS and C3 glomerulopathy

Methods: We studied the clinical profile and outcome of patients with anti complement factor H mediated disease at a tertiary care centre over 18 months. 8 patients were studied and followed up to assess their response to therapy.

Results: Cases were equally distributed between males and females. Mean age was 20.5yrs with 5 patients in the paediatric age group. All patients presented with hypertension with RPGN with active urinary sediments. Mean serum creatinine at presentation was 6.8+/-1.2. Serum c3 was low in all patients with normal c4 levels. LDH was elevated in 50% patients with schistocytes in peripheral smear. 100% patients had oliguria and were dialysis dependent at presentation. Renal biopsy showed thrombotic microangiopathy in 4 patients while features were suggestive of C3 glomerulopathy in 4 patients. Anti complement factor H antibody was elevated in all patients with a mean of 161AU/ml. All patients were managed with pulse steroids followed by oral steroids along with IV cyclophosphamide. Plasmapharesis was done in all patients. All of them showed improvement in renal function after plasmapharesis and were free from dialyisis. Among the 8 patients, one was post transplant thrombotic microangiopathy with low serum c3 with elevated anti cfh antibody. Patient responded well to our treatment and had normal renal function by the 3rd week post transplant. All 5 patients in the paediatric age group are on regular follow up with normal renal function in complete remission. One of the adult patient expired due to sepsis with septic shock. Post transplant patient expired due to intracerebral bleed during follow up. Last patient has a stable creatinine of around 2.2mg/dl and is doing well

Conclusions: Our case series shows that anti complement factor H mediated disease shows good response to immunosuppression and plasmapharesis without the need for eculizumab.

PUB358

Case Report: Recurrence of MPGN Post Transplant – Is This Mere Recurrence of Pattern or Recurrence of Disease?

Umesh L. *institute of nephrourology, Bangalore, India.*

Introduction: Recurrence of MPGN is seen in 19-65 % cases of post renal transplant and amounts for graft loss up to 35 to 50 % cases.

Case Description: 31 year old female patient diagnosed to have ESRD 3 years back initiated on MHD three times a week. She underwent deceased donor kidney transplantation after 11/2 yrs with Basiliximab as induction. Post transplant patient had DGF. Post transplant patient achieved nadir creatinine of 0.9 mg/dl by 10 days. 9 months post transplant patient developed fever, anasarca and decrease in urine output. On evaluation found to have active sediments in urine, albuminuria 3+, serum creatinine 3.5mg/dl and 24 hr urine protein 7.5 grams, low C3. Patient underwent graft biopsy. Subsequently patient received pulse steroid for 3 days and 5 sessions of plasmapheresis. Later renal biopsy report was suggestive of MPGN with focal crescents, ATN. IF showed Ig G3+, C3 3+, 3+, negative for or other immunoglobulins or compliments. As her native kidney disease was IC mediated MPGN with no light chain restriction, paraffin tissue of native kidney was reexamined for immunoperoxidase stain for and chains, which were positive. Medical oncologist opinion was taken. Patient underwent extensive work up for paraproteinemias and results were negative. Patient received 4 doses of Bortezomib. Patient's serum creatinine was reduced to 0.8mg/dl and proteinuria reduced to 800mg/day. 2 months later patient was on routine surveillance found to have increase in proteinuria with microscopic hematuria with normal creatinine. As per medical oncologist advice patient was restarted on Bortezomib. Presently her 24 hr urine protein is 600mg/day with normal creatinine.

Discussion: Conclusion: Our case is unique as we were not able to demonstrate monoclonal deposits in native kidney sample with recurrence of MPGN with monoclonal light chain deposits post transplant. Our findings emphasize for thorough evaluation for paraproteinemias in patients with idiopathic MPGN even in the absence of light chain deposition in biopsy

PUB359

Lessons from Comprehensive Analysis of a Factor I (FI) Variant in Atypical Hemolytic Uremic Syndrome (aHUS)

Anuja Java,[1] John P. Atkinson.[2] *[1]Washington University in St. Louis, Saint Louis, MO; [2]Washington University, St. Louis, MO.*

Introduction: aHUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia and acute kidney injury. Mutations in genes encoding complement proteins have been identified in ~60% of patients. Majority of these variants are variants of uncertain significance (VUS). Herein, we report functional and structural analyses on a FI variant identified in a patient with HUS.

Case Description: **Clinical history:** 22 y/o male had h/o ESRD secondary to *E. coli*-HUS. The patient underwent a renal transplant in 2006. In 2007, he developed non-Hodgkin's lymphoma and his immunosuppression was reduced. Later that year, he lost his kidney to acute cellular rejection. During evaluation for a 2nd kidney transplant, genetic testing for HUS was performed which demonstrated a VUS (R406H) in FI. He received eculizumab post-transplant. One year later, after eculizumab was discontinued, the patient lost his kidney again to acute cellular and antibody-mediated rejection. He is now being evaluated for a 3rd transplant. **Genetic analysis**: The FI variant has been analyzed by several prediction models and due to lack of consensus among these tools, was classified as a VUS. **Antigenic analysis:** The secretion of the variant protein (ELISA) was comparable to wild type (WT). Patient had a borderline low serum FI level. **Functional analysis:** Cofactor assays were performed using purified FI, C3b and with membrane cofactor protein (MCP), Factor H (FH) or Complement Receptor 1 (CR1) as the cofactor protein. WT and variant cDNAs were transfected into human 293T cells. The variant had defective cofactor activity (CA) with FH and CR1 as evident by decreased rate of cleavage of the α-chain of C3b. No defect was observed with MCP. **Structural analysis**: The side chain of R406 in FI forms a salt bridge with the carboxyl group of E123 of FH, thereby stabilizing the FI-FH binding interface. Residue E123 is a unique signature of FH. It is lacking in MCP, possibly accounting for why the R406H mutation impairs FH- but not MCP-mediated CA.

Discussion: **Summary/Lessons Learned:** It is imperative to define the functional activity of a VUS. The variant R406H is pathogenic based on defective CA. Given his clinical course, borderline low FI antigenic levels and these new functional data, we believe that the patient is at high risk of developing a thrombotic microangiopathy or an accelerated rejection in the future.

PUB360

Relapsing IgG4 Related Kidney Disease with Bilateral Ureteral Obstruction by Peri-Renal Tumors – A Case Report of 4-Year Clinical Course

Eiji Ishimura,[1,2] Shuko Ueda,[1] Nobuyuki Kuwamura,[1] Yukihiro Nin,[1] Kazuya Kimura,[1] Tokuki Yasuda,[1] Shinya Nakatani,[3] Akihiro Tsuda,[4] Masaaki Inaba,[3] Tetsuya Makino,[1] Ryusuke Kakiya.[1] *[1]Meijibashi Hospital, Matsubara, Osaka 580-0045, Japan; [2]Osaka City University Graduate school of Medicine, Abeno-ku, Japan; [3]Osaka City University Graduate School of Medicine, Osaka, Japan; [4]Department of Nephrology, Endocrinology, Metabolism, and Molecular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan.*

Introduction: IgG4 related kidney disease (IgG4RKD) is recently established as an interstitial nephritis with IgG4 positive lymphocytes infiltraion. IgG4RKD well responds to corticosteroid therapy, and its prognosis is considered to be good. Here, we report a case with IgG4RKD, in which three times relapses were seen during 4 year duration, with an unusual complication.

Case Description: A 82 year-old male was first admitted in January 2014, because of progressing renal dysfunction. Serum creatinine was 4.77 mg/dL, IgG4 1,130 mg/dL. Renal biopsy showed severe tubule-interstitial nephritis, with typical Bird's eye signs, and with numerous IgG4 positive lymphocytes infiltraion. Intravenous and oral predonisolone (PSL) improved renal function, and he was discharged with serum creatinine around 1.50 mg/dL. One and a half years later, under PSL 5 mg/day, his serum creatinine increased to 2.20 mg/dL. Second renal biopsy revealed active tubulo-interstitial nephritis, again. PSL was increased to 40mg/day, and his renal function was gradually improved. Four years later, in February 2018, his renal function was worsened, again. CT scan revealed bilateral peri-renal retroperitoneal tumors, causing obstruction of bilateral ureters. Bilateral nephrostomy catheters were inserted. At that time, an echo-guided biopsy of the tumors and kidney was performed, revealing numerous patchy infiltrations of IgG4 positive lymphocytes. Intravenous and oral PSL improved renal function, and bilateral nephrostomy catheters were removed on the 40th day, and he was discharged on 70th day, with serum creatinine 1.50 mg/dL.

Discussion: IgG4RKD has been reported to be responsive to steroid therapy (Jap J Nephrol 2011, Saeki T, et al. 2011, Saeki T, et al KI 2013). However, there are very few cases with relapsing IgG4RD in the long clinical course of corticosteroid therapy. Further, there is no case with bilateral ureteral obstruction by tumors with IgG4 infiltration, causing renal failure. The present case indicates that IgG4RKD relapse in the long course of corticosteroid therapy. Also, our case suggests that CT scan should be done to search the cause of renal failure, including retroperitoneal lesions as in the preset case..

PUB361

A Case of Proliferative Glomerulonephritis with Monoclonal IgG Deposits with Nephrotic Syndrome

Masao Kihara,[1] Hitoshi Suzuki,[1] Miki Narahara,[1] Daisuke Sato,[1] Miyuki Takagi,[1] Shigeki Tomita,[2] Yusuke Suzuki.[1] *[1]Nephrology, Juntendo University Faculty of Medicine, Tokyo, Japan; [2]Pathology, Juntendo University Urayasu Hospital, Urayasu, Chiba, Japan.*

Introduction: In most forms of immune complex–mediated glomerulonephritis, the deposited immunoglobulins are typically polyclonal. Renal disease related to glomerular deposits of monoclonal immunoglobulins includes light- and heavy-chain deposition disease, type 1 cryoglobulinemic glomerulonephritis, fibrillary glomerulonephritis, immunotactoid glomerulopathy and proliferative glomerulonephritis with monoclonal IgG deposits (PGNMID). PGNMID is a rare and recently identified disease with a poor prognosis irrespective of the treatment. We report here a case of PGNMID with positive staining for a single light-chain isotype κ and a single heavy-chain subtype IgG3 successfully treated with corticosteroids.

Case Description: A 43-year-old woman with a 3-year history of proteinuria and 2-year history of hematuria was hospitalized because of nephrotic syndrome. At the time of renal biopsy, urinalysis indicated 6.5g/day of urinary protein and microscopic hematuria. Serum creatinine was 1.5 mg/dL. Serum and urine M-protein were negative, and the free light chain κ/λ ratio was within normal limits. Renal biopsy revealed moderate mesangial proliferation and endocapillary cell proliferation. Immunofluorescence staining indicated IgG, C3 and C1q deposits in the mesangium and along the glomerular capillary walls. To rule out secondary MPGN, IgG subclass was elucidated, and detected IgG3 monoclonarity. The light-chain isotype analysis indicated κ-light chain was detected mainly in the glomerular capillary walls. Electron microscopy further showed electron dense deposits in the mesangium and subendothelial space and podocyte foot process effacement. Taken together, we diagnosed as PGNMID. After the treatment with intravenous steroid pulse and consecutive oral steroid, serum creatinine and proteinuria improved to 1.02 mg/dl and under 0.3 g/day, respectively.

Discussion: PGNMID is a novel form of proliferative glomerulonephritis, resembling immune complex–mediated glomerulonephritis. However, the glomerular deposits are a single γ heavy-chain subclass and a single light-chain isotype, most commonly IgG3 κ in the absence of serum M-spike. In patients with PGNMID, about 35% had persistent renal dysfunction, and 22% progressed to ESRD. This case suggested importance of IgG subclass analysis to diagnosis of PGNMID in cases of MPGN.

PUB362

Renal Pathological Analysis Using Galactose Deficient IgA1 Antibody Could Differentiate Secondary IgA Nephropathy from Primary IgA Nephropathy

Yoshihito Nihei, Hitoshi Suzuki, Toshiki Kano, Maiko Nakayama, Yusuke Fukao, Yusuke Suzuki. *Juntendo University Faculty of Medicine, Tokyo, Japan.*

Introduction: In several cases with IgA Nephropathy (IgAN), differenatial diagnosis is difficult due to the complication with other diseases that can induce secondary IgAN. Galactose-deficient IgA1 (Gd-IgA1) has been recognized as the key molecules in the pathogenesis of IgAN. Recently, we demonstrated that immunostaining with Gd-IgA1-specific monoclonal antibody (KM55 mAb) could differentiate IgAN from other glomerular diseases including HCV-related nephropathy (HCV-RN). We report a case of HCV-RN successfully treated by Daclatasvir and Asunaprevir by definitive diagnosis using KM55 mAb.

Case Description: A 66-year-old man presented massive proteinuria (5 g/gCr) and admitted to our hospital. He has presented with microscopic hematuria and proteinuria from the age of 56. After 7 years from the onset of urinary abnormalities, levels of urinary protein increased up to 5 g/gCr, and kidney biopsy was performed. Pathological findings of kidney biopsy specimens revealed mesangioproliferative glomerulonephritis with IgA and C3 deposition, and he was diagnosed with IgAN. Blood examination revealed liver dysfunction by HCV infection. Then, we re-analyzed biopsy specimens using KM55 mAb. KM55 mAb was negative in this case and thus he was diagnosed as HCV-RN. Then, he received antiviral treatment with Daclatasvir/Asunaprevir. Microscopic hematuria improved, and proteinuria decreased (1.5 g/gCr) by 24 weeks. After 2 years from treatment with Daclatasvir/Asunaprevir, level of proteinuria was 0.8 g/gCr.

Discussion: Patients with HCV infection have a higher risk of end-stage renal disease. Definitive diagnosis HCV-RN from IgAN is not easy in patients HCV positive. KM55 mAb is a strong tool to differentiate secondary IgAN from primary IgAN

PUB363

An Unusual Case of Serology Negative Crescentic Glomerulonephritis

Sreedhar R. Adapa,[1] Jean Hou,[2] Harpreet S. Dhindsa,[1] Hemant Dhingra,[1] Amarinder Singh Garcha.[1] *[1]The Nephrology Group, Inc, Fresno, CA; [2]Cedars Sinai Medical Center, Los Angeles, CA.*

Introduction: Anti-GBM (anti-glomerular basement membrane) disease and ANCA vasculitis can coexist but very rare. Seronegative anti GBM disease occurs in 3-4% and seronegative ANCA disease occurs in 10-20% of patients. We describe an unusual renal biopsy showing pathological features of both anti GBM and ANCA crescentic glomerulonephritis; however, serologies were negative for anti GBM antibody and ANCA antibodies.

Case Description: A 46-year-old female presented with history of fatigue and intermittent painless gross hematuria for one month. Physical examination revealed pulmonary congestion and edema. Labs showed hemoglobin 8.7 mg/dl, BUN 85 mg/dl and creatinine 10.8 mg/dl with nephrotic range proteinuria. The patient was emergently started on hemodialysis. Renal imaging showed poor definition of the pelvicaliceal collecting system, normal sized kidneys and bladder wall thickening. Serologies revealed negative ANA, ANCA, anti GBM titers and normal complements. The patient underwent cystoscopy for hematuria, which revealed catheter associated bladder mucosal changes, with no tumors. However, there was light bloody efflux from both ureteral orifices. A renal biopsy was performed and revealed 90% glomerular involvement by active crescents. Immunofluorescence revealed linear glomerular capillary wall staining for IgG. While the majority of the crescents were active and cellular, there was also temporal heterogeneity, with few subacute (fibrocellular) and rare remote/fibrous crescents. This heterogeneity is unusual for anti-GBM nephritis, where all crescents are typically in the same, active stage. Despite the finding of linear GBM staining for IgG, the appearance of the crescentic GN was more consistent with an ANCA-associated vasculitis. The findings raised the possibility of a dual disease process; however, serologic studies for both anti-GBM and ANCA were negative. The patient was treated with pulse dose steroids and cyclophosphamide. Unfortunately, the patient developed infectious complications to cyclophosphamide and treatment was terminated.

Discussion: This case signifies the overlapping features of both anti GBM and ANCA crescentic glomerulonephritis on renal biopsy, but with negative serologies. Although rare, the possibility of atypical anti-GBM and ANCA antibodies, which are not detected by standard commercial assays, should be considered in such cases.

PUB364

Steroid-Resistant Nephrotic Syndrome in a Patient with Lupus: Is It Only Lupus?

Rodrigo Sepúlveda, Eric Roessler, Juan P. Huidobro, Gonzalo P. Mendez. *Pontificia Universidad Católica de Chile, Santiago, Chile.*

Introduction: Renal involvement in systemic lupus erythematous (SLE) is frequent and it has many therapeutic options. Nephrotic syndrome (NS) is a classic manifestation of class V lupus nephritis (LN), but it can be also due to lupus podocytopathy, a condition with excellent response to steroids. We present a case of steroid-resistant NS with diagnosis

of LN, whose further clinical and laboratory work-up revealed an unexpected cause of nephrosis in LN.

Case Description: A 21 year old woman with history of hypothyroidism, oral ulcers, anemia and foamy urine. Laboratory tests showed: serum creatinine 0.7 mg/dL, albumin 2 g/dL, total cholesterol 297 mg/dL, proteinuria in nephrotic range and positive antinuclear antibodies 1:320. Renal biopsy showed LN class II, with mesangial deposits of IgG, IgM, C1q and C3. Electron microscopy showed diffuse foot processes effacement and immune complexes in mesangium, without subepithelial, subendothelial or membranous deposits. The patient was treated with anti-proteinuric measures, corticosteroids, hydroxychloroquine and azathioprine. She persisted with nephrotic range proteinuria and severe hypoalbuminemia despite normal blood pressure and no clinical or laboratory evidence of active SLE. A change of LN class or lupus podocytopathy was suspected, and immunosuppression was intensified. Since nephrotic proteinuria persisted, a second renal biopsy and genetic study of NPHS2 mutation was performed. Sequencing NPHS2 gene resulted in a compound heterozygous mutation with substitutions on p.R229Q and p.A284V. The renal biopsy showed focal segmental glomerulosclerosis and the electronic microscopy revealed diffuse damage of podocytes, with signs of scarring and resolving immune deposits.

Discussion: A persistent nephrotic syndrome in a patient with controlled SLE despite adequate treatment should raise the suspicion of change in the class of LN and/or the superposition of a lupus podocytopathy. For those cases with no response to treatment, unusual causes of heavy proteinuria should be considered in the differential diagnosis. Genetic causes of nephrotic syndrome in young patients with SLE should be part of the clinical and laboratory work-up of these type of patients.

PUB365

Treatment Response in Membranoproliferative Glomerulonephritis with Negative Immunofluorescence

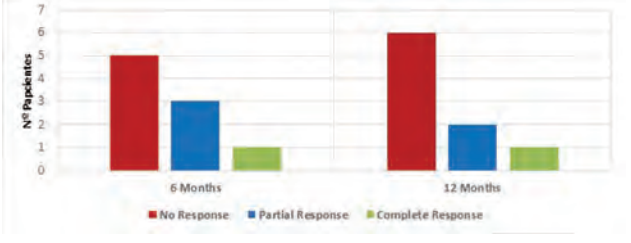
Luis A. Castillo. *Fresenius Medical Care, Santa Marta, Colombia.*

Background: Recent advances in understanding the role of the alternative pathway of complement in membranoproliferative glomerulonephritis (MPGN) consist in evaluating the findings of the immunofluorescence (IF): MPGN immune-complex or complement-mediated. If none of these causes is present, then chronic thrombotic microangiopathy is the main cause of MPGN. However, reports on the clinical evolution of these patients are limited. The objective of this study was to evaluate the treatment response in patients with MPGN and negative IF.

Methods: Analytical and retrospective study. Patients with MPGN pattern through renal biopsy and negative IF were included. Each sample was studied by light microscopy and included Hematoxylin, PAS, and Jones and trichrome stain. The immunofluorescence was performed using direct antibodies against IgG, IgA, IgM, C1q, C3, albumin, fibrinogen, Lightweight Kappa and Lambda chains. Patients were evaluated according to response groups: complete response, partial response and no-response at 6 and 12 months of treatment with Immunosuppressants (MMF or CYC) and glucocorticoids (prednisone).

Results: We included 9 patients with mean age of 33.8 ± 13.1 years, of which 67% were male. 5 (62%) patients started with anemia and thrombocytopenia. The most frequent clinical presentation was asymptomatic urinary alterations (70%). The means values of baseline proteinuria (mg/24h) (1014 ± 1173) at 6 (942 ± 722) and 12 (958 ± 613) months did not show statistically significant differences ($p<0.05$). After 6 months of treatment, 4 (44%) patients achieved response (33% partial and 11% complete). 6 (66%) failed to achieve response at 12 months.

Conclusions: In our study, immunosuppressive therapy did not show statistically significant benefits in MPGN with negative IF at 6 and 12 months of treatment. Chronic thrombotic microangiopathy may be the cause of the MPGN and a formal trial with eculizumab well-characterized patients is warranted.



Response to immunosuppressive treatment of MPGN and negative IF

PUB366

Treatment of Fibrillary Glomerulonephritis with Bortezomib-Dexamethasone: A Case Report

Abdallah Sassine Geara,[2] Matthew Palmer,[1] Brendan M. Weiss,[1] Jonathan J. Hogan.[2] *[1]University of Pennsylvania, Philadelphia, PA; [2]Hospital of the University of Pennsylvania, Haddonfield, NJ.*

Introduction: Fibrillary glomerulonephritis (GN) is a poorly understood glomerular disease with no proven treatments and a poor renal prognosis. We present the case of a fibrillary GN successfully treated with bortezomib-based therapy.

Case Description: A 59-year-old Hispanic male had a past medical hypertension and microscopic hematuria for many years, for which he had undergone a renal ultrasound and cystoscopy which did not reveal an etiology. He developed acute kidney injury (SCr 2.3 mg/dL from baseline 1.1 mg/dL). A urinalysis showed moderate blood, 3+ protein, and microscopy showed RBC 50-100 dysmorphic/hpf. Urine protein:creatinine ratio (UPCR) was 1.6 g/g. Serologic testing for hepatitis B and C viruses, HIV, ANCA's, C3 and C4 were negative or normal. A kidney biopsy was diagnostic of fibrillary glomerulonephritis. He was treated with weekly subcutaneous bortezomib 1.3 mg/m2 oral dexamethasone 40 mg on days 1, 8 and 15 repeated every 28 days. The evaluation for monoclonal gammopathy with serum protein electrophoresis and serum free light chain was negative. After his second month of treatment, he developed steroid-induced hyperglycemia requiring insulin therapy. With 5 cycles of therapy, his serum creatinine improved to 1.5 mg/dL, UPCR ratio improved to 0.1 g/g, and microscopic hematuria improved to 2-5 RBC/hpf. At last follow-up, 8 months after stopping treatment, his SCr was 1.8 mg/dL, UPCR was 0.05 g/g, and urinalysis showed 20-50 RBC/hpf.

Discussion: We present a case of fibrillary glomerulonephritis successfully treated with bortezomib-dexamethsone. The effectiveness of bortezomib-based regimens in fibrillary glomerulonephritis requires further exploration.

laboratory trends

	Initial presentation	Treatment start	After 5 cycles	8 months after the end of therapy
sCr (mg/dL)	2.3	1.8	1.5	1.8
Alb (g/dL)	3.5	3.5	3.8	4.2
UPCR (g/g)	1.60	1.30	0.1	0.05
Urine RBC/hpf	50-100		2-5	20-50

Cytokine Profile and Renal Response in Lupus Nephritis Women

Camilla A. Lima,[1] Gisele Vajgel,[1,2] Suelen C. Lima,[3] Lucila Maria Valente,[2] Paula S. Sandrin-Garcia.[1] *[1]Biomol Lab, LIKA/UFPE, Recife, Brazil; [2]Nephrology, Hospital das Clinicas UFPE, Recife, Brazil; [3]UFPE, Recife, Brazil.*

Background: The importance of cytokine profile in LN is controversial in spite of their role in disease activity. This study measured six cytokines in LN outpatients and analyzed outcomes.

Methods: Serum cytokines (IL-2; IL-4, IL-6, IL-10, TNF-α, IL-17) from 59 LN and 40 healthy control women were measured by Cytometric Bead Array (CBA) using CBA Human Th1/Th2/Th17 Kit. Renal response and lupus activity were defined according to KDIGO guidelines and SLEDAI respectively. Statistical analyses were done using the GraphPad Prism 6.0.

Results: In LN group mean age was 35y (±10), 68% was non-white women with median LN diagnosis of 88 (62-156) mo and median SLEDAI was 7.7 (0-12) during serum collection. The healthy control group presented mean age of 60y (±5) and 65% non-white women. Their kidney biopsy showed proliferative lesions (class III or IV) in 85% of cases and they were using maintenance therapy in 86% of cases, mostly with Mycophenolate Mophetil (72.4%). Complete or partial response was present at 75.4%, non-response in 14% and decline of renal function in 10.5% of cases. Serum levels of all the cytokines analyzed were significantly increased in LN patients when compared to healthy controls ($p < 10^{-4}$). Similarly, all cytokines were higher in responsive (partial and complete) group than non-responsive group ($p < 10^{-5}$) and IL-17 showed higher values in the responsive group (42.37 ± 7.86 pg/mL). However, statistically significant differences were not found after 4 years of follow-up. Regarding to LN activity, IL-10 showed increased levels in active LN patients (SLEDAI ≥10) (5.07 ± 1.56 pg/mL) in comparison with inactive LN patients (SLEDAI <10) (4.67 ± 1.29 pg/mL) ($p = 0.037$). Additionally, IL-10 levels are correlated with higher values of proteinuria and TNF-α levels ($r = 0.02$ and $p = 0.02$; $r = 0.3$ and $p = 0.02$; respectively). Finally, higher TNF-α levels (4.76 ± 1.24 pg/mL) were correlated to LN class IV ($r = 0.41$; $p = 0.004$) when compared to class III (4.16 ± 0.23 pg/mL).

Conclusions: The anti-inflammatory IL-10 was increased in active lupus probably in effort to control disease activity. Class IV LN had higher TNF-α levels, which may be related an increased inflammatory process and tissue damage. Higher serum six citokines are found in responsives compared to non-responsives, however baseline levels are lacking and this did not predict long term outcomes.

PUB368

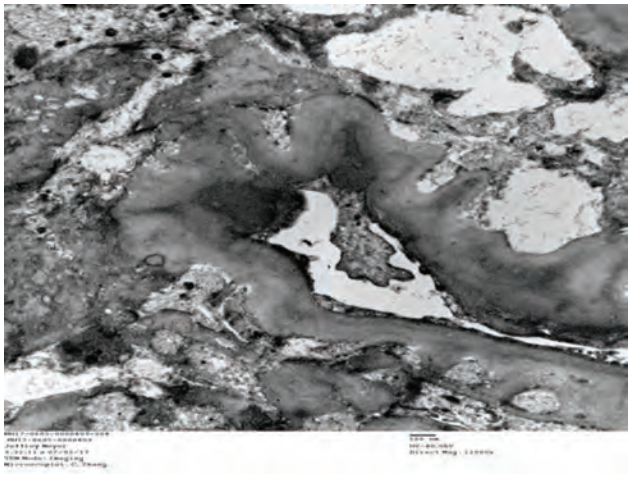
Subacute Bacterial Endocarditis (SBE) Presenting as ANCA-Associated Vasculitis (AAV)

Christopher G. Acker. *Richmond Nephrology Associates, Richmond, VA.*

Introduction: The history, and laboratory evaluation may suggest the diagnosis of an AAV, leading the clinician to treat empirically (without renal biopsy). Described is a case of Enterococcus faecalis endocarditis (EFE) masquerading as an AAV.

Case Description: A 73-year-old male presented with a history of hypertension, benign prostatic hypertrophy and new onset anemia. Five months earlier he had experienced onset of hematuria, undergone urologic evaluation showing cortical renal cysts and renal asymmetry. At the time of presentation, serum creatinine was 2.1 mg/dL. Additional labs showed a hematocrit of 23%, and urinalysis dipstick positive for blood. Hepatitis B and C serologies, HIV, ANA, anti-double-stranded DNA, anti-RNP/Sm, anti-SSA/SSB all negative. C3 was initially normal, low on repeat (76mg/dl); C4 was normal. The ANCA returned abnormal (PR3+, MPO-), and a renal biopsy was performed, notable for absence of crescents and necrosis, but positive for subepithelial, intramembranous, and subendothelial electron dense deposits. Blood cultures were positive for Enterococcus faecalis. Echocardiography showed an aortic vegetation, leading to the diagnosis of EFE SBE. He was initiated on antibiotic therapy. Due to continued complaints of back pain, an MRI was performed, revealing discitis/osteomyelitis.

Discussion: The appropriate history, biochemical findings, serologies, and positive PR3Ab must be interpreted with caution as the possibility of an underlying infection needs to be considered. Approximately four reported cases of EFE with PR3Ab positivity have been noted previously. While uncommon, SBE as a cause for PR3Ab positivity needs to be a consideration.



Rare subepithelial immune type electron dense deposits.

PUB369

Rituximab in Minimal Change Disease

Jason M. Kidd, Katie Bean. *VCU Medical Center, Richmond, VA.*

Background: Adults with minimal change disease are often steroid dependent. Rituximab (RTX) is increasingly being used in the treatment of minimal change disease (MCD) but data is lacking. Most studies have had small numbers of patients.

Methods: We retrospectively reviewed 7 consecutive patients with steroid dependent* MCD who received RTX from 2014-2018 at one academic medical center. Five patients (71%) were African American women. Ages range 23-62 (median: 30). RTX was administered 1000 mg IV spaced 2 weeks apart. Notably, 2 patients did not receive a 2nd dose as intended and subsequently relapsed. *defined as relapsing during glucocorticoid taper or within 2 weeks of discontinuation of glucocorticoids

Results: 4 patients achieved complete remission (defined as UP/C ≤0.3 g) and 3 patients had a partial remission (defined as UP/C between 0.3 g and 3.5 g and a 50% reduction of proteinuria) after treatment with RTX. Six patients were nephrotic at the time of treatment with RTX (defined as UP/C > 3.5, hypoalbuminemia and edema). Six patients were on steroids at time of treatment, 1 patient was on tacrolimus monotherapy. 3 patients had relapses of nephrotic syndrome, 2 received repeat doses of RTX, 2 only had one dose initially and 1 was lost to follow up. Follow up has ranged from 2-37 months (median: 24 months). Patient demographics are noted in table. Prior to receiving RTX, 2 patients required short term dialysis, 2 patients had venous thromboses, 4 were hospitalized for sepsis and 6 were admitted to the hospital with volume overload. Adverse events from Rituxan have been limited to 1 patient with alopecia. There were no infusion reactions.

Conclusions: Our small study shows RTX is effective in decreasing proteinuria in a largely African American cohort of patients. Randomized trials are needed but RTX should be considered as a treatment in steroid dependent minimal change disease.

Patient Demographics

Patient	Age at infusion	Sex	Race	Peak UP/C (g)	Most recent UP/C (g)	Current Prednisone dose (mg)	Months since last RTX
1	28	M	White	13	0	0	37
2	57	F	African American	13.1	0	2.5	36
3	23	F	African American	20.2	15*	unknown	27
4	30	F	African American	17.5	0	0	24
5	37	M	White	18.2	0.4	0	20
6	27	F	African American	6.9	0.1	20	2
7	62	F	African American	23.1	2	20	4

*Pt had partial remission (UP/C 0.5) after 1 dose of RTX, returned with disease flare and lost to follow up

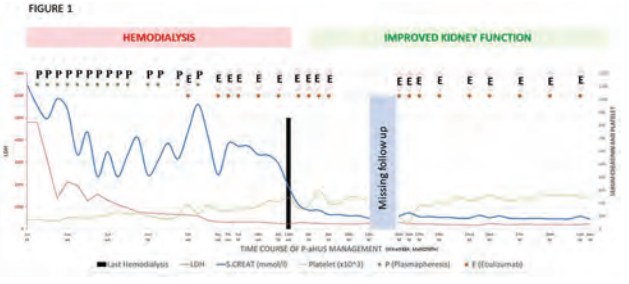
Individualized Eculizumab Every 3 Months Maintains Successful Remission In Pregnancy-Associated Hemolytic Uremic Syndrome with Hybrid CFHR1/CFH Gene: Case Report and Review of Literatures

Sami A. Alobaidi,[1,2] Ammar Aldabbagh,[1] Amany S. Alamoudi,[1] Murad Almowarey,[4] Ahmed Akl.[1,3] *[1]Department of Medicine, Dr. Soliman Fakeeh Hospital, Jeddah, Saudi Arabia; [2]Department of Medicine, University of Jeddah, Jeddah, Saudi Arabia; [3]Urology & Nephrology Center, Mansoura, Egypt; [4]King Fahad Hospital, Medina, Saudi Arabia.*

Introduction: Pregnancy-associated atypical hemolytic uremic syndrome (P-aHUS) is a rare condition and affects 1 of every 25,000 pregnancies. P-aHUS is characterized by very high maternal mortality as well as severe morbidity. More than half of all patients eventually develop end-stage renal disease in less than 1 month if untreated. Most cases of P-aHUS (79%) manifest in the postpartum period; this is probably due to the complement's involvement in aHUS pathogenesis. Eculizumab, a terminal complement inhibitor, is approved for aHUS treatment. However, its use is limited due to cost, unknown duration of treatment, and vague dose intervals to keep patients in remission.

Case Description: In this case report, we present a 26–year-old female with P-aHUS with hybrid CFHR1/CFH gene. Eculizumab was initiated after 5 weeks of being on hemodialysis and plasmapheresis sessions. Full remission successfully achieved after 6th dose of Eculizumab, within 13 weeks of onset of aHUS. She was in full remission with Eculizumab, however, due to financial issues Eculizumab was set in hold due to inability to financially cover the cost. Within 6 months, she suffered recurrence of the disease and Eculizumab was re-instated. After re-inducing full remission, the patient was switched to Eculizumab every 3 months instead of the recommended manufacture dose interval of every 2 weeks. We followed this patient for 3 years and she continued to be in remission based on clinical and laboratory data.

Discussion: In conclusion, achievement of successful and maintenance of remission of P-aHUS in this patient who had limited access to Eculizumab raise the attention of the efficacy of Eculizumab at longer time intervals. However, it is time to consider conducting a long-term study to learn about the safety and efficacy of this approach, which may have a major financial advantage for patients.



PUB371

Campylobacter Rectus and Cnm-Positive Streptococcus mutans Strains in the Oral Cavity Exacerbate Urinary Protein Levels in IgAN Patients

Taro Misaki,[1] Shuhei Naka,[6] Kaoruko Wato,[2] Yasuyuki Nagasawa,[3] Seigo Ito,[5] Ryota Nomura,[2] Michiyo Matsumoto-Nakano,[4] Kazuhiko Nakano.[2] *[1]Seirei Hamamatsu General Hospital, Hamamatsu, Shizuoka, Japan; [2]Osaka University Graduate School of Dentistry, Suita, Osaka, Japan; [3]Hyogo College of Medicine, Nishinomiya, Japan; [4]Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan; [5]National defense medical college, Tokorozawa, Japan; [6]Okayama University Hospital, Okayama, Japan.*

Background: Some strains of *Streptococcus mutans*, a major pathogen of dental caries, harbour the *cnm* gene which encodes a collagen-binding protein (Cnm) that has been demonstrated to be associated with urinary protein levels in IgAN patients. Periodontitis-related pathogens, such as *Campylobacter* or *Treponema* species, have recently been shown to be associated with IgAN. The purpose of the present study was to analyse the association of IgAN with *Campylobacter rectus*, *Treponema denticola* and *cnm*-positive *S. mutans* in the oral cavity of humans.

Methods: The presence of *C. rectus*, *T. denticola* and *cnm*-positive *S. mutans* strains in saliva samples of 117 IgAN patients and 56 health controls was evaluated by PCR, and the subjects' clinical parameters were analysed.

Results: *C. rectus* and *cnm*-positive *S. mutans* were significantly more prevalent in the IgAN group than in the control group ($p < 0.05$). Additionally, the *C. rectus*-positive and *cnm*-positive *S. mutans* group was shown to be more closely associated with urinary protein levels than the other groups in IgAN patients.

Conclusions: Our results suggest that harbouring *C. rectus* and/or *cnm*-positive *S. mutans* strains in the oral cavity could be associated with urinary protein levels in the IgAN patients.

PUB372

Acquired Angioedema: A Unique Complication in a Patient with Lupus Nephritis

Rohan V. Mehta,[1,2] Jason Cobb,[4] Rahul Mehta.[3] *[1]Open Door Health Centers, Eureka, CA; [2]Nephrology, Emory University, Atlanta, GA; [3]University of Virginia, Charlottesville, VA; [4]Emory University School of Medicine, Atlanta, GA.*

Introduction: Acquired angioedema (AAE) is a rare syndrome of recurrent episodes of angioedema without urticaria, which has been associated with B cell lymphoproliferative disorders and rarely with autoimmune diseases. In lupus, AAE may arise from an antibody mediated functional deficiency of C1 esterase inhibitor (C1INH) - a key inhibitor within four interlinked inflammatory cascades.

Case Description: A 28-year-old black woman with quiescent Lupus Nephritis class III & V presented with recurrent edema of the face, arms and abdomen. She had no family history of angioedema and denied allergies. Physical examination revealed bilateral proptosis, edema of the face, arms and abdomen. Respiratory and cardiovascular examinations were unremarkable. CT scan of the head and neck showed periorbital and neck soft tissue swelling with bilateral proptosis. Laboratory data revealed a serum creatinine of 1.7 mg/dl (baseline), leukocyte count of 12,000/microliter and hemoglobin of 10 g/dl. Hypocomplementemia was evident (C3 21 mg/dl and C4 11 mg/dL); anti-DsDNA antibody was 140 IU/ml and urine protein/creatinine ratio was 1700 mg/gm. No clinical improvement was noted after three days of high dose intravenous steroids. Further investigations revealed a C1INH protein level of 23 mg/dL (15-35 mg/dL), functional level of 15 percent (normal > 67 percent), very low C1q level (15 percent) and presence of antibodies to C1INH.Rituximab 1 gram produced an expedient clinical recovery.

Discussion: Angioedema is a life-threatening condition involving the mucosa of the gastrointestinal and respiratory tract. Acquired angioedema differs from hereditary angioedema by absence of family history and late onset of disease. Majority of patients with AAE have been found to have an underlying disorder and about thirty percent test positive for associated antibodies. In lupus patients with angioedema, antibodies to C1INH have been identified. These antibodies lead to an acquired consumption of C1INH resulting in a low or normal C1INH protein level, a low functional percentage of C1INH, low C4 and C1q. Rituximab (a chimeric monoclonal antibody directed at B cells), has been tried in some cases of antibody mediated AAE with a favorable rapid response, when conventional therapies have failed. In summary, we present a case of steroid resistant AAE probably due to Lupus induced antibodies to C1INH and suggest one possible treatment option in Rituximab.

PUB373

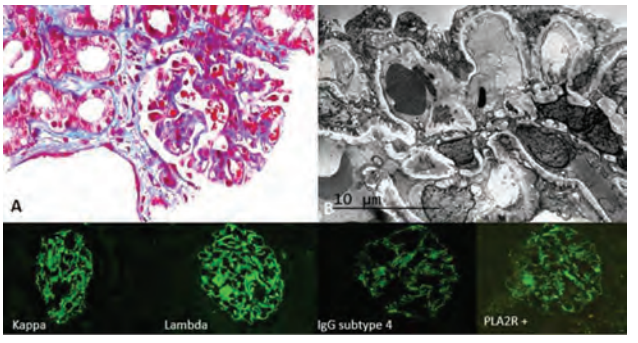
An Uncommon Case of Seronegative Primary Membranous Nephropathy in a Young Hispanic Patient

Don H. Esprit,[2] Abhilash Koratala.[1] *[1]University of Florida, Gainesville, FL; [2]Northern Florida Kidney Care by NPS, Gainesville, FL.*

Introduction: Membranous nephropathy (MN) is the most common cause of idiopathic nephrotic syndrome in non-diabetic white adults. The mean age of incidence of Primary MN is between 50 and 60 and is most common in whites followed by Asians, Blacks, and Hispanics. Most cases of PMN have circulating IgG4 autoantibody to the podocyte membrane antigen PLA2R (70%). A minority of the patients have thrombospondin type 1 domain containing 7A (THSD7A) antibodies. It is noteworthy that about 15% cases have biopsy evidence of PLA2R staining indicating recent immunologic disease activity despite negative serum antibody levels. Herein, we present a case of young Hispanic male with biopsy-proven primary MN with positive PLA2R staining but negative circulating antibodies.

Case Description: A 34-year-old Hispanic man with no significant medical history presented with worsening extreme generalized edema. Laboratory data was consistent with nephrotic syndrome with a urine protein-creatinine ratio of 11 g/g, LDL cholesterol 279 mg/dL and serum albumin of 1.1 g/dL. Further work up for HIV, viral Hepatitis, syphilis and common vasculitides was negative. Testing for PLA2R and THSD7A antibodies was negative as well. A renal biopsy was obtained, which demonstrated thickened capillary loops with subepithelial electron dense deposits and diffuse podocyte foot process effacement. Immunofluorescence was strongly positive for PLA2R, suggestive of primary MN [Figure]. He was started on RAAS blockade, statin and diuretic therapy with symptomatic improvement. He was instructed to follow up with Nephrology in a few months to determine the necessity for immunosuppressive therapy.

Discussion: Take home point: Primary MN is typically a disease of middle-aged White men but should be included in the differential diagnosis of nephrotic syndrome in patients of any age and race. Moreover, while serological anti-PLA2R testing has diagnostic value, it must be interpreted in context with patients' clinical characteristics and histological PLA2R staining in seronegative patients is recommended.



PUB374

Clinical Significance on the Difference in Character of Glomerular Tip Lesion in Adult Nephrotic Focal Segmental Glomerulosclerosis (FSGS): A Retrospective Cohort Study

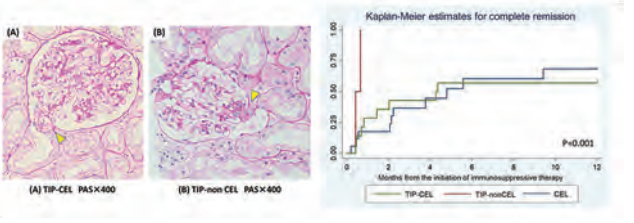
Takaya Ozeki,[1] Michio Nagata,[2] Takayuki Katsuno,[1,3] Sawako Kato,[1] Yoshinari Yasuda,[1] Naotake Tsuboi,[1,4] Shoichi Maruyama.[1] *[1]Nagoya University Graduate School of Medicine, Nagoya, Japan; [2]Kidney and Vascular Pathology, University of Tsukuba, Tsukuba, Japan; [3]Department of Nephrology and Rheumatology, Aichi Medical University, Nagakute, Japan; [4]Department of Nephrology, Fujita Medical University, Toyoake, Japan.*

Background: In Columbia classification, locating FSGS lesion in tip domain is prioritized than its pathological character. Hence, patient with glomerular tip lesion (GTL) are usually categorized into tip variant (TIP), not cellular variant (CEL) even if the lesion is cellular type. This diagnostic process on GTL has not been discussed well. We investigated the clinical importance of the GTL among adult nephrotic FSGS patients with TIP.

Methods: A retrospective cohort study; Among 183 biopsy-proven FSGS during 2005-2015, 48 patients who fulfilled the criteria below were included to analyses: ≥20 years old, nephrotic syndrome (serum albumin ≤3.0 and UPCR ≥3.5), received immunosuppressive therapy and whose pathological slides or paraffin blocks were available for review. All pathological slides were reviewed on light microscopy by 3 nephrologists and 1 renal pathologist. Among TIP cases, patients were divided into 2 subgroups based on the dominant character of GTL: cellular type (TIP-CEL) and non-cellular type (TIP-nonCEL). The clinical manifestation and treatment course were compared among the subgroups.

Results: Among 48 patients, 16 were TIP (33.3%) and 17 were CEL (35.4%). Among 16 TIP, 14 cases were categorized into TIP-CEL and 2 cases into TIP-nonCEL. There was no difference in the details of immunosuppressive treatment among the subgroups. Even though TIP-nonCEL, comparing with TIP-CEL or CEL, manifested higher creatinine (1.63 vs 0.99 vs 1.50 mg/dL) and larger urinary protein level (11.31 vs 5.33 vs 7.40 g/gCr), TIP-nonCEL showed excellent therapeutic reactivity which was comparable to that of MCD to attain complete remission. On the other hand, TIP-CEL showed similar treatment response to CEL.

Conclusions: The diagnostic hierarchy of Columbia classification on FSGS may be confusing because it contains both aspects of location and characteristics of FSGS lesions. In adult nephrotic FSGS, therapeutic reactivity of TIP might be depended on their pathological character; presence or absence of cellular lesion.



PUB375

Clinicopathological Features in Lupus and Nonlupus Membranous Nephropathy

Laura Onuchic, Pamela B. Larrea, Ligia C. Battaini, Cristiane B. Dias, Luis Yu, Viktoria Woronik, Lectícia Jorge. *University of Sao Paulo, Brazil, São Paulo, Brazil.*

Background: Membranous nephropathy (MN) is well established as one of the morphologic presentations of systemic lupus erythematosus and idiopathic nephrotic syndromes. The aim of this study was to compare clinical, biochemical and histological characteristics of patients diagnosed with nonlupus MN to class V lupus nephritis (CVLN).

Methods: All MN and CVLN cases diagnosed by kidney biopsy in our center between 2009 and 2016 were retrospectively analyzed. Clinical and laboratorial data were collected at baseline and at the end of follow up.

Results: The prevalence of male gender and older age was significantly higher in the MN group (65.2% *vs* 13.0%, p<0.001 and 48.4±14.7 *vs* 37.0±11.0 years, p<0.001, respectively). The MN group presented higher baseline serum creatinine (Cr, mg/dL) {1.08

(0.79;1,88) *vs* 0.74 (0.58;1.32), p<0.05}, higher proteinuria (g/day) {7.2 (5.1;10.2) *vs* 2.7 (1.1:3.9), p<0.01} and lower serum albumin (mg/dL) (2.1±0.77 *vs* 2.8±0.93, p<0.001) when compared to the LN group. After a mean follow-up of 3.0 years (1.1; 6.9) in the MN group and 2.9 years (1.0; 5.3) in LN, we observed that both groups presented reduction in proteinuria, however the levels were still higher in the MN group {1.7 (0.3;3.8) *vs* 0.5 (0.1;1.2) p<0.001}. Following the same trend, the MN group maintained higher Cr levels {1.36 (0.90; 2.55) *vs* 0.75 (0.50; 1.00)}. Among the optical microscopy findings, the only significant difference was a higher frequency of mesangial hypercellularity in the CVLN than MN group (58.7% *vs* 37.0% of glomeruli; p=0.015). Immunofluorescence (IF) findings are reported in *Figure 1*.

Conclusions: While optical microscopy was scarcely efficient in differentiating MN from CVLN, IF findings were significantly different between the two groups, particularly those related to mensangial deposits. We also underscore the difference in renal function behavior: stable in CVLN while dropping in MN during the follow-up time.

Clinicopathological Characteristics of FSGS and Their Correlation with Histologic Variants in Selected Population

Nitin K. Bajpai,[1] Amit Gupta,[2] Manas R. Patel.[3] *[1]Department of Nephrology, All India Institute of Medical Sciences (AIIMS) Jodhpur, Jodhpur, India; [2]Department of Nephrology, SGPGIMS, Lucknow, India; [3]Department of Nephrology, SGPGIMS, Lucknow, India.*

Background: FSGS is a histological diagnosis in which there is nephrotic renage proteinuria and that leads to hypertension and renal failure. Five histological variants of FSGS. Not otherwise specified (NOS), perihilar variant, cellular variant, tip variant and collapsing variant.

Methods: Study Design: We have included 110 patient of biopsy proven FSGS diagnosed between January 2010 to December 2012 retrospectively and collected the clinical data and histopathology report of Primary FSGS from institute's hospital information system. who fulfilled inclusion criteria. **Kidney biopsy methods**: Histopathology reports were classified according to Columbia classification guidelines. **Clinical data and definitions:** Standard clinical definition used for data. All patients received oral prednisolone at a dose of 60 mg/m^2 for at least 16 weeks **Statistical Analysis**: Data were analyzed with SPSS version 18.

Results: A total 110 biopsy proven FSGS patient biopsy were recruited retrospectively from January -2010 to December 2012 and clinical finding were noted from our electronic hospital information system. Higher degree of Hypertension and renal failure was seen in perihilar variant and 24 hour proteinuria was maximum in cellular variant. Table 1 Interstitial fibrosis, tubular atrophy and fibrointimal thickening were maximum in perihilar variant. Whereas glomeruloscelerosis was seen in 100% cases of Cellular variant. Table-2. Remission rate after one year is higher in TIP variant as compared other variants. Table 3

Conclusions: In the studied population we found that majority of patient had NOS variant. Cellular variant has highest grade of proteinuria whereas perihilar variants greater degree of renal failure at presentation. One third have complete remission whereas one fourth have partial remission.

PUB377

Significantly Different Patterns of Serum Oxidative Stress Levels in Children with Nephrotic Syndrome and Children with IgA Nephropathy

Takuji Enya,[1] Kohei Miyazaki,[1] Tomoki Miyazawa,[1] Mitsuru Okada,[1] Tsukasa Takemura,[2] Keisuke Sugimoto.[1] *[1]Kindai University Faculty of Medicine, Osaka, Japan; [2]Kushimoto Municipality Hospital, Wakayama, Japan.*

Background: Oxidative stress (OS) has been reported to play an important role in several renal diseases, including nephrotic syndrome (NS) and IgA nephropathy (IgAN). However, no comparison study has been reported. This study was conducted to investigate the OS activity in both patient groups.

Methods: Children with NS (n = 5) and those with IgAN (n = 7) at first onset were enrolled. The plasma levels of biological antioxidant potential (BAP) and reactive oxygen metabolite-derived compounds (dROM) were measured. The dROM and BAP levels were <300 U.CARR and 2000 mmol/l higher than normal, respectively. A normal BAP/dROM level was defined as ≥10. The patient groups were compared, and the relationships of BAP and dROM levels to albumin, creatinine, uric acid, urinary protein, total cholesterol, triglyceride, and C-reactive protein levels were studied.

Results: Serum BAP levels were significantly lower in the NS group (1529 ± 259) than in the IgAN group (P < 0.001). The IgAN group had significantly higher dROM levels (394 ± 107) than the NS group (n = 0.003). BAP/dROM level was low, without significant differences, in both groups. A positive correlation was observed between the low CRP and dROM levels in the IgAN group (P = 0.02).

Conclusions: In our study, evaluation was limited to the first episode of the diseases. Even though their potential antioxidant capacities were comparable, the factors involved in the abnormality of the oxidative stress balance differed significantly between the two patient groups. As dROM increases in vasculitis, endothelial cell injury might be involved in the high dROM level in IgAN. A previous study reported a positive relationship between albumin concentration in human preparation and BAP level. Hypoalbuminemia and lipid abnormalities are considered to be involved in the reduction of BAP level, and the same tendency was observed in this study. OS activity significantly differed between the NS and IgAN groups. This helps to clarify the pathophysiological features of NS and IgAN, and support additional treatment for both diseases.

PUB378

Hemolysis-Derived Heme: A Contributing Factor in Thrombotic Microangiopathy

Kioa L. Wijnsma,[1] Susan Veissi,[4] Elena Volokhina,[2] Nicole Van De Kar.[3] *[1]Pediatric Nephrology, Radboudumc, Radboud Institute for Molecular Life Sciences, Amalia Children's Hospital, Nijmegen, Netherlands; [2]Radboud university medical center, Nijmegen, Netherlands; [3]UMC St. Radboud Nymegen, Nijmegen, Netherlands; [4]Radboud medical center, Nijmegen, Netherlands.*

Background: Although Shiga toxin (Stx)-producing *E. coli* hemolytic uremic syndrome (STEC-HUS) is one of the most common causes of acute kidney injury in children, the exact pathogenesis is still only partially understood. Due to endothelial injury caused by the Stx, the cascade leading to thrombotic microangiopathy (TMA) commences. Yet, there is wide variability in clinical presentation and outcome ranging from no chronic sequalae to severe neurological impairment and end stage renal disease. One possible explanation for this broad range of clinical outcome could be the enhancement of TMA through other additional factors. We hypothesized that extracellular accumulation of heme, as present during extensive hemolysis, could amplify TMA.

Methods: In this study, we measured levels of extracellular heme and its scavengers (hemopexin and heme-oxygenase 1; HO-1) in a cohort of 48 STEC-HUS patients and assessed the effects of these disease specific heme concentration, in combination with Stx, on glomerular microvascular endothelial cells (GMVECs).

Results: Significantly elevated heme levels up till 21.2 μM were found in STEC-HUS patients compared to controls (median of 0.9 μM). These elevated heme levels correlated nicely with plasma hemopexin levels (R^2 -0.737). Furthermore, heme is internalized in GMVECs and subsequently led to a significant increase in reactive oxygen species (ROS). Translocation of NFκB and tissue factor indicated enhancement of pro-inflammatory and thrombotic state. Interestingly, GMVECs showed a clear decrease of HO-1 after co-stimulation with Stx2.

Conclusions: We are the first to show elevated heme levels in patients with STEC-HUS. Moreover, these heme levels contribute and even amplify the cascade leading to TMA. This effect is even more pronounced in STEC-HUS since Stx inhibits the upregulation of HO-1.

PUB379

A Case of Nephrotic Syndrome Secondary to Mercury Poisoning Due to Chronic Usage of Ayurvedic Medications

Abhijit K. Korane.[2,1] *[1]Sunrise hospital, Kolhapur, India; [2]Medicine, Dr.D.Y.Patil Medical College., Kolhapur, India.*

Introduction: Acute and chronic mercury exposure represents a potential threat to community health. Mercury poisoning can occur as a result of occupational hazard or herbal medicine. All compounds of mercury are toxic but differ in the routes of absorption, clinical findings, and responses to therapy. The clinical effects of mercury poisoning depend on the form and the route of entry to the organism. Neurologic, gastrointestinal and renal systems are predominantly affected depending on the route of exposure. Traditional Ayurvedic medicines originated in India 2000 years ago. Approximately one billion people use ayurvedic medicines. These medicines contain minerals & heavy metals like lead, Mercury, Selenium, Copper which are known to cause renal failure.

Case Description: 25 year old un-married female engineer came with the chief complaint of peri-orbital swelling and swelling of both feet since two months. On further enquiry patient gives history that since last six months, she had taken ayurvedic medicine for her irregular menses. On examination her vitals were stable except her B.P which was170/110. Her lab reports were Total Protein -2.4 mg/dl, Serum Albumin- 1.5mg/dl, Serum Cholesterol- 281.4mg/dl, Urine protein- ++++, Urine spot protein314, Urine spot creatinine - 93.7. Urine protein creatinine ratio was 3.0. On these basis patient was diagnosed to have Nephrotic Syndrome. As patient is young female considering SLE her Serum ANA & Serum DSDNA was done and her reports came negative. Simultaneously her renal biopsy had done shows membranous glomeruloathy. To rule out primary idiopathic membranous glomerulonephritis, her Anti-Phospholipase A2 receptor IgG(PLA2R) sent which was < 0.6 (> 20 positive) which is negative. Now considering her past history, her serum heavy metal levels were sent and its reports were following Sr. Mercury-16.6μg/L. She was initiated on mercury chelating agent, BAL following which her mercury levels dropped down to 2μg/L. Her proteinuria dropped to normal range over next six months without other therapy.

Discussion: This case report emphasizes the importance of public education on poisoning and specifically, potential hazards of mercury for preventive community health. High risk of suspicion in patients with secondary nephrotic syndrome needs to be kept with history of consumption of Ayurvedic medicines.

PUB380

The Clinical Significance of C-Reactive Protein (CRP) and Erythrocyte Sedimentation Rate (ESR) in Patients with Systemic Lupus Erythematosus (SLE)

Danna Ma,[2] Yali Zheng.[1] *[1]Ningxia People's Hospital, Yinchuan, China; [2]Ning Xia Peolple Hospital, Yinchuan, China.*

Background: To discuss the clinical significance of CRP and ESR in SLE patients by a retrospective analysis.

Methods: 80 SLE cases were divided into 3 Groups,by differences in disease activity, whether complicated by infection and by different organs damaged. To analyse the level of CRP, ESR in different groups.

Results: 1) General data: There was an increased CRP in 36 cases (45%), and an increased ESR in 52 cases(65%). SLE injury multiple systems, the most frequently injuryed organ was the kidney (52 cases, 65%). 2) The CRP level was significantly increased in cases complicated by infection($p<0.05$). The increased level of CRP was significantly correlated with serosa damage($p < 0.05$). There was no correlation with systemic damage such as hematological system, kidney, skin and mucous membrane, joint, nervous system damage ($p > 0.05$). 3) The level of ESR was significantly increased in the patients with organs damage including hematological system, kidney, and serosa damage ($p < 0.05$), but not in the patients with mucous membrane and the skin, joint, nervous system damage ($p > 0.05$).

Conclusions: The level of CRP probably has no relation with SLE disease activity, the level of increased ESR may be associated with SLE disease activity. The level of CRP is associated with SLE with infectious disease. In terms of organ damage, the level of CRP was associated with serosa damage, the level of ESR was associated with blood system, kidney, serosa damage.

PUB381

Complex Regional Pain Syndrome (CRPS) Is Common in Loin Pain Hematuria Syndrome (LPHS)

Gregory L. Braden,[2,1] Abhinav K. Tiwary,[1] Daniel L. Landry.[2,1] Kidney Care and Transplant Services of New England *[1]Medicine, University of Massachusetts Medical School/Baystate, Springfield, MA; [2]Kidney Care and Transplant Associates of New England, Springfield, MA.*

Background: LPHS causes severe flank and lower abdominal pain with micro or macro hematuria. We now describe 8/32 patients(pts) with biopsy proven LPHS who often have CRPS associated with attacks of LPHS.

Methods: All medical records of our 32 renal biopsy proven LPHS patients (Pt) were reviewed for episodes of CRPS associated with this syndrome.

Results: Renal bx showed thin glomerular basement membranes in 3 Pts, thick glomerular basement membranes in 4 Pts and normal basement membranes in 1. CRPS occured as ipsilateral (IL) arm, leg, flank or abdominal pain with warm (red) or cool (blue) skin hypersentitive to touch with livedo reticularis & skin swelling on the same side as the loin pain attack. Pt 1: IL arm, back, flank & leg CRPS recurrent many times then finally cured by cervical & splancnic blocks and laparascopic sympathectomy and laparascopic renal denervation. Pt 2: IL arm, back, & flank CRPS before and after renal autotranplant. Abd CRPS occurred at tranpant site and resolved after transplant nephrectomy. Pt 3: Recurrent IL flank CPRS after laparascopic renal neurectomy improved by splanchnic block and duloxetine. Pt 4: Recurrent IL flank CRPS improved with splanchnic blocks. Pt 5: After bilateral renal autotransplant IL back & flank CRPS resolved with splanchnic blocks, gabapentin and pregabalin. Pt 6: IL flank CPRS resolved on its own. Pt 7 After left renal autotransplant, IL CRPS over the autotransplant still recurring. Pt 8: Recurrent L>R flank CRPS treated with an intrathecal pain pump with major improvement.

Conclusions: CRPS occurs in up to 25 % of Pts with LPHS & must be recognized & treated with anti-neuropathic procedures and neuropathy medications rather than opioids. CRPS can occur before and after renal autotransplantation and laparacopic renal neurectomy and may be the cause for failure of these procedures to eliminate pain in LPHS. CRPS in LPHS is self limiting and gradually improves with proper therapy

PUB382

Trends in Glomerular Disease Epidemiology Among Adults in Saudi Arabia, 1997-2017

Abdulkareem Alsuwaida,[1] Lamees I. Al-mezaini,[2] Noura Ahmed,[1] Amaar A. Bakhit,[4] Junaid Wadera,[5] Feras A. Alsuwaida,[6] Mohamed C. Kechrid,[9] Abdulrahman K. Alabdulsalam,[7] Noura Aloudah,[3] Majed M. Alanazi,[10] Talal A. Alfaadhel,[1] Hanadi M. Alhozali,[3] Ghadeer A. Mokhtar.[8] *[1]King Saud University, Riyadh, Saudi Arabia; [2]King Saud University, Riyadh, Saudi Arabia; [3]king abulaziz medical city, Riyadh, Saudi Arabia; [4]King Saud University Medical City, Riyadh, Saudi Arabia; [5]King Khalid University Hospital, Riyadh, Saudi Arabia; [6]King Saud University, Riyadh, Saudi Arabia; [7]National Guard King Abdulaziz Medical City, Riyadh, Saudi Arabia; [8]King Abdulaziz University, Jeddah, Saudi Arabia; [9]Security Forces Hospital, Riyadh, Saudi Arabia; [10]King Abdul Aziz Medical City, Riyadh, Saudi Arabia.*

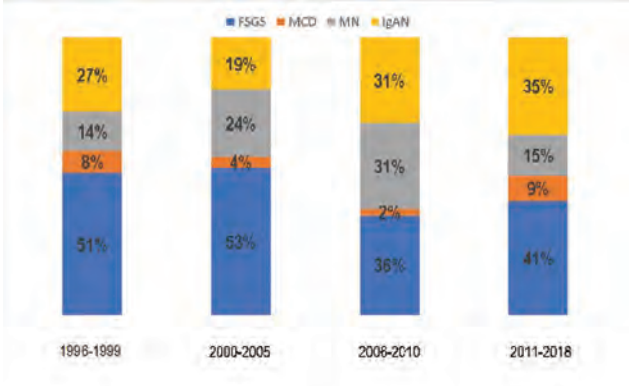
Background: We aimed to examine temporal and demographic trends in renal biopsy glomerular disease diagnosis frequencies in Saudi Arabia over the last two decades.

Methods: In this retrospective, observational study, we identified all patients with a native kidney biopsy between 1996 and 2017. Biopsy era (before 2000, 2001-2005,2006-2010 and 2011-2018) and demographics and the relationship with the prevalence of various glomerular disease were our primaries.

Results: The study included 1481 Saudi patients had a kidney biopsy with 316 patients less than 18 years and 52% were female. The commonest secondary cause of was systemic lupus erythematosus. Focal segmental glomerulosclerosis in renal biopsy specimens continues to be the commonest pathology with preserved frequencies over the three decades (51%, 53%, 36% and 40.0% of diagnoses, respectively; P for trend 0.6). The frequency of IgA nephropathy initially stable but then increased significantly in the last decades. However, the incidence of MPGN declined significantly (27.3%, 11.1%, 9.4% and 3.6%, respectively for trend 0.001). The frequencies of other primary glomerular disease subtypes remained stable (Figure 1).

Conclusions: We have observed a significant change in relative renal biopsy frequencies of many glomerular disease subtypes over the last two decades. There is a significant increase in the prevalence of IgA nephropathy while MPGN continues to decrease. Infection-related forms of GN is declining significantly, in contrast to antigenic related GN

is becoming a predominant disease. This may support the need to investigate more the potential environmental exposures to diet and allergens and it is a role in glomerular disease.



Renal biopsy diagnosis frequencies of the most common primary glomerulonephritis subtypes for biopsy era.

PUB383

A Quartet of ANCA Associated Glomerulonephritis and Vasculitis Cases with Initial Presentation of Gastrointestinal (GI) Symptoms, Which Often Are Missed

Mansoor N. Ali. *Renal Medicine, Calderdale and Hiddersfield Hospitals NHS Trust, Leeds, United Kingdom.*

Introduction: Antineutrophil cytoplasmic antibodies (ANCA) associated vasculitis, is one of most common causes of new onset glomerulonephritis in adults. The condition is an auto-immune disease characterised by an inflammatory response within the mural vessels of multiple organs leading to extensive inflammation, damage and necrosis. The response produces ANCA autoantibodies against myeloperoxidase (MPO-ANCA) or proteinase-3 (PR3-ANCA). I describe below case report series for patients presenting with GI symptoms leading to delay in diagnosis and management.

Case Description: 1) A 42yrs old patient of Chinese origin, presented through emergency department with >3 weeks of diarrheal illness and acute kidney injury (AKI). 2) A 68 yrs old Caucasian patient admitted to gastroenterology ward with abdominal pain and per rectal (PR) bleeding. AKI noted, fluids given and discharged as gastroenteritis. 3) A 69 yrs old patient of Bangladeshi origin had 3 months history of recurrent admissions to medical admissions unit with history of abdominal pain, diarrhea and weight loss. 4) A 70 yrs old Caucasian elderly patient with preceding symptoms of malaise, weight-loss, presented with (PR) bleeding to the general surgeons with AKI. Initial presentation and symptoms prompted acute medical and surgical teams to focus entirely on the causes of diarrhea, pre-renal causes of AKI and further investigations mainly stool C+S, flexible sigmoidoscopy and colonoscopy. Due to persistent renal impairment on recurrent admissions, nephrology consult was sought where multisystem involvement of ANCA associated vasculitis was diagnosed with immunology and histology. In one case, renal impairment progressed to ESRF, 3/4 have residual CKD.

Discussion: The diagnosis of ANCA associated vasculitides is complicated by marked difference in symptoms, signs, disease activity, chronicity and severity of the disease. Nonspecific symptoms of general fatigue, malaise, weight loss, upper airway and pulmonary symptoms, and renal impairment are neither sensitive nor specific. However diarrheal illness are although not uncommon and documented in MPO vasculitis; may completely distract health professionals, and instead lead them to focus on gastrointestinal causes of diarrhea especially inflammatory bowel disease or cancerous lesions resulting in delay in diagnosis and treating vasculitis.

PUB384

Clinico-Pathological Study of C3 Glomerulonephritis at a Tertiary Care Centre

Umesh L. *institute of nephrourology, Bangalore, India.*

Background: Aim - To study the clinico-pathological profile of patients with C3 glomerulonephritis at a tertiary care centre.

Methods: A prospective observational study of all cases of C3 glomerulonephritis was done between August 2016 and December 2017. C3 glomerulopathy was defined by predominant glomerular C3 fragment deposition defined as C3c intensity 2 orders of magnitude more than any other immune reactant on a scale of 0 to 3.

Results: C3 glomerulonephritis was present in 2.68%of all biopsies int he study period. The mean age was 35±2 years of which there was slight male preponderance. Nearly all patients had hypertension (93.7%) while 21.8% had pre existing diabetes. More than two third of patients presented with RPGN (72%). All patients had active urinary sediments. More than half of the patients (56.25%) had low serum C3 levels in our study. All patients had normal serum C4 levels. Anti CFH antibody titres were measured in 6 patients of with it was elevated in 2 patients (33.3%). On LM the dominant lesion was crescentic GN (43.75%). On IF, all patients had dominant C3 staining. Also 3 (9.37%) patients had IgG staining of 1+ intensity. EM study was done in two patients and was suggestive of DDD in one patient (3.15%). All patients were managed with pulse steroids followed by oral steroids. IV Cyclophosphamide was used monthly for 6 doses in 14 patients (43.7%) while oral cyclophosphamide was used in 2 patients (6.25%). Plasmapharesis was done in patients with elevated anti CHF antibody and in patients with diffuse crescents (11 patients -34.37%). Also 11 patients required haemodialysis (34.37%). Among the 11 patients who were dialysis dependent, 4 have recovered completely and are in complete remission with normal renal function. Of these two had elevated anti CFH antibody titers while the other two had diffuse crescents.

Conclusions: C3 glomerulonephritis has emerged as a new entity in the recent past with significant percentage of our patients presenting with RPGN with hypertension. On light microscopy, the most common presentation was crescentic glomerulonephritis, One third of our patients had advanced renal failure requiring haemodialysis. Plasmapharesis was done in one third of patients. Patients with anti CFH antibody were successfully treated with IV cyclophosmamide and plasmapharesis

PUB385

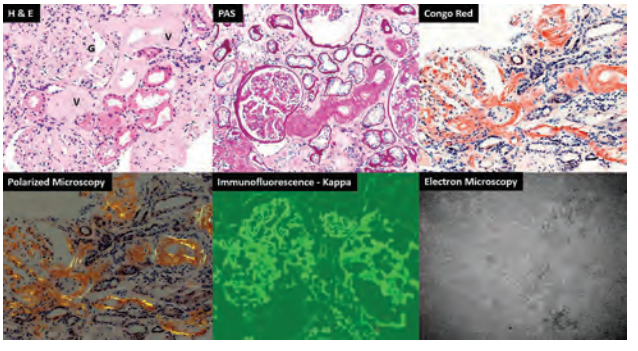
Non-Diabetic Renal Disease in Diabetics: Suspicion Is the Key

Abhilash Koratala, Gajapathiraju Chamarthi, William L. Clapp. *University of Flroida, Gainesville, FL.*

Introduction: Renal biopsy should be considered in diabetic patients who have persistent microscopic hematuria, absence of diabetic retinopathy, immunological abnormalities and/or uncharacteristic course of serum creatinine to exclude non-diabetic renal disease.

Case Description: A 63-year-old White man with a history of diabetes mellitus type 2 diagnosed ~30 years ago associated with non-proliferative diabetic retinopathy, hypertension, CKD stage 3 and CHF was seen in Nephrology clinic for evaluation of worsening kidney function. His diabetes was well-controlled with a hemoglobin A1c of 6.3% and BP in the clinic was 124/75mmHg. Labs showed serum creatinine of 5.1 mg/dL `(~2.7 two months prior and 1.4 a year ago) with an eGFR of 11ml/min and a urine protein-creatinine ratio of 3g/g (no baseline available). Urinalysis was unremarkable except for 3+ proteinuria on dipstick. Obstructive nephropathy was excluded by imaging. Serum and urine electrophoresis and immunofixation were negative for monoclonal protein. Our patient had lost ~ 44ml/min of GFR in just one year in the setting of well-controlled diabetes and hypertension, which is unusual for diabetic nephropathy. Therefore, we obtained a renal biopsy which demonstrated severe κ light chain (AL) amyloidosis [Figure]. A serum free light chain assay obtained retrospectively after the biopsy showed elevated κ/ λ ratio of 8.66. An endomyocardial biopsy excluded cardiac amyloidosis. Bone marrow biopsy was negative for amyloidosis but showed 2% abnormal plasma cells consistent with monoclonal gammopathy of undetermined significance (or more appropriately, 'renal significance' in this case). His renal function continued to worsen requiring initiation of hemodialysis. Chemotherapy with Cyclophosphamide, bortezomib and dexamethasone (CyBorD) is being planned.

Discussion: Take-home points: (a) Non-diabetic renal disease should be suspected in diabetic patients with unexplained worsening of creatinine despite the presence of retinopathy, (b) Serum free light chains should be obtained in addition to immunofixation to screen for paraproteinemia.



PUB386

Changing Patterns of Glomerular Disease in Saudi Children, 1997-2017

Abdulkareem Alsuwaida,[1] Lamees I. Al-mezaini,[1] Noura Ahmed,[1] Amaar A. Bakhit,[2] Junaid Wadera,[3] Feras A. Alsuwaida,[4] Mohamed C. Kechrid,[5] Abdulrahman K. Alabdulsalam,[6] Noura Aloudah,[7] Majed M. Alanazi,[8] Talal A. Alfaadhel,[1] Hanadi M. Alhozali,[9] Ghadeer A. Mokhtar.[9] *[1]King Saud University, Riyadh, Saudi Arabia; [2]King Saud University Medical City, Riyadh, Saudi Arabia; [3]King Khalid University Hospital, Riyadh, Saudi Arabia; [4]King Saud University, Riyadh, Saudi Arabia; [5]Security Forces Hospital, Riyadh, Saudi Arabia; [6]National Guard King Abdulaziz Medical City, Riyadh, Saudi Arabia; [7]king abulaziz medical city, Riyadh, Saudi Arabia; [8]King Abdul Aziz Medical City, Riyadh, Saudi Arabia; [9]King Abdulaziz University, Jeddah, Saudi Arabia.*

Background: There have been significant changes in the incidence of different glomerular disease in adults. We aimed to trends in renal biopsy glomerular disease diagnosis frequencies in Saudi children over the last three decades.

Methods: In this retrospective, observational study, we identified all patients less than 18 years with a native kidney biopsy between 1996 and 2017. Biopsy era (before 2000, 2000-2009, and 2010-2018) and demographics and the relationship with prevalence of various glomerular disease were our primary outcome.

Results: In total, 289 cases of renal biopsy were analyzed with the median age of the patients was 13 years and 52.6% of the patients were female. Secondary glomerulonephritis accounted for 28.7% and Lupus Nephritis (LN) is the commonest cause noted in 72.3%. Minimal change disease (MCD), and focal segmental glomerulosclerosis (FSGS) were the leading primary glomerulonephritis diagnoses observed in 66%. The frequency of membranoproliferative glomerulonephritis (MPGN) decrease significantly to 6.7% in most recent biopsy era versus 35.3% in the era earlier than 2000 ($p < 0.003$). The frequency of IgA nephropathy (IgAN) and membranous nephropathy (MN), doubled in the latest era.

Conclusions: Primary glomerular disease continued to be the predominant kidney disease in Saudi Arabia with MCD and FSGS being the most common pathology. The incidence of MPGN has decreased in the last decades possibly related to improved socioeconomic conditions and decline in regional endemic diseases. LN is the commonest cause of secondary GN.

PUB387

Study of Remission and Relapse in IgA Nephropathy with Steroid Therapy

Hideo Tsushima. Nara Medical University *Nara Medical University, Kasihara-city, Japan.*

Background: Prognosis for the development of end-stage renal disease (ESRD) in the patients with relapsed IgA nephropathy have not fully understood.

Methods: We retrospectively investigated the clinical and histological renal prognostic markers and cause of relapse in the cases of IgA nephropathy whom were performed renal biopsy from January 1980 to December 2013 and were received steroid therapy. We defined that remission was less than 0.3g/gCr or negative in dipstick three times in a row. And we defined that relapse was more than 0.5g/gCr or 1+ in dipstick three times in a row after remission.

Results: One hundred sixty five patients who had the diagnosis of IgA nephropathy were enrolled. Mean age at the time of renal biopsy was 40.2±6.1 years old. Urinary protein was 1.07±0.2 g/gCr. When clinical parameters were evaluated by univariate analysis, relapse was closely associated with the degree of proteinuria. The rate of glomerular sclerosis and cresents at initial biopsy did not contribute to relapse. Relapse had an equally poor prognosis as non-remission.

Conclusions: Our findings demonstrated that remission of proteinuria was a prognostic index for the preservation of renal function. The severity of gromeruli at initial renal biopsy did not correlated with future reccurence of IgA nephropathy.

PUB388

Urinary Myo-Inositol as a Potential Marker for Focal Segmental Glomerulosclerosis: NMR-Based Metabolomics Study

Young Lee Jung,[1] Jung Nam An,[2] Jin Seong Hyeon,[3] Seung Hee Yang,[4] Jang-Hee Cho,[5] Jung Pyo Lee.[2] *[1]Seoul National unioversity Hospital, Bucheon, Republic of Korea; [2]Seoul National University Boramae Medical Center, Seoul, Seoul, Republic of Korea; [3]Korea Basic Science Institute, Seoul, Republic of Korea; [4]Kidney Research Institute, Seoul National University, Seoul, Republic of Korea; [5]Kyungpook National University Hospital, Daegu, Republic of Korea*.

Background: Minimal change disease (MCD) and focal segmental glomerulosclerosis (FSGS) have similar histological findings initially, however, response to steroid treatment and long-term prognosis are quite distinct from each other. Therefore, it is of great importance to discriminate FSGS from MCD in the early phase of disease and predict clinical prognosis.

Methods: Discovery set consisted of 185 urine samples (62 healthy controls, 81 MCD, and 42 FSGS) collected at the time of kidney biopsy from 2010 to 2017 at Seoul National University Hospital and Seoul National University Boramae Medical Center. As validation set, we used 61 urine samples (12 healthy controls, 26 MCD, and 23 FSGS) from Gangdong Kyung Hee University Hospital and Gyeongbuk National University Hospital. Characteristic differences of urine metabolites depending on MCD and FSGS were examined using 800 MHz nuclear magnetic resonance (NMR) spectroscopy. After normalization by urine creatinine, the values were transformed to log values.

Results: Of 73 urine metabolites, log-transformed myo-inositol was significantly higher in FSGS patients compared with control patients (2.63-fold; $P < 0.001$) and with MCD patients (2.79-fold; $P < 0.001$). Log-transformed myo-inositol showed an inverse relationship between the initial chronic kidney disease stages ($P < 0.001$) or estimated glomerular filtration rate at baseline ($R^2 = 0.465$, $P < 0.001$). In addition, it was significantly associated with plasma level of soluble urokinase-type plasminogen activator receptor in FSGS patients ($R^2 = 0.228$, $P < 0.001$). Validation set revealed that log-transformed myo-inositol in urine samples of FSGS patients increased by 2.6-fold ($P < 0.001$) and 1.8-fold ($P < 0.05$) than control patients and MCD patients, respectively.

Conclusions: Myo-inositol, as urine metabolite, discriminated FSGS patients from MCD or control patients at the time of early diagnosis and significantly associated with initial renal function. Further studies including the correlation with clinical prognosis and the possible mechanism will be performed.

PUB389

Effect of Epipharyndeal Abrasion Therapy (EAT) on the Remission of IgA Nephritis/Vasculitis

Masashi Mizuno, Michio Fukuda, Tadashi Oikawa, Satoru Kominato, Minamo Ono, Taisei Suzuki, Nobuyuki Ohte. *Department of Cardio-Renal Medicine and Hypertension, Nagoya City University, Mizuho-ku, Japan.*

Background: Epipharyngeal Abration Therapy (EAT) is expected to contribute to the treatment for IgA-nephritis/vasculitis, fibromyalgia, chronic fatigue, atopic dermatitis, Palmoplantar pustulosis.

Methods: Effect of EAT using 0.5%- zinc chloride on the cumulative incidence of complete remission of nephropathy (CR, defined as urinary red blood cell less than 1/HPF and proteinuria less than 30 mg/gCre) was studied on 20 patients with IgA -nephritis/vasculitis (9 male, 32 median-years) [UMIN000009157].

Results: Fifteen patients achieved CR for median treatment duration of 7 months. The time from onset, diagnosis, and initiation of the combination therapy with tonsillectomy and steroid-pulse therapy to EAT did not influence to CR (HR 0.87-1.19, NS). Hematuria (/HPF, p=0.8), proteinuria (mg/gCre, p=0.4), glomerular filtration rate (mL/min/1.73m2, p=0.6), and Oxford-MEST-C score (NS) did not affect the cumulative incidence of CR. Of note, in 19 patients, hematuria was completely diminished. None of the 20 patients experienced adverse event (eg. infectious events).

Conclusions: We defined the CR of hematuria as less than 1/HPF. However, hematuria 1-4/HPF did not demonstrate increased activity of IgA-nephritis/vasculitis because patients with IgA-nephritis/vasculitis can exhibit thin glomerular basement membrane independent of activity of nephropathy. Most patients in our study cannot achieve CR by combination therapy with tonsillectomy and steroid-pulse therapy. Further study is needed to investigate the effect of EAT as initial therapy on CR of IgA-nephritis/vasculitis.

PUB390

Metabolomics Based Biomarkers as Clinical Outcome Indicator in Minimal Change Diseases

Young Wook Choi,[1] Jung Nam An,[2] Jin Seong Hyeon,[3] Jinhyuk Kim,[9] Seung Hee Yang,[4] Sangho Lee,[8] Jang-Hee Cho,[5] Dong Ki Kim,[6] Geum-Sook Hwang,[7] Jung Pyo Lee.[2] *[1]Seoul National University, Boramae Medical Center, Seoul, Republic of Korea; [2]Seoul National University Boramae Medical Center, Seoul, SEOUL, Republic of Korea; [3]Korea Basic Science Institute, Seoul, Republic of Korea; [4]Kidney Research Institute, Seoul National University, Seoul, Republic of Korea; [5]Kyungpook National University Hospital, Daegu, Republic of Korea; [6]Seoul National University Hospital, Seoul, Republic of Korea; [7]Korea Basic Science Intsitute, Seoul, Republic of Korea; [8]Kyung Hee University Hospital at Gangdong, Seoul, Republic of Korea; [9]SMG-SNU Boramae Medical Center, Seoul, Republic of Korea*.

Background: Minimal change disease (MCD) is well known as one of the glomerulonephritis (GN) that recur frequently. We investigated the clinical outcome of Metabolomics based biomarkers in patients with MCD.

Methods: Urine samples from healthy control (n=61), primary MCD (n=81) and MCD follow up (n=35) were analyzed with NMR-spectroscopy. Metabolites were then quantified and compared between groups.

Results: In the urine samples, metabolites that showed a clear difference between the healthy control group and the MCD group were analyzed. In addition, when these metabolites level were completely remission in the MCD follow up group, they were restored to the healthy control group level.

Conclusions: In this study, we suggest that metabolites biomarker is a reliable tool for the prediction of MCD prognosis and guidance of therapeutic plans.

PUB391

Cellular Crescents in Class V Lupus Nephritis: Mere Coincidence or More Than That?

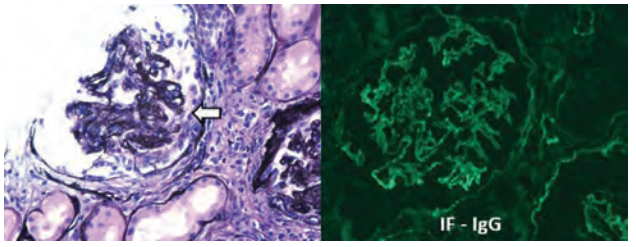
Abhilash Koratala, Xu Zeng, Olanrewaju A. Olaoye, Mark S. Segal. *University of Florida, Gainesville, FL.*

Introduction: Membranous nephropathy (MN) is typically not associated with glomerular crescents. However, crescentic MN has been reported to occur in conjunction with anti-GBM antibody disease, ANCA vasculitis and IgA nephropathy. In membranous (class V) lupus nephritis (LN), cellular crescents may be seen when it occurs together with class III or IV proliferative LN. In addition, fibrous or fibrocellular crescents may be seen in class V as a sequela of previous proliferative, crescentic glomerulonephritis. Herein, we report a unique case of class V LN associated with cellular crescents, but no endocapillary proliferation or necrotizing lesions.

Case Description: A 51-year-old AA woman with a history of SLE presented to our clinic to establish care for LN. She was first diagnosed with class IV LN 6 years prior to presentation, at which time she was treated with prednisone and 6 monthly cycles of cyclophosphamide. Post-treatment biopsy demonstrated class III LN and she was started on Mycophenolate mofetil (MMF) 1000mg bid maintenance therapy but was tapered off after 1 year of treatment. A year later, MMF was restarted when she presented with alopecia and proteinuria of~2 g/g. After 1 year, her proteinuria was 0.6 g/g with preserved renal functuion all this time (Scr <1mg/dL) and her rheumatologist stoped the MMF and initiated belimumab. She was lost to follow up after a few months and the belimumab was stopped. On her own she took MMF 250mg bid for some time, but stopped due to GI side-effects. At presentation to us, her Scr was 1.63 mg/dL with proteinuria of 3.3 g/day. A renal biopsy was

performed, which demonstrated class V LN with cellular crescents [Figure]. We treated her with pulse corticosteroids and started enteric-coated mycophenolic acid.

Discussion: To the best of our knowledge, cellular crescents in association with isolated class V LN has never been reported. In the absence of endocapillary proliferation, the cellular component of these crescents is likely constituted by glomerular parietal and visceral epithelial cells as opposed to macrophages. At this time, the prognostic significance of crescents is unclear.



PUB392

Glomerular Diseases Induced by Medications: Clinical Picture, Histopathology and Outcomes

Sophia Lionaki,[1] Hara Gakiopoulou,[2] Georgios Liapis,[3] Petros Sfikakis,[4] Athanasios Tzioufas,[5] John Boletis.[1,6] *[1]Nephrology, Laiko Hospital, Athens, Greece; [2]Pathology, National & Kapodistrian University of Athens, Athens, Greece; [3]Pathology, Laiko Hospital, Athens, Greece; [4]Internal Medicine, National & Kapodistrian University of Athens, Athens, Greece; [5]Pathophysiology, National & Kapodistrian University of Athens, Athens, Greece; [6]Medicine, National & Kapodistrian University of Athens, Athens, Greece.*

Background: The aim of this study was to describe the clinical and histopathological characteristics of patients with drug-induced glomerular diseases along with the related clinical syndrome and the long-term outcome after discontinuation of the offending medicine.

Methods: All cases with any type of biopsy proven glomerular disease, which was associated with administration of a certain medication were studied retrospectively. Demographics and patients' characteristics were recorded along with the related clinical and histopathological picture, the treatment and the outcome during the follow up time.

Results: Eight patients with glomerular diseases associated with medicines were identified. Six of them were females with a mean age of 59.6(±18.8) years. The renal biopsy was performed within 3-17 days from onset of symptoms, which included either nephrotic syndrome (n=4) or nephritic syndrome with acute renal dysfunction (n=4). Patients with acute nephritic syndrome reported general symptoms including fever, arthralgias, fatigue, anorexia and rash. Histopathological evaluation revealed minimal change disease in 3 patients, membranous nephropathy in 1, pauci-immune glomerulonephritis in 2 and lupus like nephritis (WHO Class III, καIV) in 2. The medicines, which were associated were d-penicillamine, tamoxiphen, OH-chlorokine, NSAIDs, propyl-thiouracile, etarnecept, methimazole and infliximab. The median value of serum creatinine was 0.5 (min: 0.5, max: 2.7 mg/dl), of 24-hour proteinuria was 5530 mg (min: 630, max: 240000 mg) while 4 of the patients had active urine sediment. In patients with nephrotic syndrome discontinuation of the offending drug lead to complete remission within a few weeks. Patients with acute nephritis required treatment with cyclophosphamide and glucocorticoids for 3-6 months, in addition to the removal of the offending drug.

Conclusions: In this small series of patients with glomerular diseases associated with medicines discontinuation of the related drug lead to remission of the nephrotic syndrome within a few weeks while patients with acute nephritic syndrome required treatment with cyclophosphamide and glucocorticoids for 3-6 months, in addition to the removal of the offending drug.

PUB393

Eculizumab Improves Outcomes in Patients with Thrombotic Microangiopathy Without ADAMTS-13 Deficiency in Comparison with Therapeutic Plasma Exchange

Miguel Uriol Rivera,[1] Aina Obrador,[2] Sheila Cabello Pelegrin.[3] Son Espases TMA Group *[1]Hospital Universitario Son Espases, Palma de Mallorca, Spain; [2]Son Espases University Hospital, Palma de Mallorca, Spain; [3]Hospital Universitari Son Espases, Palma de Mallorca, Spain.*

Background: Thrombotic microangiopathy (TMA) is a life-threatening disease or complication. Early therapeutic plasma exchange (TPE) is the first line recommended treatment; unfortunately, in patients with TMA without ADAMTS-13 deficiency, the prognosis did not change over time. The introduction of the anticomplement C5 therapy (Eculizumab) indicated for atypical hemolytic uremic syndrome (HUS), may improve the prognosis of TMA. The potential differences on efficacy between TPE in comparison with Eculizumab for the TMA control has not been evaluated. Objective: To compare the efficacy of the use of TPE versus Eculizumab on the risk of chronic renal replacement requirements or death (outcome) in patients with TMA.

Methods: This a retrospective study. Patients of the tertiary referral hospital with TMA and without ADMST-13 deficit or patients with HUS and renal proven biopsy were included. Period evaluated: from January/2008 to February 2018.

Results: 37 patients were evaluated. Mean age 41 years. Sex: Female: 24(64%). TPE was used in 17(46%) and Eculizumab on 20(54%) of the patients. No differences on age, sex, hemoglobin, lactate dehydrogenase, platelets count, urgent dialysis requirements or admission at intensive care unit between groups were observed. 11(27%) patients met study outcome, 8 patients were treated with TPE and 3 with eculizumab. From those treated with TPE, 8 (47%) met outcome (x2:0.04; P=0.82), while in those treated with Eculizumab, it was observed only in 3(15%) patients (x2: 12,65; P<0.01); moreover, in 8 patients initially treated with TPE, the use Eculizumab as a rescue treatment was required. The comparative analysis shows that the odds ratio of chronic renal replacement needs or death in patients treated with TPE versus Eculizumab was 18.4 (95%CI, 3.5 to 97.0).

Conclusions: There is an important difference between TPE in comparison with Eculizumab in the prognosis of the TMA without ADAMTS-13 deficiency. The use of the Eculizumab should be considered as a first line treatment option in these patients.

PUB394

Tonsillectomy with Steroid Pulse Therapy for IgA Nephropathy

Yusuke Fukao, Hitoshi Suzuki, Toshiki Kano, Yuko Makita, Yusuke Suzuki. *Juntendo University Faculty of Medicine, Tokyo, Japan.*

Background: IgA nephropathy (IgAN) is the most frequent cause of primary glomerulonephritis worldwide. The clinical course of IgAN is extremely variable and ranges from asymptomatic microscopic hematuria to rapidly progressive renal failure. Although the pathogenetic mechanisms of IgAN are still obscure, galactose-deficient IgA1 production may be in the mucosa-bone marrow axis. Indeed, some clinical studies indicated that tonsillectomy plus steroid pulse (TSP) therapy have favorable effects on IgAN. In present study, we evaluated the efficacy of TSP therapy compared with renin-angiotensin system inhibitor (RAS-i) alone for IgAN in our cohort.

Methods: We retrospectively recruited 141 biopsy proven patients with IgAN from 2012 to 2015. The observation period in this study was 24 months. Those patients were divided into three treatment groups; TSP group (n=88), Tons group (n=25) who received tonsillectomy alone, CT group (n=28) who treated with RAS-I, but not any immunosuppressant. Primary evaluation items were the disappearance of urinary protein and microscopic hematuria indicating clinical remission.

Results: At the time of renal biopsy, the amount of urinary protein excretion was 0.7g/gCr in TSP group and 0.4g/gCr in CT group. Degree of hematuria was severe in TSP group than in CT group. Age, gender, serum creatinine, and eGFR were not different between each group. During the intervention period, TSP has the strong effect on improvement of urinary protein compared with CT group (p<0.01). Remission rate of hematuria in TSP group (75.4%) was greater than other groups (Tons group: 55.6%, CT group: 50%). Those therapeutic effect persisted until the final observation. TSP therapy also has an effect to reduce serum level of IgA (26% decreased, p<0.01). The Cox regression model showed that the TSP therapy was more effective in clinical remission than treatment with RAS-I alone.

Conclusions: TSP therapy successfully induced higher clinical remission even in the clinically severe cases of IgAN as compared to sole tonsillectomy or RAS-i therapy.

PUB395

Risk Factors for ESRD in Lupus Nephritis Class IV

Camila B. Oliveira, Denise M. Costa, Gisele Vajgel, Maria Alina G. Cavalcante, Lucila Maria Valente. *Hospital das Clinicas - UFPE, Recife(PE) BRAZIL, Brazil.*

Background: Lupus nephritis (LN) class IV is the most common renal manifestation of SLE and represents an important cause of morbidity and mortality. The purpose of this study was to determine risk factors for ESRD in patients with LN class IV.

Methods: Retrospective cohort of adult patients with biopsy proven LN class IV (ISN/RPS classification). Exclusion criteria were biopsy with <10 glomeruli and follow-up <12 months. Clinicopathological characteristics and long-term follow-up were analyzed.

Results: Baseline characteristics of 89 patients with LN class IV are shown in Table 1. After a follow-up of 57.2± 37.6 months, 73% of patients achieved complete or partial remission and 24.7% progressed to ESRD. The final sCr was 1.9±1.1mg/dl and CrCl was 65.0±41.7ml/min/1.73m^2. The risk factors for ESRD were class IV-G (RR 3.92, 95%CI 1.25–12.24;p=0.006), interstitial fibrosis (IF) ≥25% (RR 2.63, 95%CI 1.19-5.91;p=0.012), chronicity Index (CI) ≥4 (RR 3.64, 95%CI 1.47–9.00;p=0.002) and no remission (NR) in 12 months (RR 9.32, 95%CI 2.98–29.20;p<0.001). In multivariate analyses, NR in 12 months was associated to a risk for ESRD of 9.32 (95%CI 2.96-29.4;p<0.001).

Conclusions: Class IV-G, IF>25% and CI≥4 were associated with higher risk of ESRD. However, the main risk factor of ESRD was NR in 12 months.

Table 1. Baseline characteristics of 89 patients with LN class IV

Baseline characteristics	LN Class IV N=89
Mean age, years	31.0 ± 9.5
Gender (female), %	95.5
Race (non-white), %	65.2
Rapidly progressive glomerulonephritis, %	40.4
Hypertension (BP≥140x90mmHg), %	79.5
Serum creatinine, mg/dl	1.7 (0.9 - 3.0)
CrCl, ml/min/1.73m2	38.8 (19.9 - 77.8)
Proteinuria, g/24h	3.8 (2.2 - 5.9)
Hematuria, %	88.6
Class V, %	39.3
Wire-loops, %	30.3
% biopsy with crescents	61.8
% glomeruli with crescents	25.3 (0.0 - 40.0)
Fibrinoid necrosis, %	4.5
IV-G/IV-S, %	61.8/38.2
Interstitial fibrosis/Tubular atrophy, % Absent 1 – 24% ≥25%	4.5/5.6 50.0/77.5 45.4/16.9

Can Severe Thrombocytopenia Lead to Kidney Injury

Samer Mohandes,[1] Abigail B. Shoben,[2] Sergey V. Brodsky,[3] Brad H. Rovin,[1] Lee A. Hebert.[4] samer mohandes *[1]Ohio State University Wexner Medical Center, Columbus, OH; [2]The Ohio State University, Columbus, OH; [3]OSU, Columbus, OH; [4]Ohio State University Medical Center, Columbus, OH.*

Background: The gamut of anticoagulation related nephropathy (ARN) has expanded beyond its initial identification as warfarin related nephropathy to include other oral anticoagulants. Idiopathic thrombocytopenic purpura (ITP) is an immune mediated thrombocytopenia diagnosed by exclusion of other causes of thrombocytopenia and characterized by recurrent episodes of severe thrombocytopenia. We undertook this study to assess whether episodes of severe thrombocytopenia are associated with worsening kidney function

Methods: A retrospective study of all patients admitted to a single center between 10/1/2006 and 9/30/2017 and diagnosed with ITP. Mean creatinine levels done in the 5 day period before the nadir were compared with the mean 15 days after to identify a statistically significant trend.

Results: 191 patients were identified that had adequate testing for the analysis. The meain increase in the serum creatinine following the nadir platelet level was 0.156 mg/dl with a 95% confidence interval of 0.021-0.292 and a p value of 0.024.

Conclusions: This exploratory study shows a small but significant mean increase in serum creatinine (0.156 mg/dl), p value= 0.024 at the nadir level of thrombocytopenia. This suggests that severe thrombocytopenia may also contribute to anticoagulation related nephropathy.

PUB397

Urinary Biomarkers in the Prediction of Prognosis and Treatment Response in IgA Nephropathy

Timm H. Westhoff,[1] Thomas Rauen,[2] Jürgen Floege,[3] Frederic Bauer,[4] Felix S. Seibert,[5] Nina Babel,[6] Frank Eitner.[7] *[1]Ruhr-University Bochum, Germany, Herne, Germany; [2]University Hospital Aachen, Aachen, Germany; [3]RWTH University of Aachen, Aachen, Germany; [4]Ruhr-University Bochum, Herne, Germany; [5]University Hospital Marien Hospital Herne, Herne, Germany; [6]Ruhr University Bochum, Herne, Germany; [7]Bayer AG, Wuppertal, Germany.*

Background: The addition of immunosuppression to supportive care reduces proteinuria in a subset of patients with IgA nephropathy (IgAN) but is associated with an increased rate of adverse events. The present work investigates whether urinary biomarkers are able to identify subjects who benefit from immunosuppression and to predict the progression of disease in a sub-cohort of the STOP-IgAN trial.

Methods: Urinary neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), calprotectin, and the product of tissue inhibitor of metalloproteinase-2 and insulin-like growth factor-binding protein 7 (TIMP2, IGFBP7) were measured in all available urine samples obtained at the time point of enrollment in the STOP-IgAN trial (n=113).

Results: Biomarker concentrations in both the overall study population and the subgroup with additional immunosuppression did not differ in subjects reaching vs. not reaching full clinical remission, eGFR loss ≥15, or 30 ml/min/1.73 m² over the 3-year trial phase (p>0.05 each). Receiver-operating characteristic curves showed a poor predictive accuracy of each biomarker for the above mentioned parameters in the overall study population (areas under the curve ≤0.611). Accordingly, there was neither a significant correlation of any biomarker and adverse outcome in linear regression analysis, nor between biomarker concentrations at enrolment and change in the eGFR over the 3-year observation period.

Conclusions: NGAL, KIM-1, calprotectin, and [TIMP-2]x[IGFBP7] had neither a prognostic value for the progression of IgAN, nor for the response to immunosuppression in the present sub-cohort of the STOP-IgAN trial. The search for appropriate biomarkers for an individualized treatment strategy in IgAN continues.

PUB398

Treatment Strategy in a Case of Uncertain Glomerulonephritis

Golriz Jafari,[1] Anita Kamarzarian,[1] Raghu Konanur venkataram.[2] *[1]UCLA-Olive View Medical Center, Los Angeles, CA; [2]Olive View- UCLA Medical Center, Porter Ranch, CA.*

Introduction: Evaluation of patients with nephrotic range proteinuria usually entails urinalysis, autoimmune/infectious serologies and immunoglobulins. These tests may hint at a potential underlying cause which would lead to a kidney biopsy to confirm the diagnosis. Alsowhen all tests are negative and there is not a clear etiology (e.g. diabetes mellitus), a biopsy is also warranted. This patient presents with multiple potential etiologies of glomerulonephritis (GN) however biopsy may result in an unnecessary risk.

Case Description: 59 year old male with hypertension, diabetes, pulmonary hypertension, hepatitis C (HCV) cirrhosis and prior Hepatitis B infection referred to nephrology for proteinuria evaluation. Uprt/Ucr peaked at 4gm and Cr 2.15 (eGFR 33 ml/min/m²); HCV RNA 3.1M IU/ml, ANA 1:320, cryoglobulin 10%, serum immunofixation with IgM kappa and lambda spike, Urine immunofixation negative; C3 76 mg/dl, C4 8 mg/dl; dsDNA, ANCA, HIV and RPR screens negative; UA 46 RBCs and 6 WBCs. Renal biopsy was considered due to multiple potential etiologies of proteinuria i.e. HCV, MPGN, SLE, IgA, paraproteinemia associate GN, however patient was considered to have high bleeding risk (platelet 87K and INR 1.4). Therefore patient was treated empirically for HCV associated cryoglobulinemia with glecaprevir and pibrentasivir for 12 weeks. Hematology evaluation recommended rituximab therapy for the cryoglobulinemia since the most likely etiology of the abnormal immunofixation result rather than a plasma cell disorder. He also received tenofovir to prevent hepatitis B reactivation. After treatment Cr improved to 1.53 mg/dl and Uprt/Ucr 0.6 gm, complements normalized and UA with 4RBCs and 0 WBC.

Discussion: The standard approach in patients with nephrotic range proteinuria, an active urinary sediment and multiple positive serologies would be to perform a kidney biopsy. In this case after evaluating the potential risks associated with biopsy, the differential and treatment options, we decided to treat empirically. Whilst it is true the patient may have had MPGN or Membranous GN, in this case would be secondary to the HCV infection. If there was underlying lupus nephritis, the patient may have responded to rituximab otherwise biopsy would be reconsidered for lack of response. Therefore it poses less potential harm to treat the most likely underlying etiology and evaluate response in certain situations.

PUB399

Urinary Membrane Attack Complex (UMAC) Perspectives as a Biomarker for Monitoring Response to Treatment in Focal and Segmental Glomerulosclerosis (FSGS)

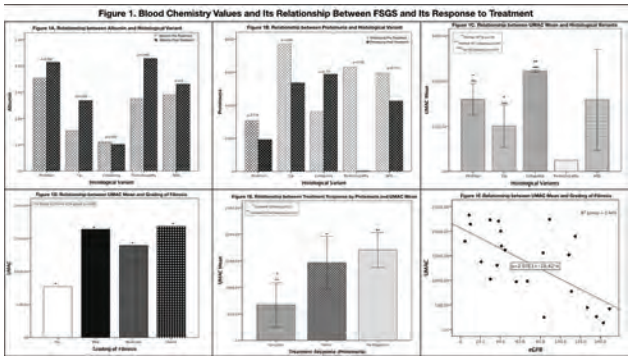
Juan C. Trimino,[1] L. M. Perez-Navarro,[2] Virgilia Soto,[3,1] Rafael Valdez-Ortiz.[1] *[1]Hospital General de Mexico, Mexico, Mexico; [2]Hospital General de México Dr. Eduardo Liceaga, México, Mexico; [3]INC Ignacio Chavez, Mexico City, Mexico.*

Background: The role of UMAC in the FSGS is unknown. Has been reported that complement activation is present in FSGS patients and associated with disease severity. The aim was assessed the relationship between UMAC and the classification of FSGF and treatment response.

Methods: Longitudinal study in patients with FSGF. We evaluated fibrosis grade, urea, creatinine, albumin, CKD-EPI and UMAC. UMAC was quantified by mass spectrophotometry. Student's t-test, one-way ANOVA, 95% CI, and p <0.05 were performed as statistically significant.

Results: 25 patients with diagnosis of FSGF were evaluated, 9 perihiliar, 10 tip, 2 collapsing, 2 NOS, 2 podocytopathy; the average age was 34±16 years with no significant statistical difference between groups (*p*= 0.81). Significant differences were identified between the groups in the basal and final levels of albumin, while, urea and proteinuria only presented significant difference in basal level. The mean of UMAC was 1258.92±765.19 pg/ml, with significant differences between the groups; although, no differences were found in the UMAC levels with the degree of fibrosis (p= 0.10), subjects without fibrosis had the lowest levels of UMAC 770.1±579 *vs* 1680.31±490.1 severe fibrosis. The 100% of patients received induction treatment with corticosteroids, 88% ACEI, 84% statins, 16% steriods+CNi, 8% calcium channel blockers. The UMAC levels were lower in the group with complete response to treatment, with differences between groups (p= 0.003). UMAC had significant correlation with final proteinuria (r=0.5, p=0.01) and CKD-EPI. **Figure 1.**

Conclusions: The UMAC represents the final stage of activation of the complement system. Our results showed that high levels of UMAC in patients with FSGF with a statistical correlation, had the worst varieties. The patients who had the benign varieties, responded better to treatment; however, these results must be confirmed with a higher number of patients in prospective studies.



PUB400

Clinical Experience with 21 Adults Affected by Post-Infectious Glomerulonephritis

Àlex Favà,[1] Ariel Tango barrera,[2] Isabel Giménez,[3] Aroa Rovira,[4] Rafael Alvarez,[5] Josep M. Cruzado,[4] Joan Torras,[6] Xavier Fulladosa.[7] *[1]Hospital de Bellvitge, Barcelona, Spain; [2]H. Universitario Bellvitge, Barcelona, Spain; [3]Moises Broggi Hospital, Barcelona, Spain; [4]Hospital Universitari de Bellvitge, Barcelona, Spain; [5]Bellvitge Hospital, Barcelona, Spain; [6]Laboratory Experimental Nephrology, IDIBELL. Hospital Universitari de Bellvitge, Barcelona, Spain; [7]Hospital Universitari De Bellvitge, L'Hospitalet de Llobregat, Spain.*

Background: Post-infectious glomerulonephritis(PIGN) is an entity related to childhood and throat infections. It has a well-defined clinical and histological presentation, showing a favourable prognosis. However, in last decades, the improvement in antimicrobial therapies and the population ageing has led to a radical change in this entity in terms of clinical features and prognosis.

Methods: We retrospectively analysed all the PIGN cases diagnosed between 2012 and 2017 from our pathology department archive.

Results: Our study population consisted of 21 cases, with a male:female ratio of 4.25:1. The median follow-up was of 232 days (mean 367). 28% of patients presented chronic kidney disease, 38% diabetes, 62% hypertension, 19% cancer, 33% alcoholism and 10% cirrhosis. The most common site of infection was skin (23%), followed by respiratory tract (19%), preceding in a mean of 15 days the nephritic event. Remarkably, in 28% of the cases, a previous infectious event was unnoticed. Staphylococcus (33%) and Enterobacteriaceae (33%) were the most common identified infectious agents. Hypocomplementemia was present in 57% and was restored in all cases, although 50% occurred after 3 months of nephritis. Nephrotic syndrome was present in 14%. IgA dominiant PIGN occured in 23% of cases, and a "C3 dominant" pattern was presented in 19%. 46% of patients required hemodialysis initially, with 24% finally remaining in chronic hemodialysis program. Only 19% of patients recovered previous renal function. Steroid therapy was used in 76% of cases.3 patients died before six month by infection related causes.

Conclusions: According to our results, PIGN shows a poor prognosis in adult population, and comorbidity burden might be an explanation. In addition, the lack of a previous infectious event, the slow complement restoration and its immunofluorescence patterns akin to other entities make its diagnosis difficult. More evidence is required to define the most appropriate management in these cases.

PUB401

Beverage Intake by US Adolescents: Analysis of National Health and Nutrition Examination Survey (NHANES) Data, 2009-2014

Uma D. Alappan,[1] Martine Ferguson,[2] Beverly J. Wolpert.[1] *[1]Center for Food Safety and Applied Nutrition, Office of Analytics and Outreach, Division of Public Health Informatics and Analytics, U.S. Food and Drug Administration (FDA), College Park, MD; [2]Center for Food Safety and Applied Nutrition, Office of Analytics and Outreach, Biostatistics and Bioinformatics Staff, U.S. Food and Drug Administration (FDA), College Park, MD.*

Background: To examine beverage intake among U.S. adolescents by demographic and health characteristics.

Methods: We analyzed data from 7242 participants aged 14-18 years old (3758 males, 3484 females) with ≥1 day of beverage intake reported in the 2009–2010, 2011–2012, and 2013-2014 U.S.-representative National Health and Nutrition Examination Surveys (NHANES). Beverage types included milks, fruit juices, sports drinks, waters, coffees, and other (combined because of sparsity: protein powder, energy, and cereal drinks). Demographic and health characteristics included sex, age, race/ethnicity, education, household income, body mass index (BMI), diabetes, anemia, sedentary and physical activity time per typical day, waist-to-height ratio, and menses onset age. Analyses accounted for the NHANES survey design and incorporated appropriate weighting. The habitual consumption method was used, along with the Multiple Source Method to estimate usual beverage intake (grams). Proportions of respondents consuming each beverage type and per-consumer mean beverage intake (g/day) were calculated. Because of strong correlations between some variables (e.g., age/education, and BMI/waist-height ratio), univariate logistic models estimated associations with beverage consumption (weighted %). For variables with significant associations (p<.05), t-tests were carried out on least-squares means to assess where differences rested. P-values were Bonferroni-adjusted for multiple comparisons.

Results: Males consumed milks, sodas, and sports drinks more often than females. Blacks consumed juices more often than all other races. Hispanics consumed juices more often than Whites and sodas more often than all others. Significant associations were found between beverage type consumed and sex (p=.01), age (p=.0052), race/ethnicity (p=.0004), education (p=.0015), diabetes (p<.0001), anemia (p=.0092), sedentary time per typical day (p<.0001), BMI (p<.0001), and waist-height ratio (p<.0001).

Conclusions: Few analyses have been conducted to assess beverage intake patterns in adolescents. Results from this study contribute new information to help address the gap, inform future studies of health risks by subgroup, and target education to this age-group.

PUB402

Nutritional and Anthropometric Assessment During and After Ramadan in a Cohort of Hemodialysis (HD) Patients in Jeddah, Saudi Arabia

Bayan M. Tashkandi,[1] Dina A. Tallman,[1] Deepinder Kaur,[1] Hanadi M. Alhozali,[2] Pramod Khosla.[1] *[1]Nutrition and Food Science, Wayne State University, Detroit, MI; [2]Department of Medicine, King AbdulAziz University Hospital, Jeddah, Saudi Arabia.*

Background: During the annual festival of Ramadan (R), Muslims world-wide undergo a period of fasting from sunrise to sunset. Studies suggest that this period of cyclic fasting does not affect the healthy individual but its effect on HD patients is not well documented. Inadequate food intake, muscle loss and inflammation are common in HD. In Saudi Arabia, the number of HD patients increased 14% from 2014 to 2016. While the majority of patients insist on fasting during R, any associated health risks are not well documented. The aim of this pilot study was to assess dietary, anthropometric and biochemical parameters in HD patients over the R period.

Methods: The study was conducted in an out-patient dialysis clinic in Jeddah (n=23, 10 males, age 43±15 yrs, thrice-weekly dialysis, vintage 93±54 months, Kt/V 1.38±0.33). Both 24h diet recall and 3d food records were analyzed using Food Processor ESHA Research. Body mass index (BMI), handgrip strength (HGS) using a Jamar dynamometer, malnutrition-Inflammation Score (MIS) and biochemical parameters were also evaluated during R and two months following R.

Results: Among R participants, the intake of calories, protein, and fat was significantly higher during R while there was no significant difference in carbohydrate intake. Two-months post R, calorie, protein and fat intake had declined by 24%-36% compared to the values noted during R. Absolute carbohydrate intake was not significantly different during or 2 months post R. No differences were noted in BMI, HGS or MIS during this time-period. While there were temporal fluctuations in serum albumin, creatinine and sodium, the values pre and 2 month post R, were not significantly different. Blood glucose, potassium and phosphorus did not change over the course of the study.

Conclusions: Our preliminary data indicates that in HD patients observing R, while alterations in diet and clinical parameters fluctuate, most return to pre R values within 2 months of the end of the R period. The impact on other parameters (e.g. plasma lipoproteins) is currently under evaluation. (BT is a recipient of a scholarship from the Ministry of Education, Saudi Arabia)

PUB403

Hypercholesterolemia as a Risk Factor of Coronary Artery Disease in Hemodialysis Patients: 10-Year Outcome of the Q-Cohort Study

Toshiaki Nakano,[1] Hiroto Hiyamuta,[1] Shigeru Tanaka,[2] Masatomo Taniguchi,[3] Kazuhiko Tsuruya,[4] Takanari Kitazono.[5] *[1]Kyushu University, Fukuoka, Japan; [2]Fukuoka Dental College, Fukuoka, Japan; [3]Fukuoka Renal Clinic, Fukuoka, Japan; [4]Nara Medical University, Kashihara, Japan; [5]Department of Medicine and Clinical Science, Fukuoka, Japan.*

Background: The prevalence of atherosclerotic diseases including coronary artery disease, peripheral artery disease and stroke is higher in chronic kidney disease (CKD) patients. However, the risk of hypercholesterolemia for cardiovascular disease (CVD) in hemodialysis (HD) patients is still debated. Inflammation and malnutrition may affect dyslipidemia-induced CVD in HD patients. The aim of this study is to investigate the risk of hypercholesterolemia for CVD in a 10-year cohort of hemodialysis patients.

Methods: A total of 3,529 Japanese HD patients aged ≥18 years were prospectively followed for 10 years in this study. Patients were divided into four groups (Q1:<131 mg/dL, Q2:131–152 mg/dL, Q3:152–178 mg/dL, Q4:≥178 mg/dL) by quartiles of serum total cholesterol levels. We estimated the relationship between serum total cholesterol levels and the incidence rate of coronary artery disease (CAD), brain infarction (BI), peripheral artery disease (PAD) and combination of CVDs in 10 years.

Results: During a follow-up period, 460 (13%), 379 (11%) and 261 patients (7%) developed CAD, BI, and PAD, respectively. The incidence of CAD and PAD, and combination of CVDs increased linearly with higher total cholesterol levels. In multivariable-adjusted Cox analysis, a high total cholesterol level was an independent risk of CAD incidence (hazard ratio [HR], 1.37; 95% confidence interval [CI], 1.03–1.82; P=0.03 for Q4 vs. Q1) and CVDs combination (HR, 1.26; 95% CI, 1.05–1.51; P=0.02 for Q4 vs. Q1), after adjustment for confounding factors including serum albumin and C-reactive protein (CRP). There is no significant interaction between serum total cholesterol and serum albumin or CRP regarding CAD and CVD.

Conclusions: Serum high total cholesterol level is an independent risk factor for CAD in HD patients. Hypercholesterolemia still has a risk of CAD even after CKD patients have undergone maintenance HD.

PUB404

Correlation Between Dietary Components Measured in 24-Hour Urine Tests and Food Records in Patients with Kidney Disease

Melanie Betz,[1] Fredric L. Coe,[2] Arlene B. Chapman.[2] [1]*University of Chicago Medicine, Chicago, IL;* [2]*University of Chicago, Chicago, IL.*

Background: Food Records (FR) are used widely in research and clinical care. Twenty-four hour urine collections (24UV) are considered the gold standard to measure dietary sodium (Na), potassium (K), phosphorus (P), calcium (Ca), magnesium (Mg), and protein. Little research has been done to validate FRs obtained in a clinical setting against biological measurements. The objective of this project was to determine if FR obtained as routine care correlates with 24UV measurements of Na, K, P, Mg, Ca and protein performed at different time points.

Methods: FRs and 24UVs were completed as routine care in the nephrology clinic at University of Chicago Medicine. A Registered Dietitian provided patient instruction and analyzed the FR with National Data Research System, 2017. FR results were compared to a 24UV done closest to the date of the FR. Pearson's correlation was used to compare each nutrient measured via FR and 24UV.

Results: A total of 33 patients were included with a mean age of 50 years, BMI of 25.3kg/m^2 and estimated glomerular filtration rate of 67ml/min (n=28); 91% were Caucasian. Diagnoses included autosomal dominant polycystic kidney disease (45.5%), nephrolithiasis (48.5%) or other (6.1%). Average time between FR and urine was 97 days (range of 0-533); adjustment for time with ANOVA did not improve correlations, therefore was not adjusted for in calculations. Sodium (r=0.55, p=0.001) and Mg (r=0.46, p=0.008) measured via FR correlated significantly with 24UV.Sodium was consistently underestimated by FR; Mg was overestimated. Dietary K (r=0.16, p=0.389), P (r=0.22, p=0.217), Ca (r=0.06, p=0.743) and protein (r=0.26, p=0.138) did not correlate with 24UV.

Conclusions: Sodium and Mg intake measured via FR significantly correlated with 24UV done at separate times. Overestimation of Na by FR is possibly due to underreporting. Underestimation of Mg intake is likely due to low intestinal absorption. Given variability of absorption of Ca and P from hormonal regulation, correlation would not be expected. Lack of correlation for protein and K could be explained by daily variability in intake, unknown physiologic factors, time difference between urine and FR, or difficulty obtaining adequate detail for analysis of a FR.

PUB405

Validation of the Sarcopenia Index to Assess Muscle Mass in the Critically Ill: A Novel Application of Kidney Function Markers

Erin F. Barreto,[1] Janelle O. Poyant,[3] Hongchuan H. Coville,[2] Ross Dierkhising,[4] Cassie C. Kennedy,[4] Ognjen Gajic,[4] Erin Nystrom,[1] Naoki Takahashi,[1] Michael Moynagh,[4] Kianoush Kashani.[1] [1]*Mayo Clinic, Rochester, MN;* [2]*University of Central Florida, Gainesville, FL;* [3]*Tufts Medical Center, Boston, MA;* [4]*Mayo Clinic, Rochester, MN.*

Background: Adverse outcomes for hospitalized patients with sarcopenia are well documented, and identification of patients at risk remains challenging. The sarcopenia index (SI), previously defined as (serum creatinine/serum cystatin C)x100, could be an inexpensive, readily accessible, objective tool to predict muscle mass and risk for adverse clinical outcomes. The aim of this study was to assess the validity of the SI as a predictor of muscle mass.

Methods: Retrospective study of critically ill adults admitted to Mayo Clinic from 2012 -2015 with suspected sepsis and an available creatinine and serum cystatin C. Muscle surface area was quantified at the L3/4 vertebral level in patients with an abdominal CT scan (CTMSA). Multivariable regression modeling was used to assess the relationship between SI and CTMSA, as well as short-term clinical outcomes.

Results: The 171 included had a mean weight and body mass index (BMI) of 75.2 ± 16.4 kg and 26.0 ± 4.6 kg/m^2 and abdominal CT scans were available for 81 (47%) patients. The SI correlated with CTMSA (r = 0.40). After adjustment for age, sex, severity of illness, and BMI, SI was independently associated with muscle mass (P=0.001). A decrease in the SI (indicative of lower muscle mass) was also associated with frailty and worse short-term clinical outcomes.

Conclusions: The SI, a simple calculation from kidney function markers, is a significant predictor of muscle mass in this validation cohort of ICU patients. A low SI was associated with longer hospital length of stay and frailty. Future studies could explore whether the use of SI assists with identifying patients likely to benefit from pharmacotherapy-, nutrition-, or physical therapy-based interventions.

Eating Disorder Nephropathy: A Case Series Study

Hirokazu Marumoto, Takaya Sasaki, Nobuo Tsuboi, Masahiro Ishikawa, Makoto Ogura, Takashi Yokoo. *Division of Kidney and Hypertension, The Jikei University School of Medicine, Tokyo, Japan.*

Background: Eating disorders (EDs), such as anorexia nervosa and bulimia, are psychiatric disorders frequently found in young women, with a substantially increasing prevalence in recent years. EDs are often intractable and induce the development of various physical disorders, including renal dysfunction and mineral disorder, occasionally progressing to end-stage kidney disease (ESKD). At present, information is limited regarding the renal manifestations, so no consensus has been established regarding the clinical practice guideline for ED patients referred to nephrologists. The study aimed to clarify the clinicopathological characteristics of ED nephropathy (EDN).

Methods: Patients with EDN who were referred to and cared for at our related facilities from January 1992 to December 2017 were retrospectively analyzed. The renal outcomes were defined as doubling of the serum creatinine level and/or progression to ESKD.

Results: The present study included 14 female cases. The mean age at the ED onset was 22.3 years, and the duration from the onset to the initial visit with a nephrologist was 17.8 years. At the first visit with a nephrologist, the serum creatinine level was 1.6 mg/dl, serum potassium level was 2.7 mmol/l, and body mass index (BMI) was 13.1 kg/m^2. All cases showed hypokalemia and either addictive vomiting or diuretics/laxatives abuse. During the average observation period of 5.8 years, renal outcomes occurred in 9 cases, and 2 died due to their ED. The body weight, BMI and estimated glomerular filtration rate at the first visit in the group who developed renal outcomes were significantly lower than in those who did not develop renal outcomes. A renal biopsy was performed in four cases. One early case of ED showed hypertrophy of the juxtaglomerular apparatus, while three advanced cases showed glomerular collapse and interstitial fibrosis predominantly in sub-capsular regions, consistent with peripheral circulatory failure and low-potassium nephropathy.

Conclusions: Advanced renal impairment and a severely lean state at the first visit may be predictors of poor renal outcomes in cases of EDN. In a majority of patients with EDN, the degree of renal injury is already severe at the time of their first referral to a nephrologist. Improving the renal outcomes of EDN may require tighter collaboration with psychiatrists and earlier intervention by nephrologists.

PUB407

A Whole Food Plant-Based Diet Can Be Safe and Beneficial in Dialysis Patients: A Case Report

Rebeca D. Monk,[1] Darlene H. Steele.[2] [1]*University of Rochester, Rochester, NY;* [2]*Fresenius Kidney Care, Penfield, NY.*

Introduction: The demonstrated benefits of a whole food plant-based diet (WFPBD) include weight loss, lipid reduction, improved glycemic control in diabetics and regression of atherosclerosis in patients (pts) with coronary artery disease. Small studies utilizing a WFPBD, low animal protein intake, or addition of fruits and vegetables to the diets of pre-dialysis pts with chronic kidney disease (CKD) have demonstrated lower phosphorus (phos) and FGF 23 levels (both associated with higher mortality), improvement in metabolic acidosis, and less GFR decline without adverse effects. Utilization of a WFPBD in dialysis pts, however, is deemed potentially dangerous due to risk for low serum albumin and hyperkalemia.

Case Description: A 58-year-old woman with type 1 DM, HTN, CAD s/p MI and CVA was denied listing for kidney transplant. Following this, she embarked on a purely WFPBD. Potassium (K) levels in the 6's (often requiring 1K dialysate) were common before she started the diet. Diet included beans, peanut butter, hummus, grains, vegetables, fruits. Her labs improved significantly with the diet (see table). K was checked frequently. PM isulin dose decreased by 38%. Weight decreased from 69 kg to 65.6 kg in 2 months with BMI decline from 26.1 to 24.8. The pt reported improved energy.

Discussion: Potential adverse effects of the standard American diet and animal protein intake in CKD pts include greater phos absorption, inflammation, vacular calcification, a dysbiotic microbiome, acid generation, and high K. The higher fiber WFPBD generates base, reduces serum phos, enhances weight loss, and may improve the microbiome. In this pt, phos decreased rapidly, albumin remained > 4 and potassium did not increase. A WFPB diet may offer significant health benefits without risk for hypoalbuminemia or hyperkalemia.

Patient Labs Before and After WFPBD

Labs:	Month Before WFPBD Started:	Month After WFPBD Started
Potassium	5.8, 5.2	5.5, 5.7, 5.9, 5.5, 5.1
Bicarb	23	29
Albumin	4.5	4.3
Phos	5.4	3.8

PUB408

Utilizing Dialysis Clinical and Laboratory Markers to Identify Risk for Major Depression Disorder in Dialysis Patients

Ahmad Kaddourah,[1] Abdullah Hamad,[1] Tarek A. Fouda,[2] Mostafa F. Elshirbeny,[3] Rania A. Ibrahim,[1] Shaza Y. Elsanoosi,[4] Fadwa S. Al-Ali.[1] [1]*Hamad Medical Corporation, Doha, Qatar;* [2]*Hamad medical cooporation, Doha, Qatar;* [3]*HMC, ----Doha, Qatar;* [4]*Hamad medical corporation, Doha, Sudan.*

Background: Depression is the most common psychiatric disorder in patients with end-stage renal disease (ESRD) on dialysis. Despite of being widely prevalent, depression is often underdiagnosed in this population. Diagnostic screening surveys are available to identify high risk patients; however, these tools are time consuming and not applied regularly in busy dialysis units. We hypothesize that risk of depression can be predicted using common clinical variables which are screened frequently in dialysis units.

Methods: We conducted a prospective cross-sectional study in ESRD patients receiving either hemodialysis (HD) or peritoneal dialysis (PD) in the main ambulatory dialysis unit in the state of Qatar. Eligibility criteria was all adult ESRD patients who have been receiving dialysis for at least one month duration. All enrolled patients underwent depression screening using the Center for Epidemiologic Studies Depression Scale (CESD-R) which has been validated by the American Psychiatric Association' Diagnostic and Statistical Manual (DSM-V) for a major depressive episode. Clinical variables were enrolled of logistic and linear regression models to assess the correlation.

Results: 253 patients with ESRD on dialysis were enrolled. 157 (62%) patients were on HD and 96 (38%) on PD. 122 (48%) patients had depression disorder, defined as CESD-R score ≥ 16. No significantly difference in depression prevalence was detected between HD and PD patients (P=0.55). Bivariate analysis showed that depressed patients have lower hemoglobin levels (mean log Hgb 2.4 (±0.1) vs 2.3 (±0.1), P= 0.04) and higher Hb1AC levels (mean log Hb1Ac 1.8 (±0.2) vs. 1.7 (±0.2), P=0.04) than non-depressed patients. Univariate regression analysis revealed no significant correlation between depression disorder and BMI, serum albumin, Vitamin D level, parathyroid hormone level, serum calcium, phosphate level, nor Kt/V.

Conclusions: Up to 50 % of our adult ESRD patients on dialysis have depressive disorder as per CESD-R score. Our data suggests that Hgb and Hb1AC levels can be utilized to predict patients at increased risk of depression. This will allow early diagnosis and management of depression which can imrpove clinical outcomes.

PUB409

Intradialytic Hypertension and Mortality Risk Among Hemodialysis Patients In National Kidney and Transplant Institute

Amerigo S. Bautista,[1] Concesa Casasola,[1] Romina A. Danguilan,[1] Eduardo K. Lacson.[2] *[1]National Kidney and Transplant Institute, Quezon City, Philippines; [2]Tufts University School of Medicine, Boston, MA.*

Background: Hypertension is prevalent in hemodialysis patients and contributes to cardiovascular morbidity and mortality.

Methods: Blood pressures before and after hemodialysis were recorded and used to classify patients during the baseline period (N=153). Patients were followed for up to 2 years or until death.

Results: The cohort's mean age was 59.3 years old with male predominance (56%) and DM nephropathy (48.4%) as primary renal disease. The intradialytic hypertension group (n=47) had significantly higher change in systolic blood pressure (16.4 vs – 3.2 mmgHg), post dialysis systolic (165.2 vs 147.5mmHg) and mean arterial (106 vs 97.8mmHg) blood pressure compared to 106 patients without intradialytic hypertension. One and two year overall cumulative survival of patients with intradialytic hypertension compared to patients without were 95.1% vs 92.86% and 66.12% vs 63.03%, respectively. Risk for all cause mortality non-significantly trended lower with intradialytic hypertension (HR=0.98, p=0.271), female gender (HR=0.77,p=0.495) and use of calcium channel blockers (HR=0.764, p=0.46).

Conclusions: In this South East Asian national referral center, intradialytic hypertension did not increase the hazard for 2 years all cause mortality of hemodialysis patients.

Prevalence of High Blood Pressure Among Teenagers, With Its Pattern and Related Factors

Jafar Al-Said. *Bahrain Specialist Hospital, Manama, Bahrain.*

Background: Hypertension prevalence is increasing worldwide. Studying the BP among teenagers might give some ideas regarding preventive measures that can decrease the incidence of HTN during adult life. **Aim of this study:** 1-Identify the prevalence of high BP among teenagers. 2-Determine the pattern of the high BP, whether systolic or diastolic. 3-Identify the factors that are related to high BP among this age group.

Methods: This is a cross sectional study with screening of teenagers between 13-20 years attending thirteen middle and high schools in Bahrain. All the students were screened. The consent was obtained from the school administration and the parents. Demographic factors were collected. BP was checked after 3 minutes rest while sitting on an armed chair with both feet on the ground. Two measurements were obtained from the Lt. arm with one minute interval. Ht., wt. and waist circumference were measured for each student. Data were analyzed with SPSS 18. P<0.05 was required for rejecting the null hypothesis.

Results: 2467 students were included. Mean age was 13.5 years (SD 2, SE 0.04). Males were 53%, Mean wt. was 56kg (SD 18.4, SE 0.4). The mean waist circumference was 73.8 cm (SD 17, SE 0.35). Mean Ht. was 157cm (SD 11, SE 0.23). Mean BMI was 22 Kg/m^2 (SD 5.8, SE 0.11). 53% of the students had high BP according to their age, gender and height percentiles. The high BP within the hypertensive ranges were more than the measures within the Prehypertensive range (40% versus 23%). P 0.043 The BP was inversely correlated with age and BMI. The correlation coefficient for age was -0.32, P <0.0001. The correlation coefficient for BMI was -0.068, P 0.003. Systolic BP rather than diastolic BP was more prevalent, 19% versus 4%. P 0.027. Age, gender, waist circumference, nationality and pulse rate were the independent variable related to high BP in mulitvariate regretion model.

Conclusions: There was an unexpected high prevalence of elevated BP among teenagers. The pattern of the high BP was surprisingly systolic rather the diastolic. Hypertensive BP levels were higher than prehypertensive levels. The young age and low BMI were associated with higher BP. These findings would suggest a complete different pattern of BP among teenagers. More research focused efforts are required to elaborate on each of these points to determine significant monitoring and preventive strategies.

PUB411

Real Harakiri Sagliker Effect: Hypertensionologist's Hypertension: Ambulatory Blood Pressure Monitoring of Doctors: Combination-Compilation of Reverse White Coat and Physical Exercise Effects

Yahya Sagliker. *Sagliker Hypertension Unit, Adana, Turkey.*

Introduction: It is known some normals and hypertensives get higher BP when facing medical environments or devices. Effect called WCE or WCH.We examined if same be also found in doctors in outpatient clinics. This is first medical hypothesis so far on subject

Case Description: 58 Doctors examined daily 12 hypertensives by measuring BP themselves with classical manual recorders by pumping the cuffs, every 10 minutes for two hours first day, then relaxed consecutive day, similarly two hours. Same time doctor's SBP, DBP, MAP, HR (by Mobilograph ABPM machine) were measured, two hours NE,E,VMA, metanephrine in urines and plasma NE,E, PRA, A, A II examined. in doctors. Additionally plasma A II levels examined just before BP recordings in first stress day. Doctors' all those parameters decreased from first stress day to the second relaxation day.. Interestingly plasma AII decreased from time of prerecordings to time of postrecordings in first stres day. P values for differences were less than 0,001.

Discussion: Doctor's had higher SBP,DBP,MAP,HR,PRA,A, cathecolamins in urines and plasma after examinations. Reduction of AII at time of postrecordings be explained by AII's short half life. If AII be examined continously during measurements, could be found higher at first but decreasing tremendously by time till end-point. Staff could face complications, cerebrovascular attacks, myocardial infarctions, blindness if they have hypertension or prone to it. Doctors manual recordings were a reverse white coat effect plus hand grip exercise test and dangerous. In developping countries as Turkey, India, Pakistan, Bengladesh, China, Endonesia, Maleysia where 100-150 patients examined and BP recorded daily only by one doctor, manual recorders be banned by legistlations and started first in history via ASN, ISH, WHO. And this novel phenomenon should be called Sagliker Effect. This is a sine qua non humanity task.

Table 1. Parameters before and after stress and after relaxation

Individualized Hypertension Treatment: More Information, Better Results

Yossi Chait,[1] Joseph Horowitz,[1] Barbara A. Greco,[3] Michael J. Germain.[2] *[1]University of Massachusetts, Amherst, MA; [2]Renal and Transplant Assoc of New England, Hampden, MA; [3]Renal and Transplant Associates of New England, Springfield, MA.*

Background: High blood pressure (BP) is a leading cause of death and disability in the US and worldwide. Approximately 1 of 3 U.S. adults (75 million) has high blood pressure, and only about half treated with antihypertensive therapy achieve the recommended blood pressure target. Our aim was to observe BP outcomes in standard hypertensive management augmented by hemodynamic information.

Methods: A hemodynamic measurement using noninvasive impedance cardiography (NICaS) was recently added in our hypertension (HTN) clinic, a part of a nephrology group that manages chronic kidney disease (CKD) and referred resistant hypertension patients. Clinicians were informed about measured hemodynamic parameters, however, there were no algorithmic changes made in the HTN treatment protocol. We retrospectively collected

data for patients that had at least one hemodynamic measurement and at least one follow-up visit.

Results: We found 86 eligible patients; mean (SD) number of hemodynamic measurements was 1.6 (0.8). Mean (SD) age was 62.6 (18.1) years, 48 (56%) were female, and 39 (45%) had CKD. Systolic BP (SBP) and diastolic BP (DBP) at time of initial hemodynamic measurement (initial) and at most recent office visit (current) are reported in Figure 1. Target BP results for non-CKD (SDP<140 and DBP<90 mmHg) and CKD (SDP<130 and DBP<80 mmHg) are shown in Figure 2. Mean number of HTN meds was unchanged (2.54 and 2.46, respectively).

Conclusions: Impedance cardiography is a simple, noninvasive method for evaluating underlying hemodynamic drivers of HTN and provides clinically important BP-complementary information for treatment. The encouraging BP reductions prompted us to initiate a new study that compares standard care with a new protocol comprising hemodynamic and pulse wave velocity measurements and a tailored algorithm for medication changes.

Posterior Reversible Encephalopathy Syndrome (PRES) with Acute and Chronic Kidney Disease (AKI/CKD): Five Cases in Eight Years - Should Nephrologists Consider It More Frequently?

M M Papaginovic,[1] E. Mojico,[2] M E Nicolini,[2] M H Serrano,[3] P R Martinez,[2] R d Martinez.[3] the working group *[1]Uspallata 3400, Complejo médico Churruca visca, Buenos Aires, Argentina; [2]Hospital Churruca, Buenos Aires, Argentina; [3]hospital churruca, AVELLANEDA, Argentina.*

Introduction: PRES is a clinical and radiological condition with manifestations such as headaches, seizures and altered mental status that shows reversible cortico-subcortical vasogenic edema in Neuroimaging, predominantly bilateral. It is associated with arterial hypertension(AH), autoimmune disease, AKI/CKD, drugs and pregnancy It is usually reversible and recurrent Magnetic resonance(MRI) is the gold standard to diagnose and detect lesions in PRES

Case Description: We present 5 cases of women patients with acute neurological symptoms in the context of AH,AKI/CKD MRI/CT diagnosed PRES Four of them needed RRT All of them recovered after controlled AH (See Summary of the patient's history, MRI findings and final outcome)

Discussion: PRES is a rare disease related to different clinical entities and different pathophysiological origins that causes a delay in diagnosis Our cases are clinical entities with different backgrounds and heterogeneous pathophysiological bases All pacients were women and presented AH and seizures, only one was recurrent and affected 2 or more cerebral lobes Early diagnosis makes a difference in patient outcomes It usually resolves, being the triggers usually identifiable AKI/CKD are cormobid factors for PRES so it is important to consider them at the time of diagnosis in patiens with neurological symptoms

Predictability of Elevated Troponin for Angiographic Coronary Artery Disease in Patients with CKD

Bhavin Chokshi,[1] Balaram krishna J. Hanumanthu,[2] Sachin Batra,[2] Poonam Mahato,[2] Muhammad I. Pervez,[2] Lilian L. Bizzocchi,[2] Belinda Jim.[3] *[1]Jacobi Hospital Medical Center, Bronx, NY; [2]Jacobi Medical Center, Bronx, NY; [3]Albert Einstein College of Medicine, New Hyde Park, NY.*

Background: Troponins are elevated in patients with myocardial damage. An association exists between angiographic coronary artery disease (CAD) and troponin elevation in patients with normal kidney function; however, this association remains unclear in patients with chronic kidney disease (CKD). Mild to moderate elevation of troponins are frequently seen in this patients and interpretation for the most part is at the discretion of the treating physician.

Methods: We retrospectively reviewed all coronary angiograms performed at our center between April 2007 to May 2017. Baseline demographic, laboratory, and angiographic characteristics were analyzed using STATA® software. KDOQI staging for CKD was used and GFR was calculated using CKD-EPI formula. Angiographic finding was categorized as normal, mild (<50%), moderate (50-69%), and severe (≥70%) stenosis of any major epicardial coronary artery.

Results: Of the 795 patients, 433 were men (54%). Mean age of the patients was 63 +/- 27 years. Prevelance of hypertension and diabetes mellitus was significantly higher in patients with CKD stages 3-5 compared to normal GFR ($p < 0.001$) but other risk factors for CAD were similar in between groups. Multivariate logistic regression analysis showed no significant difference in mean troponin I (cTnI) levels in severe and non- severe coronary artery stenosis across any CKD stage. However, statistically significant peaks were observed in patients with CKD stages 4 and 5 (20.9 times, P<0.001 [CI 13.5-28.4] and 6.4 times, P=0.007 [CI 1.72-11.1] respectively). Patients with severe (>70% stenosis) CAD had higher mean cTnI levels compared to non-severe stenosis (p<0.02). ROC curve showed cTnI > 0.304 ng/mL had 60% sensitivity, 61.6% specificity and positive likelihood ratio 1.56 for finding severe stenosis.

Conclusions: We found no significant association between modest elevation in Troponin I and angiographically signifcant coronary disease in patients with any stage of CKD. Troponinemia >0.304 ng/mL in proper clinical setting and a rising trend may require additional work up including cardiac catheterization in patients with CKD as per our analysis.

Variables	GFR ≥90 (n = 339)	GFR 60-89 (n = 180)	GFR 30-59 (n = 180)	GFR 15-29 (n = 25)	GFR <15 (n = 71)
Non-severe stenosis (mean; SD)	4.5 ± 0.9	2.0 ± 0.8	6.4 ± 1.4	14.0 ± 11.5	3.0 ± 7.4

Treatment and Prognosis of Malignant Hypertension

Guangqun Xing. *The Affiliated Hospital of Qingdao University, Qingdao, China.*

Background: We systematic analyzed the data on treatment of MHT to find a way for best outcome.

Methods: 30 patients diagnosed with MHT were enrolled in this study. The clinic data,treatment strategy and prognosis were analyzed.

Results: The better effect could be expected during 6 months. The plasma level of rennin and aldosterone were higher than the normal at the initiation stage of MHT. However

the presence of thrombotic microangiopathy (TMA) was not found to predict end-stage renal disease(ESRD).

Conclusions: RAAS activation was involved in the pathogenesis of MHT with both primary or secondary origin. RAAS blacker, especially captropril was selected as the first choice for the treatment on MHT despite much higher serum creatinine in the common sense. Long duration at least for 6 months treatment with RAAS blockers could reach the best outcome. The etiology treatment should be initiated for good of patients' future prognosis.

Mechanisms of Cardiovascular Complications in CKD: Research Focus of the German Transregional Collaborative Research Center SFB/TRR219

Heidi Noels,[1] Nikolaus Marx,[5] Jürgen Floege,[4] Michael Böhm,[2] Joachim Jankowski.[3] SFB/TRR219 *[1]RWTH Aachen University, Aachen, Germany; [2]Saarland University Medical Center, Homburg, Germany; [3]RWTH Aachen University, Aachen, Germany; [4]RWTH University of Aachen, Aachen, Germany; [5]University hospital Aachen, Aachen, Germany*.

Background: Patients with chronic kidney disease (CKD) exhibit a massively increased risk for cardiovascular events, and traditional strategies to improve cardiovascular outcome have largely failed in the context of CKD. The classical cardiovascular risk factors such as smoking or overweight have less impact on cardiovascular disease in CKD patients compared to the general population, indicating that in addition to traditional risk factors, novel and hitherto unknown mechanisms may be important in driving cardiovascular disease in CKD and that CKD *per se* represents an independent risk factor for cardiovascular events.

Methods: Reducing cardiovascular mortality in CKD patients through novel therapeutic strategies first requires the identification and understanding of CKD-specific pathological mechanisms. To achieve this goal, two German universities, the RWTH University of Aachen and the Saarland University, have initiated the Transregional Collaborative Research Center 219 (SFB/TRR219) "Mechanisms of Cardiovascular Complications in Chronic Kidney Disease" (www.sfb-trr219.de). This consortium aims to analyze the multi-faceted mechanisms of CKD-related cardiovascular disease in experimental and clinical studies, with a total of 17 interdisciplinary research teams from cardiology, nephrology, biophysics and molecular biology joining forces.

Results: Our current understanding of the increased cardiovascular risk in CKD is based on the interaction of the kidney with the circulation (encompassing the vascular system and blood) and the myocardium. This increases cardiovascular risk by triggering pathological mechanisms. In analyzing these mechanisms and their role in the complex interaction between kidney, vasculature and heart, the SFB/TRR219 is mainly focusing on increased calcification, inflammation, oxidative stress, fibrosis, thrombosis and neurohumoral dysregulation in CKD.

Conclusions: By collaborative and translational research based on existing interactions between groups of different clinical and methodological expertise, the German SFB/TRR219 pursues the overall long-term goal to gain understanding of the renal and cardiovascular interactions that may contribute to the development of novel treatment strategies to decrease cardiovascular risk in CKD patients.

Pathological Analysis and Serum Reactivity of Anti-GBM Disease/IgG1 Is Dominantly Deposited in the Glomeruli in Anti-GBM Disease

Yayoi Ogawa,[1] Hideki Takizawa,[2] Yoshinosuke Shimamura.[2] *[1]Hokkaido Renal Pathology Center, Sapporo, Japan; [2]Teine Keijinkai Hospital, Sapporo, Japan.*

Background: Anti-glomerular basement membrane glomerulonephritis (anti-GBM GN) is caused by circulating autoantibodies against mainly the noncollagenous-1 (NC-1) domain of the alpha 3 chain of type IV collagen. NC-1 domain must be dissociated in order for autoantibody binding to occur. 30% of anti-GBM GN patients are seropositive with anti-neutrophil cytoplasmic antibody (ANCA). Bowman et al reported IgG1 and 4 were dominant in the patient serum and renal eluates, Here we analyze the IgG subclass deposited on GBM in anti-GBM GN cases and patient's serum reactivity to glomeruli in biopsied tissue of ANCA-associated vasculitis (AAV), and other GN cases to evaluate the production of autoantibody formation in anti-GBM GN.

Methods: Kidney biopsy specimens from 16 patients diagnosed with anti-GBM glomerulonephritis between April 2009 and March 2018 were identified in Hokkaido Renal Pathology Center. Renal frozen tissue of AAV (anti-GBM seronegative) and other glomerular diseases were stained by a serum from the patient with anti-GBM disease using indirect immunofluorescence method.

Results: The age range was 15 to 83 years. Serologic titers for anti-GBM were raised (7.1->350) in all cases, and serologic studies for ANCAs were positive in 4 cases. One case superimposed IgA nephropathy, and other one showed remarkable granulomatous inflammatioLight microscopy revealed crescentic formation (80.5±17.8%) and linear GBM staining was detected by immunofluorescence study. The number of preserved glomeruli was correlated with baseline eGFR (R^2=0.4407, p<0.01). 14 renal tissues were available for staining with anti-IgG1,2,3, and 4. IgG1 dominant staining was detected in all 14 cases. Cases with more than 2 times brightness of IgG1 staining were seen in younger cases (p<0.05). Glomeruli of biopsied tissue of AAV cases were stained with serum IgG of anti-GBM disease, although glomeruli of MCNS were negative.

Conclusions: IgG1 was mainly deposited on GBM in anti-GBM disease similar to the previous report (Bowman et al, Clin Exp Immunol 1987). The serum reactivity to GBM in AAV suggests that the rupture of GBM is one of the triggers for the pathogenesis of anti-GBM and ANCA double positive disease.

PUB418

Selection of Housekeeper Genes for Real Time Quantitative PCR (qRT-PCR) Analysis of Rat Kidney Tissues Under Ischaemic and Toxicological Conditions

Sanjeeva C. Herath,[1] Kylie M. Taylor,[1] Amy Au,[2] Zoltan H. Endre,[2] Jonathan H. Erlich.[1] Australian Renal Biomarker Reference Laboratory *[1]University of New South Wales, Kensington, NSW, Australia; [2]Prince of Wales Hospital, Randwick, NSW, Australia*.

Background: Appropriate selection of housekeeper genes (HKG's) is pivotal to obtaining accurate and reproducible results in qRT-PCR. Studies have shown that the more commonly used HKG's are not constant under different experimental conditions. Hence we aimed to determine the most opitmum HKG's and normalization factor (NF) for the study of target gene expression in rat kidney tissues.

Methods: Control and adenine fed Sprague Dawley (SD) rats were equally divided into 6 intervention groups consisting of 8 biological replicates. The intervention groups consisted of a subclinical CKD (sCKD), acute kidney injury (AKI), AKI on a background of sCKD, recovery and a control group. AKI was induced with cisplatin or ischaemia. sCKD was induced with 0.25% adenine. 10 commonly used candidate HKG's from different functional classes were selected.. The stability of gene expression was analyzed utilizing NormFinder, Genorm, BestKeeper and comparative delta Cq statistical algorithms. Weighted rank aggregation by Brute force method and by cross entropy Monte Carlo method was used to achieve a consensus rank of genes.

Results: Results: Ranking of the candidate HKG's by each algorithm is listed below in table 1 below (see table) PABPN1, HMBS, YWHAZ, YWHAG and SDHA were respectively determined to be the 5 most stable HKG's by consensus ranking. The optimum number of HKG's needed for most stable normalization factor (NF) was determined to be 3 with 2 also giving an improved result. By comparison, the commonly used GAPDH and 18S were the least stable of all 10 HKG's studied.

Conclusions: Construction of a normalisation factor by utilizing two or three most stable HKG's which includes HMBS and PABPN1 produces the least variability to control for experimental errors and adjusted for inter-sample variations in rat kidney studies

Funding: Government Support - Non-U.S.

Double-Negative T Cells in Human Renal Cell Carcinoma – Potential Target for Immune Checkpoint Inhibition

Johanna T. Kurzhagen,[1] Sanjeev Noel,[1] Mohanraj Sadasivam,[1] Sul A Lee,[1] Jing Gong,[1] Abdel Hamad,[1] Phillip M. Pierorazio,[3] Hamid Rabb.[2] *[1]Johns Hopkins University, Baltimore, MD; [2]Johns Hopkins University School of Medicine, Baltimore, MD; [3]Brady Urological Institute, Johns Hopkins University, Baltimore, MD.*

Background: $CD4^-CD8^-$ double-negative (DN) T cells are an unconventional subset of T cells, that are found in normal human and mouse kidney. Their immunomodulatory potential has been proposed in hematological malignancies and melanoma. Immune cells are involved in the pathogenesis of renal cell carcinoma (RCC). However, whether DN T cells are present in RCC is not known.

Methods: RCC and normal tissue adjacent to the tumor were collected from 11 RCC patients after nephrectomy. Kidney mononuclear cells were isolated immediately following tissue procurement and immunophenotypic analyses was performed for $CD45^+$, TCR^+, $CD4^+$, $CD8^+$, $CD20^+$, $CD16^+$, $CD14^+$, $CD11c^+$ and $CD206^+$ cells using flow cytometry.

Results: The mean age of the cohort was 59.8 years. The average maximal tumor diameter was 6.8 cm. Our results demonstrate the presence of DN T cells in RCC tissue as well as in normal kidney tissue (N) with a similar frequency (N: 5.86%, RCC: 6.17%, p=0.918). This was in spite of a significant increase of $CD45^+$ lymphocytes in the RCC tissue in comparison to the normal kidney tissue (N: 8.22% vs. RCC: 44.76%, p=0.001).

In contrast, B cells ($CD20^+$) and M2 macrophages ($CD206^+$) were significantly decreased in tumor tissue ($CD20^+$: N: 21.2% vs. RCC: 5.91%, p=0.002; $CD206^+$: N: 8.44% vs. RCC: 0.90%, p=0.003). There was no significant difference in TCR^+, $CD4^+$, $CD8^+$, $CD16^+$, $CD14^+$ and $CD11c^+$ cell frequencies between RCC and normal kidney tissue (see figure).

Conclusions: This data demonstrates that DN T cells are present in RCC tissue with a frequency similar to "normal" kidney tissue. Given recent data showing PD1 expression on DN T cells, these cells could be potential targets for checkpoint inhibitors and other immunotherapeutic approaches.

Funding: NIDDK Support, Private Foundation Support

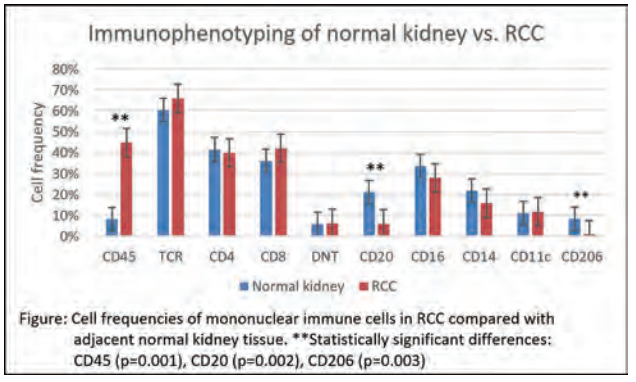

Figure: Cell frequencies of mononuclear immune cells in RCC compared with adjacent normal kidney tissue. **Statistically significant differences: CD45 (p=0.001), CD20 (p=0.002), CD206 (p=0.003)

PUB420

Emerging Role of Post-Translational Modifications in CKD and Cardiovascular Disease

Vera Jankowski,[3] Heidi Noels,[2] Joachim Jankowski.[1] *[1]RWTH Aachen, Aachen, Germany; [2]RWTH University Aachen, Aachen, Germany; [3]University hospital RWTH Aachen, Aachen, Germany.*

Background: Post-translational modifications of proteins and peptides have recently gained much attention, as they are involved in the pathogenesis of cardiovascular disease and eventually also in the progression of chronic kidney disease.

Methods: We provide an overview of post-translational protein modifications such as carbamylation, glycation and oxidation, starting with their definitions, mechanisms and clinical relevance in the setting of chronic kidney disease and cardiovascular disease.

Results: The methods currently used for the identification and especially quantification of post-translational modifications are described and potential treatment options in the context of post-translational modifications are reviewed.

Conclusions: We concluded that advancements in mass-spectrometry-based methods will certainly boost the clinical utility of sample analyses, leading to the identification of novel disease markers and/or pathophysiologically relevant factors

PUB421

Angiopoeitin-2 and Procalcitonin as Biomarkers of Atrial Fibrillation in CKD and Sepsis

Jack Bontekoe,[2] Vinod K. Bansal,[1] Justin Lee,[2] Debra Hoppensteadt,[1] Paula D. Maia,[3] Jawed Fareed.[1] *[1]Loyola University Medical Center, Maywood, IL; [2]Loyola University Stritch School of Medicine, Howell, MI; [3]Loyola University of Chicago, Maywood, IL.*

Background: Angiopoeitin-2 is a 497 amino acid protein which is involved in vascular remodeling. Procalcitonin (PCT) is a 116-amino acid pro-peptide expressed in non-neuroendocrine tissues. Both biomarkers are upregulated in response to inflammation and cellular injury, particularly in the setting of bacterial sepsis. Ang-2 and PCT are elevated in stage 5 chronic kidney disease on hemodialysis (CKD5-HD), but their relevance with inflammatory cardiac conditions, such as atrial fibrillation (AF), has not been established. Monitoring Ang-2 and PCT levels in CKD5-HD patients may have a dual predictive role in the evaluation of AF and sepsis. Comorbid AF amplifies circulating levels of Ang-2 and PCT are upregulated in CKD5-HD.

Methods: Plasma levels of PCT, CD40-L, CRP, vWF, D-dimer, Ang-1 and Ang-2 were measured in 93 CKD5-HD patients and 50 normal controls using ELISA methods. Patient records established comorbid AF (n=23) and history of sepsis (n=35, mean days from resolution=762, SD=730).

Results: PCT levels were significantly elevated in CDK5-HD patients with comorbid AF (p= 0.0270) but not in patients with a history of sepsis (p=0.3441). In patients with a history of sepsis, PCT levels were elevated only in those patients with comorbid AF (p=0.0405). Notably, of the other inflammatory biomarkers measured, only Ang-2 levels resulted in differentiating between CKD5-HD patients with a history of sepsis (p=0.0138).

Conclusions: In CKD5-HD patients, increased pro-inflammatory processes associated with AF substantially increases PCT and Ang-2 levels. In patients with a history of sepsis, only those with AF demonstrated elevated ANG-2 and PCT levels, therefore measurement of these biomarkers may be useful in the evaluation of AF in post-septic CKD5-HD patients. Sustained inflammation as a result of sepsis may predispose patients at a greater risk of developing AF. Evaluation of this relationship may further elucidate the role of inflammation and the long-term effect of endothelial damage in the pathogenesis of AF.

PUB422

Upregulation of Biomarkers of Neurovascular Diseases in Patients with Stage 5 CKD

Justin Lee, Jack Bontekoe, Vinod K. Bansal, Jose Biller, Debra Hoppensteadt, Paula D. Maia, Trung Phan, Jawed Fareed. *Loyola University Medical Center, Maywood, IL.*

Background: Patients with stage 5 chronic kidney disease (CKD5D) have a higher risk for developing neurovascular complications. Chronic inflammation from renal failure increases the risk for these diseases through oxidative stress and vascular dysfunction. To profile levels of inflammatory and hemostatic biomarkers in CKD5D plasma, and relate measurements to neurovascular diagnoses and demonstrate their relevance to neurovascular deficit.

Methods: Eleven plasma biomarker levels in CKD5D patients (n=97) and healthy controls (n=17-50) were measured using sandwich ELISA method. The biomarkers in this study were of inflammation and hemostatic dysregulation, which included angiopoietin-1 (Ang-1), angiopoietin-2 (Ang-2), CD40 ligand (CD40L), C-reactive protein (CRP), D-dimer, intercellular adhesion molecule-1 (ICAM-1), NACHT, LRR, and PYD domains-containing protein 3 (NALP3), plasminogen activator inhibitor-1 (PAI-1), procalcitonin (PCT), tumor necrosis factor alpha (TNFα), and von Willebrand factor (vWF). Of the 97 CKD5D patients, 24 had CCAD, 19 had ICAD, and 23 had acute stroke. The results were expressed as mean ± standard error of the mean. Statistics were performed with Mann-Whitney t-tests, Kruskal-Wallis non-parametric ANOVA, and non-parametric Spearman correlations.

Results: All of the biomarkers had elevated levels in CKD5D plasma, except for PAI-1 (p=0.9764), compared to controls. Statistical significance was only found between CKD5D (+) and (-)ECAAD NALP3 (p=0.0299), and between (+) and (-)stroke D-dimer (p=0.0258). Ages between each (+) and (-) disease groups were also significant (p=0.0002 ECAAD; p<0.0001 ICAD; p=0.0157 stroke). D-dimer was correlated with age in CKD5D (r=0.2115, p=0.0375).

Conclusions: Previous studies have demonstrated a relationship between NALP3 expression and the instability of atherosclerotic plaques in ECAAD. NALP3 is a component of inflammasomes, the presence of which elevates IL-1β and IL-18, which subsequently increases risk of ECAAD and stroke. Despite upregulation, biomarker profiling is of limited use in risk stratification of neurovascular diseases among the CKD5D population, with the possible exception of NALP3 for ECAAD.

PUB423

Microdroplets in Minimal Change: A Novel Finding

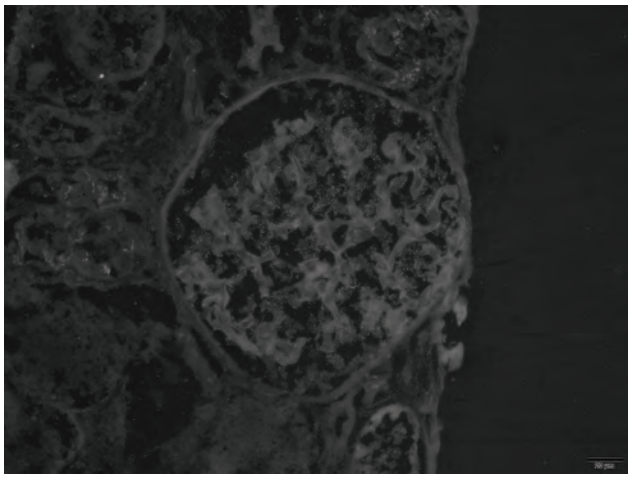
Amanda Tchakarov,[1] William F. Glass.[2] *[1]Pathology, McGovern Medical School, Houston, TX; [2]Pathology, McGovern Medical School, Houston, TX.*

Background: Minimal Change (MCD) is a frequent cause of nephrotic syndrome. MCD results from podocytopathy with filtration barrier changes causing proteinuria. While it is thought circulating mediators lead to podocytopathy, little has been determined about the mediator. In our practice we have noted that many MCD cases have IgG-positive microdroplets in Bowman's space, detectable by IF. We conducted this study to characterize these microdroplets.

Methods: Our database of imaged LM, EM, and IF stains from 2013-16 was reviewed for cases of MCD (n=42), primary FSGS (n=10), collapsing FSGS (n=4), tip lesions (n=5) and normal biopsies (n=12). The presence of microdroplets in images was noted. Additionally, a subpopulation of MCD cases was stained for IgG subtypes and C4d by IF.

Results: Database review revealed 45% (19/42) of MCD cases, 1 out of 10 primary FSGS, and 1 out of 5 tip lesion cases contained IgG dominant microdroplets. Microdroplets were absent in normal biopsies and collapsing glomerulopathy. IgG intensity ranged from weak to 1+. Some microdroplets also stained for IgA (n=1), C3 (n=1), kappa (n=11) and lambda (n=10). A subset of MCD cases (n=8) were stained for IgG subtypes, half which were originally negative for microdroplets. IgG1 microdroplets were present in 88% of cases, 25% were positive for IgG2. All cases were IgG3 and IgG4 negative. A single case, originally negative, showed no subclass staining. One case (13%) had C4d positivity.

Conclusions: To our knowledge the phenomenon of glomerular microdroplets has not been reported. Due to the location and distribution, we believe they represent endocytotic vesicles in podocytes. Subtype restriction suggests there is specific antibody binding to a mediator, possibly involved in causing podocytopathy. Further study to elucidate what the antibodies are binding is warranted. At the very least, we have found these microdroplets helpful in the confirmation of MCD in our practice.



IgG1 stain with diffuse microdroplets within Bowman's space.

PUB424

Kidney Diseases Associated with Tubular Reticular Inclusions (TRI)

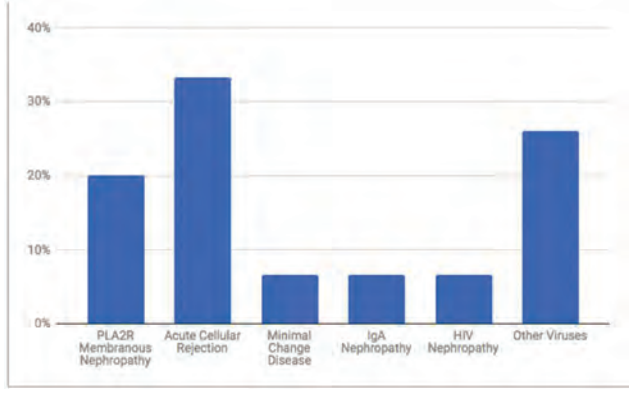
Fatima Sheikh,[1] Rimda Wanchoo,[1] Christine B. Sethna,[2] Vanesa Bijol,[3] Kenar D. Jhaveri.[1] *[1]Nephrology, Zucker School of Medicine at Hofstra Northwell, GREAT NECK, NY; [2]Cohen Children's Medical Center of NY, New Hyde Park, NY; [3]Pathology, Zucker School of Medicine at Hofstra/Northwell, GREAT NECK, NY.*

Background: Tubular reticular inclusions (TRI) in kidney biopsies are indicative of a high interferon state. They have been noted in kidney biopsies of patients with HIV nephropathy and lupus nephritis (LN). Literature is limited in other known causes of kidney diseases noted with TRI.

Methods: We reviewed all biopsies performed at our health system with findings of TRI(1 year). Clinical and pathology data were collected by chart review. Comparisons between LN patients and n-LN patients were made using student t-tests and chi-square analysis.

Results: TRI were found in 17% (55/322) of biopsies. 71% of the biopsies had LN (N = 40) & remaining 29% (N =15) had n-LN diagnoses. The 15 n-LN patients comprised of various other diagnoses (Fig). Four patients (26%) of the n-LNpatients had a virus associated disease (BK virus, parvovirus B19, hepatitis C and hepatitis B). The mean age of the LN patients was 31.5 years compared to 40.9 years in n-LN, p = 0.04. The LN were mostly females (80%) compared to the n-LN group, where 50% were females, p = 0.048. Almost 90% of LN presented with hypocomplementemia whereas only 15% of the n-LN presented with hypocomplementemia, p < 0.001. The mean presenting Scr was higher in n-LN compared to LN (2.45mg/dl vs. 1.36 mg/dl, p = 0.01). There was no significant difference in proteinuria at time of biopsy for the LN (3.69 g/day) compared to n-LN (4.82 g/day), p = 0.86. The mean 6 month Scr was 1.94mg/dl in LN patients after treatment and 1.5mg/dl in n-LN, p = 0.78. There was one LN patient and two n-LN patients that required dialysis.

Conclusions: TRI were noted in biopsies of patients with LN but also in a number of n-LN patients. Interestingly, as opposed to commonly being seen in HIV nephropathy, our pathology was mixed with new associations. The n-LN patients presented with higher serum creatinine and normal complement levels. The outcomes appear to be similar in both groups.



Pathology diagnoses of non lupus nephritis patients

Xanthogranulomatous Pyelonephritis as a CKD Cause

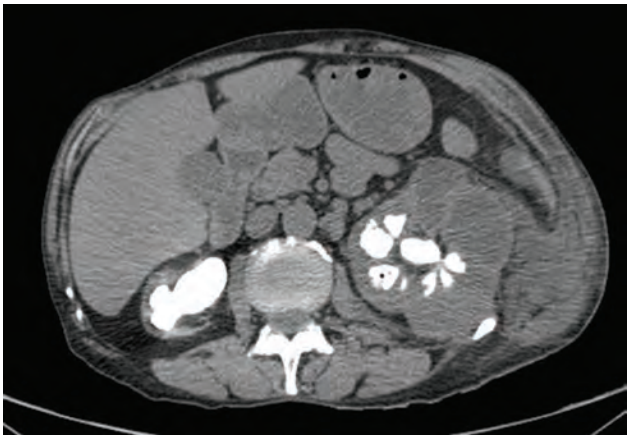
Héctor R. Ibarra-Sifuentes,[1,2] Edgar F. Carrizales Sepulveda,[2] Raymundo Vera,[2] Michelle Morcos sandino,[1] Diego Martinez yañez,[1] Regina D. Landa,[1] Fernando G. Ruiz Hernandez,[1] Angel N. Del cueto aguilera,[2] Luis I. Bonilla,[1,2] María Guadalupe R. Ramirez,[1,2] Lilia M. Rizo Topete,[1,2] Giovanna Y. Arteaga Muller.[1,2] *[1]Nephrology, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico; [2]Internal Medicine, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico.*

Background: Xantogranulomatous Pyelonephritis (XGP) is a rare chronic inflammatory condition of the kidney that appears as a complication of long-term obstruction and infection of the urinary tract. Renal parenchyma is replaced by xanthoma cells, plasma cells and histiocytes. It accounts for only 0.6% of all histologically documented cases of pyelonephritis. Due to its low frequency, most of the available information comes from case series.

Methods: The study was conducted in the University Hospital Dr. José E. González in Monterrey, during January 2012 to may 2018. All patients with XGP where retrospectively recruited for analysis. Demographics, history and physical examination, biochemical, urinalysis, urine culture and imaging studies information was extracted from patients.

Results: A total of 37 patients were included in our analysis. Females (78.4%) were affected more commonly than man. Prior renal lithiasis and urinary infection affect patients on 51.5% and 44.4% of the cases, respectively. The most common presenting symptom was flank pain (70%) and fever (63.9%). 47.5% of the cases presented with hemoglobin <10 mg/dL and 79.4% had leukocytosis. The mean GFR was 74.1 (47.8–105.3). E. coli and Morganella spp. were the most common cultured bacteria on urine. Nephrectomy was performed on all patients. Bear paw sign was only present on 9.7% of the cases (Fig 1).

Conclusions: XGP is a rare condition, commonly presenting on femele patients with prior renal lithiasis or urinary infection. The most common cultured bacteria on urine were E. coli and Morganella spp. As the main treatment modality is nephrectomy, more information about this disease is needed to improve diagnosis, management and outcomes.



PUB426

The Significance of Serum Soluble Urokinase-Type Plasminogen Activator Receptor in Diagnosing FSGS: A Meta-Analysis

Jiwon M. Lee,[1] Jae Won Yang,[2] Gaeun Kim,[5] Keum hwa Lee,[4] Jae Il Shin.[3] *[1]Chungnam National University, Seoul, Republic of Korea; [2]Wonju Christian Hospital, Wonju, GANGWON-DO, Republic of Korea; [3]Yonsei University College of Medicine, Seoul, Republic of Korea; [4]Yonsei University, Seoul, Republic of Korea; [5]Keimyung University College of Nursing, Daegu, Republic of Korea.*

Background: In the pathogenesis of focal segmental glomerulosclerosis (FSGS), circulating factors have been regarded as a significant factor, since about 40% of the patients recur after transplantation. Soluble urokinase-type plasminogen activator receptor (suPAR) has been suggested as a potential biomarker for FSGS. This study is a meta-analysis on the usefulness of suPAR for the diagnosis of FSGS.

Methods: We performed a PubMed, EMBASE and forward search of the retrieved articles and identified studies that evaluated suPAR levels in patients with FSGS, published until May 1st, 2018.

Results: Of the 187 articles reviewed, 13 fulfilled the criteria of inclusion. We observed increased level of suPAR in the FSGS patients compared to healthy controls (P<0.001, Hedge's g, 3.097, 95% confidence interval(CI), 1.666-4.527). This finding was consistent in comparison with other glomerulonephritis (GN). The suPAR levels were significantly higher in patients with FSGS compared to those with minimal change disease (MCD) (P=0.033, Hedge's g, 1.289, 95% CI, 0.107-2.471), membranous glomerulonephritis (MN) (P=0.013, Hedge's g, 1.372, 95% CI, 0.286-2.457), and IgA nephropathy (IgAN) (P<0.001, Hedge's g, 0.840, 95% CI, 0.488-1.192), respectively. Of note, however, the levels did not differ between FSGS patients with remission compared to those without (P=0.411, Hedge's g, 1.020, 95% CI -1.413-3.453).

Conclusions: The results suggested that suPAR can be a putative diagnostic indicator for FSGS in differential diagnosis of GN.

Funding: Government Support - Non-U.S.

Table 1. Summary of the all meta-analysis data

Groupwise	No. of studies	No. of subjects		Meta-analysis			Heterogeneity			Egger's test
				Hedges's g	95% CI	P-value	I^2 (%)	Tau^2	P-value	P-value

PUB427

Does ABPM Correlate with BP Diagnosis Made at Pediatric Nephrologist's Office?

Isabel Roberti,[1] Shefali Vyas.[2] [1]*Children's Kidney Center, RWJBarnabas Health, West Orange, NJ;* [2]*Children's Kidney Center, RWJBarnabas Health, West Orange, NJ.*

Background: ABPM is a helpful tool in evaluating children with variable office BPs, white coat hypertension (WCH) and uncontrolled HTN. In 2017, AAP defined the ABPM role in diagnosing/managing HTN, recommending it for any child with elevated office BP for ≥ 1 yr or with stage I HTN x 3 visits. HTN is a common reason for Ped Nephro referrals from school RN and MD's offices. Limited data exists comparing ABPM diagnosis with Ped Nephro office's BPs in children. Objective: to compare HTN diagnosis made by ABPM vs Ped Nephr office's BP and evaluate by referral source, demographic and clinical data.

Methods: ABPM was done by Welch Allyn 6100 monitor. Soergel criteria were used to define BP percentiles; SBP and/or DBP load ≥ 25% was used to diagnose HTN (% SBP and DBP > 95th). Elevated BP =90-95%, Stage I-≥95-99% and Stage II- ≥99%+5 mm Hg. Retrospective review was done in all children with 24 hour ABPM done from Jan 2011 to May 2017 at our office. IRB approval was obtained for chart access. All children diagnosed with confirmed HTN complete evaluation to r/o secondary causes and evidences of end-organ damage.

Results: 373 ABPMs were done in 361 children aged 3-21yrs (median=14yrs); 73% males; Ethnicity: 152 AA, 117 C, 71 H, 21 other. 73% had positive FH for HTN and 20% were symptomatic at presentation. LVH was seen in 14% and microalbuminuria in 9%. LVH correlated with HTN stage. **Referral source**: 263 (74%) from PMD, 29 from School RN and 63 from Pediatric sub-specialists. **Office BP diagnosis**: 51 wnl, 106 with Elevated BP, 145 Stage I HTN, 58 Stage II HTN and 1 NA. **ABPM diagnosis**:125 WCH, 61 with Elevated BP, 134 Stage I HTN, 47 Stage II HTN and 6 errors. 86 children (23%) with abnormal BP at Nephrologist office had WCH diagnosed by ABPM. **For children with HTN diagnosed by both Nephrologist and ABPM**: office HTN grade was higher in 29 and lower in 45, when compared to ABPM; discordance rate = 74/229 (32%). Masked HTN was noted in 14 children (4%). Degree of HTN and WCH didn't correlate with referral source; children referred by school RNs were more often symptomatic (38% vs 18%, p=0.01).

Conclusions: Children with suspected HTN, often symptomatic were referred from various sources for Ped Nephro consult. ABPM was confirmed as an important tool to diagnose masked HTN, WCH and clearly establish the proper level of HTN. We observed a high discordance rate of HTN Stage diagnosis which was independent from referral source.

PUB428

Trajectory of eGFR Predicts Renal Injury in Children with Multicystic Dysplastic Kidney

Kazuya Matsumura,[1,2] Kyoko Sugii,[1] Midori Awazu.[1] [1]*Keio University School of Medicine, Tokyo, Japan;* [2]*Hiratsuka City Hospital, Hiratsuka, Japan.*

Background: Children with a solitary functioning kidney have a risk of renal injury caused by hyperfiltration. Timely intervention with renin-angiotensin inhibitors may be benefical. We examined whether trajectory of estimated glomerular filtration rate (eGFR) would predict renal injury, defined as microalbuminuria/proteinuria, hypertension, and/or a decline in eGFR.

Methods: Seventeen patients (male 7, female 10) with multicystic dysplastic kidney (MCDK) (median age 13 years, range 6 to 19 years) followed in our clinic were examined retrospectively. Microalbuminuria and proteinuria were defined as urine albumin/creatinine ratio >30 mg/g and urine protein/creatinine ratio >0.15 g/g, respectively. Hypertension was determined when an average of BP measurements was ≥the 95th percentile for age, sex, and height. GFR was estimated by quintic equation for Japanese children by height and gender (2-18 years) or the revised Japanese equation for eGFR (>19 years). An eGFR decline was defined as a fall to <90 ml/min/1.73 m^2 or a decline of >5 ml/min/1.73 m^2/year for those with baseline eGFR of ≥90 ml/min/1.73 m^2 or <90 ml/min/1.73 m^2, respectively. The best-fitting model of eGFR over time was determined in each patient.

Results: Nine patients had renal injury at the time of investigation. Compared with 8 patients without renal injury, those with renal injury tended to be older (14.7±4.2 vs 11.4±4.6 years, meas±SD) and the birth weight was smaller (2538±281 vs 2966±361 g, P<0.05). Frequency of contralateral congenital anormaly of kidney and urinary tract (cyst, hydronephrosis, or vesicoureteral reflux) was not different. Trajectory of eGFR in those without renal injury was either increase (n=3) or unidentifiable (not fitting any statistical significant model but remaining stable, n=5), whereas that in renal injury group was exclusively increase followed by decline (P<0.05). The average age of the onset of eGFR decline was 9.4±4.2 years and that of renal injury (albuminuria/proteinuria 5, eGFR decline 4, hypertension 1) was 12.5±4.2 years.

Conclusions: All the children with MCDK who developed renal injury had eGFR trajectory of increase followed by decline. The peak eGFR was followed by renal injury after 3 years on average. This observation is in agreement with the hyperfiltration theory and underscores the importance of following eGFR trajectory closely especially when eGFR is increasing.

PUB429

An Unusual Case of PHA Type 1

Molly Band,[1] Kim Zuber,[2] Jane S. Davis.[3] [1]*Connecticut Children's Medical Center, Hartford, CT;* [2]*American Academy of Nephrology PAs, Oceanside, CA;* [3]*University of Alabama at Birmingham, Birmingham, AL.*

Introduction: Pseudohypoaldosteronism (PHA) is a rare pediatric condition presenting as either Type 1 or Type 2. Type 1 can be primary or transient whereas Type 2 is often congenital. Transient Type 1 PHA is often due to a UTI or a congenital malformation leading to a UTI. We describe the first documented case of PHA Type 1 in a 2-week old tiger cub at the San Diego Zoo Safari Park

Case Description: A 3-day old tiger cub at the San Diego Zoo Safari Park was rejected by his mother & hand-reared by park keepers using a formula designed for carnivores. The tiger failed to thrive, presenting with acute lethargy at 2 weeks. During initial evaluation, the cub had a cardiac arrest revived with CPR. Initial labs showed a critical K>9 mEq/dL with hyponatremia (120 mg/dL). Subcu 0.9% saline was started. Differential diagnosis included adrenal crisis thus the tiger cub was started on prednisolone and fludrocortisone. Additional testing included a urine culture, which grew *Klebsiella pneumoniae* and *Enterococcus* species. An abdominal U/S revealed hyperechoic debris swirling in the urinary bladder & renal pelvices as well as bilateral pyelectasia. Transient pseudohypoaldosteronism secondary to pyelonephritis was suspected and the tiger was started on amoxicillin and clavulanate. An adrenocorticotropic hormone (ACTH) stimulation test revealed a significantly elevated aldosterone of >4572 pmol/L, confirming the diagnosis. The veterinary staff used pediatric nephrology literature to diagnose and treat. The tiger was given antibiotics until the urine culture was negative and the U/S revealed resolution of debris. Electrolytes normalized. He began to eat, grow & eventually bond with his brother.

Discussion: Severe hyponatremia & hyperkalemia are uncommon during infancy, but can have life-threatening consequences. The differential diagnosis includes congenital adrenal hyperplasia (CAH), congenital adrenal hypoplasia, medication administration and PHA. PHA causes hyponatremia, hypovolemia, hyperkalemia, & metabolic acidosis. Type 1 PHA can either be primary (inherited) or secondary (transient). Transient PHA is reported in infants with UTIs and urinary tract abnormalities (hydroureteronephrosis, vesicoureteral reflux or obstructive uropathy). Patients with PHA should have resolution of their electrolyte imbalances with targeted treatment of the primary infection and appropriate IV fluid resuscitation, even if they are a tiger.

PUB430

Enuresis Is Common, Severe, and Persists to Older Age in Children with Sickle Cell Disease

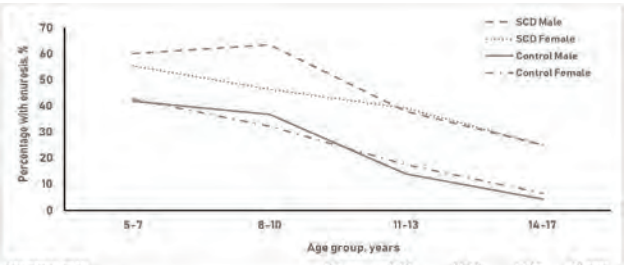
Chris Esezobor,[1,2] Patricia Akintan,[1,2] Uche E. Nwaogazie,[2] Remi Akinwunmi,[2] Rasheed A. Gbadegesin.[3] [1]*Paediatrics, College of Medicine University of Lagos, Lagos, Nigeria;* [2]*Paediatrics, Lagos University Teaching Hospital, Lagos, Nigeria;* [3]*Duke University Medical Center, Durham, NC.*

Background: Despite strong association between sickle cell disease (SCD) and enuresis, no large studies have examined, using standardized definitions, the prevalence of enuresis, its variants and risk factors in children with SCD in Sub-Saharan Africa which has the largest burden of SCD. We determined and compared the prevalence of enuresis and its various forms in children with and without SCD and identified its predictors.

Methods: Caregivers of children with SCD attending a hematology clinic in a public hospital in Nigeria were interviewed using a standard case record form. In addition, a separate record form was completed for every sibling aged 5-17 years whose haemoglobin phenotype was known. Enuresis and its variants were defined using the International Children's Continence Society's definitions.

Results: The study involved 256 children with SCD and 256 controls. The mean age of the study cohort was 9.9 (3.4), with 44.5% ≥10 years and 44.5% as females. The prevalence of enuresis was higher at 48.4% in children with SCD than in the controls with a steady decline with age (Fig. 1). The proportions with secondary enuresis (10.5% v 16.2%) were similar in both groups. However, children with SCD and enuresis were older (9.0 v 8.1 year), more likely to be aged ≥10 years (33.9% v 16.2%) and were twice likely to have ≥4 wet nights/week and non-monosymptomatic form than the controls. Pre-adolescence and enuresis in a family member were predictors of enuresis in children with SCD, whereas gender, socioeconomic status, hospitalisation in the past 12 months and receipt of blood transfusion were not.

Conclusions: Enuresis is more frequent, severe, non-monosymptomatic and likely to persist to late adolescence in children with SCD than in controls. These features make enuresis in children with SCD more difficult to treat than in controls. Younger age and enuresis in a family member are risk factors for enuresis in children with SCD.



Age group, years		5-7 n=190 (%)	8-10 n=138 (%)	11-13 n=104 (%)	14-17 n=80 (%)	All ages, n=512 (%)

Effect of a Gluten-Free Diet on Albuminuria in Patients with Celiac Disease

Howard Trachtman,[1] Jeremiah Levine,[2] Libia Moy,[2] Leora Hauptman.[3] *[1]NYU Langone Health, New York City, NY; [2]NYU Langone Medical Center, New York, NY; [3]NYU Langone, NY, NY.*

Background: Celiac disease (CD) is caused by a gluten-induced increase in zonulin production by the enterocyte. This molecule interacts with protease activated receptor 2, disrupts the tight junction in the gut epithelium, and increases the intestinal permeability to gliadin. PAR2 is expressed in podocytes raising the possibility that this glomerular epithelial cell could be a target of zonulin.

Methods: Patients who were newly diagnosed with CD, based on elevated tissue transglutaminase (tTG) and small bowel histology, were eligible for inclusion in the study. A first morning urine specimen was collected at diagnosis and at the time of the follow-up clinical assessment conducted to assess the response to the gluten-free diet (GFD). Albuminuria was measured using an ELISA kit and expressed as the albumin:creatinine ratio (ACR). Results are provided as mean±SEM.

Results: 17 patients with CD (8M:9F), all white, mean age 9.1±1.1 years old, were included in this study. 16 patients had elevated tTG IgA and the other patient had IgA deficiency with an elevated tTG IgG. At diagnosis, 1 child was receiving escitalopram and a second recombinant human growth hormone. After the initial assessment, 2 patients took lansoprazole but it was discontinued 2 months before the follow-up evaluation. None were receiving immunosuppressive medications. BP, serum creatinine and albumin concentrations were normal in all patients. The mean interval on the GFD was 6.1±0.7 months. The initial ACR was 20.7±5.2 (4 had values above 30 μg/mg) that fell to 10.4±1.5 μg/mg at the repeat evaluation, P=0.035.

Conclusions: Our findings indicate that patients with CD have low-grade albuminuria at the time of diagnosis of their gastrointestinal disease. Initiation of a GFD is associated with a significant decline in albumin excretion. Further study is needed to determine whether assessment of albuminuria should be incorporated into the care of patients with CD as a marker of clinical response and whether this abnormality has any long-term adverse health consequences.

The Impact of Pathological Findings of Mitochondrial Disorders in Low Birth Weight Infants

Kohei Miyazaki,[1] Keisuke Sugimoto,[1] Takuji Enya,[2] Tomoki Miyazawa,[3] Mitsuru Okada,[1] Tsukasa Takemura.[4] *[1]Department of Pediatrics, Kinki University School of medicine, Osaka, Japan; [2]kinki university school of medicine, Osakasayama, Japan; [3]kindai University Faculty of Medicine, Izumi, Japan; [4]Pediatrics, Department of Pediatrics, Kushimoto Municipality Hospital., Wakayama, Japan.*

Background: Preterm infants with a low birth weight (LBW) show reduced numbers of nephrons at birth and a higher risk of developing kidney dysfunction during their lifetime. They demonstrate oligonephronia and focal segmental glomerulosclerosis (FSGS) lesions in their glomeruli. We examined the association between mitochondrial disorders and the pathological characteristics of LBW-related nephropathy.

Methods: We retrospectively evaluated the renal pathology in 6 infants including pairs of twins and 2 LBW infants demonstrating renal dysfunction. In addition to routine staining, the kidney biopsy specimens were analyzed using cytochrome c oxidase subunit IV (COX IV) and transcription factor A (TFAM) staining.

Results: FSGS was diagnosed in 2 and oligonephronia in 4 infants. The mean density of glomeruli was 3.8/mm^2 (0.3–7.2) Granular swollen epithelial cells (GSECs), which have previously been reported exclusively in patients with mitochondrial cytopathy, were observed in the distal tubules and/or collecting ducts in all 6 infants. Electron microscopic examination revealed that these GSECs included an increased number of enlarged mitochondria. Furthermore, we observed unbalanced expression patterns of COX IV and low expression of TFAM in the glomeruli and a part of the tubular cells.

Conclusions: FSGS, a characteristic feature of glomerular involvement in patients with mitochondrial cytopathy is very commonly observed in LBW infants. In our study, all infants did not show FSGS lesions because a renal biopsy was performed in the early stages of the disease in contrast to previous reports. However, most patients revealed similar pathological changes of mitochondrial cytopathy such as unbalanced expression of TFAM, which plays a role in maintaining the mitochondrial DNA. This finding suggests that these lesions could appear during early childhood, resulting in the development of FSGS in the future. These findings could suggest the application of a new approach targeting mitochondrial DNA to prevent the development of LBW-related nephropathy.

PUB433

Molecular Assay to Detect the Pathogenicity of Intronic Variant in NUP93 for Steroid Resistant Nephrotic Syndrome

Rini Rossanti,[1] Akemi Shono,[1] Kenichiro Miura,[2] Motoshi Hattori,[2] Shogo Minamikawa,[1] Tomohiko Yamamura,[1] Junya Fujimura,[1] Keita Nakanishi,[1] Tomoko Horinouchi,[1] China Nagano,[1] Nana Sakakibara,[1] Hiroshi Kaito,[1] Kandai Nozu,[1] Kazumoto Iijima.[1] *[1]Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan; [2]Department of Pediatric Nephrology, Tokyo Women's Medical University, Schoof of Medicine, Tokyo, Japan.*

Introduction: Advances in molecular genetics have revealed that about 30% of the cases with steroid resistant nephrotic syndrome (SRNS) are caused by single-gene mutations that highly expressed in the podocytes. More than 50 genes are known to be responsible for SRNS. One of the responsible genes is nucleoporin, 93-KD (NUP93). Till date, only few studies reported the mutations of NUP93 in SRNS. Here, we describe a NUP93 biallelic mutation in 9 years old boy with focal segmental glomerular sclerosis (FSGS). Although one was a heterozygous truncating variant, another was a novel heterozygous intronic variant which pathogenicity was unknown. To confirm the pathogenicity of the intronic variant, we conducted in vivo and in vitro analysis.

Case Description: The patient was a 9-year-old boy. He was detected proteinuria at 2 years old, and diagnosed with SRNS. The histological finding was FSGS. At the onset, hypoalbuminemia (2.6 g/dL), high serum creatinine (0.88 g/dL) with decrease renal function (eGFR 53.6L/minute/m^{2}BSA), proteinuria (urine protein creatinine ratio: 2.37), and hematuria was found. He has optic nerve atrophy as his extrarenal symptom. There were no histories of kidney diseases in the family. We found 2 novel heterozygous mutations in NUP93, c.727A>T (p.Lys243*) in exon 8 and c.2137-18G>A in intron 19. To determine the pathogenicity of the intronic variant, we conducted RT-PCR analysis, in vitro splicing assay using minigene construction and in vitro protein expression analysis. Both RT-PCR using patient's sample and in vitro splicing assay showed exon 20 skipping by the intronic variant. The in vitro protein expression analysis result showed abnormal localization in cytoplasm with the particle formation by the intronic variant. From these results, we conclude c.2137-18G>A as pathogenic by causing aberrant splicing.

Discussion: NUP93 variants are quite rare; however, we proved even the intronic variants in NUP93 can cause SRNS. Our results can help identifying more variants in this rare form of SRNS.

PUB434

The Clinical Manifestation of BK Virus Infection in Pediatric Patients with Kidney Transplantation

Yeonhee Lee,[1] Yiyoung Kwon,[1] Hyesun Hyun,[2] Heeyeon Cho.[1] *[1]Pediatrics, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Republic of Korea; [2]Pediatrics, St. Vincent's Hospital, The Catholic University College of Medicine, Suwon, Republic of Korea.*

Background: Polyomavirus BK is known as a common cause of graft failure in kidney transplant patients. There is rare data in pediatric patients, and the purpose of this study was to evaluate the clinical findings of BK virus infection and risk factor in pediatric patients with kidney transplantation.

Methods: The medical records of 30 children who received kidney transplantation from January 2002 to December 2017 in Samsung medical center were retrospectively reviewed. The screening for BK virus was performed in blood and urine by polymerase chain reaction.

Results: The median age of the kidney transplantation was 11.3 (range, 1.3-18.6) years, and male to female ratio was 2.3:1. The most common underlying disease was congenital abnormalities of kidney and urinary tract. The sixteen patients received the kidney from the deceased donors. BK viremia and viuria were detected in 9 and 6 patients respectively. The median period from kidney transplantation to BK virus detection in blood or urine was 51days (7-3,464days). Among 15 patients with BK infection, 9 patients had the deceased donor kidney. The children with BK virus infection showed the tendency that the age at the time of transplantation was younger compared with those without BK virus infection (median age 8.4 vs 11.3 years). Three patients who had the past medical history with high dose chemotherapy and autologous stem cell transplantation for solid tumor before kidney transplantation showed the high titer of BK virus in blood. However, BK virus infection did not affect the short-term renal function and graft survival in all patients because the dose of immunosuppressant decreased when BK virus was detected.

Conclusions: The results of this study suggest that the risk factors of the BK viremia in the pediatric kidney transplant patients are supposed to be younger age at the time of kidney transplantation, deceased donor kidney, and past medical history with high dose

chemotherapy. Regular monitoring for BK virus and reduction of immunosuppression is necessary to prevent graft function.

PUB435

Classical Fabry Disease in Children

Norberto Ricardo Antongiovanni,[1] Fernando J. Perretta,[2] Sebastian P. Jaurretche.[3] GINEF [1]*Nephrology, CIEEL. Instituto de Nefrologia Clinica Pergamino, Pergamino, Argentina;* [2]*Fresenius Medical Care, Escobar, Argentina;* [3]*Centro de Neurociencias Los Manantiales, Rosario, Argentina*.

Background: INTRODUCTION: Fabry disease (FD) is caused by deficient or null activity of the enzyme α-galactosidase A (α-galA) which causes the lysosomal accumulation of complex glycosphingolipids, mainly globotriaosylceramide. Affected children suffer from neuropathic pain, gastrointestinal dysfunction, hypohidrosis and intolerance to cold and heat from early childhood, which may impair quality of life and affect the daily activities of home and school. OBJECTIVE: To describe the organic commitment in children at the time of diagnosis of FD.

Methods: Patients with FD were analyzed from three reference centers in Argentina, with classical mutations of the GLA gene (E398x and p.L415P). Typical manifestations of EF were evaluated after having ruled out other causes of them.

Results: Twenty-one patients, from 2 to 16 years of age (average: 8.2 years), 12 women and 9 men were studied. Renal hyperfiltration was detected in 12/21 (57.1%); 9 girls and 3 boys. Three patients (14.3%) had GFR <90 ml / min / 1.73 m2 (2 children and 1 girl). Albuminuria was evidenced in 2 girls (9.5%). 7/21 children (33.3%) presented neuropathic pain. Cardiac involvement was detected in 4/21 patients (19%); 2 with arrhythmia (sinus bradycardia) and 2 with LVH. 5 patients (23.8%) presented angiokeratomas and only 3 (14.3%) with gastrointestinal involvement. An 11-year-old girl presented CNS involvement (NMR with white matter lesion without any other cause than FD.)

Conclusions: Children in our population experienced symptoms and signs typical of FD at an early age, with a high percentage of renal hyperfiltration. (as a probable glomerular compensation and incipient sign of nephropathy) as the most frequent renal manifestation.

Ampicillin/Sulbactam as Empiric Monotherapy In Patients Under 24 Months with 1st UTI in the Era of Antibiotic Resistance

Ji yeon Song, Seong heon Kim. *Pusan National University Children's Hospital, Yangsan, Republic of Korea*.

Background: Cephalosporin has been the most commonly used empirical agent for urinary tract infection (UTI) in children. However, the worldwide increase of extended-spectrum beta lactamase (ESBL) producers and its resistance to cephalosporin makes it difficult for physicians to choose empirical antibiotics for UTI.

Methods: All infants and young children 2 to 24 months old who hospitalized to Pusan National University Children's Hospital due to first episode of febrile UTI during the 2-year period (June 2012 to April 2014) were included in the study. The subjects were divided into two groups according to their empirical therapy whether they received cefotaxime or ampicillin-sulbactam. We determined the pathogens of UTI of young children and their antibiotic susceptibilities and compared effectiveness and adverse effect between ampicillin/sulbactam and cephalosporin.

Results: 55 patients of group A were treated with cefotaxime and 44 patients of group B with ampicillin/sulbactam as empirical antibiotics. The most common pathogen was *E. coli* in both groups and isolated *E. coli* of two groups had no significant differences in antibiotics susceptibility rate. In both groups, *E. coli* tends to be more susceptible for ampicillin/sulbactam than cefotaxime. In addition, there was no significant difference in the duration of fever (11.6 ± 15.4 vs 8.7 ± 13.3hrs, P = 0.29) after treatment between the two groups. None of the patients in both groups had initial treatment failure or recurrence due to improper treatment. The most common side effects of antibiotics agents were diarrhea (72.7% vs 74.5%, P = 1.0), elevation of liver function test (47.7% vs 52.7%, P = 0.68), and anemia (11.4% vs 23.6%, P = 0.18). Comparing the cost of treatment, we found that ampicillin-sulbactam is cheaper than cefotaxime.

Conclusions: Ampicillin-sulbactam could be effective alternative to cephalosporins as the empiric treatment in patients with 1st UTI under 24 months.

PUB437

Complement Activation Fragments Levels in Post Infectious Glomerulonephritis

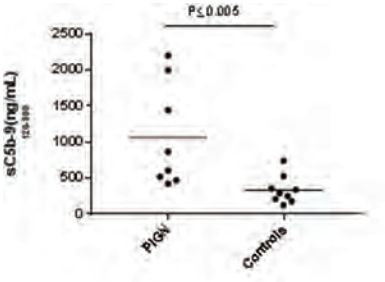
Manuel A. Pascual. CTO-IAL Group *Center of Organ Transplantation & Immunolo-allergology, Centre hospitalier universitaire vaudois, Lausanne, Switzerland*.

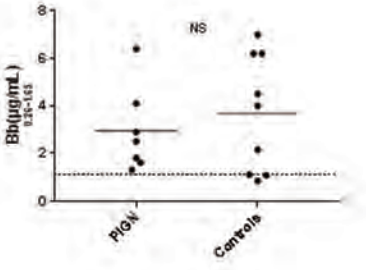
Background: Post infectious glomerulonephritis (PIGN) is the most common cause of acute glomerulonephritis in children, and it is associated with hypocomplementemia (low C3).

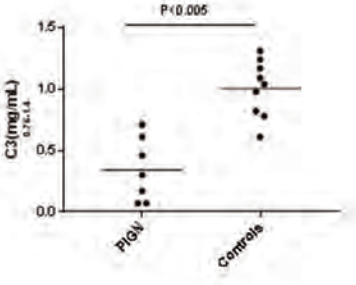
Methods: Children with PIGN (n=8) and controls (acute renal failure n=3, chronic renal failure n=1, typical hemolytic uremic syndrome n=5) were studied for plasma lytic pathway sC5b-9, alternative pathway Bb fragment, and C3 concentrations.

Results: Plasma sC5b-9 concentrations were above the normal range (120-300 ng/mL) in all PIGN patients with a strikingly high mean value of 1067±253ng/mL. The control group showed a mean value of 337±63 ng/mL. Thus, PIGN patients had significantly higher sC5b-9 levels as compared to the control group (P≤0.004). The Bb concentrations were also above the normal range (0.26-1.66 μg/mL) with a mean value of 2.9±0.6 μg/mL in PIGN and of 3.6±0.8 μg/mL in controls, however there was no significant difference in Bb concentration between both groups. C3 concentrations were below the normal range (0.75-1.4 mg/mL) in all PIGN patients with a mean value of 0.34±0.1 mg/mL. The controls had a mean value of 1.0±0.07 mg/mL. Thus, PIGN patients had significantly lower C3 levels as compared to controls (P≤0.01).

Conclusions: PIGN patients had significant higher sC5b-9 levels and significant lower C3 levels as compared to controls. These preliminary data indicate that sC5b-9 levels could be a useful marker to detect ongoing complement activation in the circulation of PIGN patients, which may have utility for therapeutic monitoring, e.g. after administration of complement inhibitors.







- Statistics analysis were done with non-parametric Mann-Whitney test

PUB438

Ethnic Population Variance in Nephron Mass in Neonates: The Miami Cohort versus International References

Marissa J. Defreitas,[1] Wacharee Seeherunvong,[1] Chryso P. Katsoufis,[1] Salih Y. Yasin,[3] Marta G. Galarza,[2] Shahnaz Duara,[2] Gaston E. Zilleruelo,[1] Carolyn L. Abitbol.[1] *[1]Pediatric Nephrology, University of Miami/Jackson Memorial Hospital, Miami, FL; [2]Neonatology, University of Miami/Jackson Memorial Hospital, Miami, FL; [3]Maternal Fetal Medicine, University of Miami/Jackson Memorial Hospital, Miami, FL.*

Background: Nephron endowment, the number of functioning nephrons at birth, may determine an individual's adult longevity. Preterm birth is associated with developmental programming of hypertension and cardiovascular disease. A non-invasive and economical surrogate of nephron mass is the ultrasound (US) measurement of renal dimensions. Limited studies have suggested subclinical ethnic variations in kidney volume and function in children but not in neonates.

Methods: In a prospective cohort study, 157 neonates were enrolled at birth; 140 singletons [71 term (T), 69 preterm (PT)] and 17 twins. Race/ethnicity were recorded. Renal measures were assessed by US and renal function by serum creatinine (SCr) and cystatin C (CysC) based equations for estimated glomerular filtration rate (eGFR). A table of reference values (RV) for kidney size parameters from 5 countries was extracted from the literature and included 871 healthy term neonates.

Results: The Miami Cohort is primarily an ethnic/racial minority with an Hispanic/Non-White demographic [144/157=92%]. KL and TKV correlated closely with all body anthropometrics and gestational age (GA) ($p<0.001$). TKV correlated significantly with eGFR. TKV for PT and twins was significantly different from term singletons ($p<0.001$ for all). TKV/BSA (ml/m2) was normally distributed, independent of GA, and similar among T and PT singletons. Both TKV and TKV/BSA were significantly decreased for twins compared to singletons. The Miami Cohort Term infants had lower TKV and TKV/BSA than that of the international RV.

Conclusions: There is a wide regional variation in nephron mass reflective of the gene-environmental influence on nephrogenesis. Absolute TKV is a primary determinant of kidney function; whereas, TKV referenced to BSA (ml/m2) reflects nephron endowment individualized to body size. Support of post-natal nephrogenesis in preterm infants is essential if their nephron endowment is to be maintained. Follow-up of post-natal renal growth and function is warranted in individuals born preterm.

Prediction of the Renal Elimination of Drugs with Cystatin C versus Creatinine: A Systematic Review

Erin F. Barreto,[1] Andrew D. Rule,[1] M. hassan Murad,[2] Kianoush Kashani,[1] John C. Lieske,[1] Patricia J. Erwin,[1] James Steckelberg,[1] Ognjen Gajic,[4] Joel M. Reid,[1] Sandra Kane-Gill.[3] *[1]Mayo Clinic, Rochester, MN; [2]Mayo clinic, Rochester, MN; [3]University of Pittsburgh, Pittsburgh, PA; [4]Mayo Clinic, Rochester, MN.*

Background: Cystatin C has been proposed as an adjunct or alternative to creatinine for drug dosing. The association of renal function estimated by cystatin C with drug clearance, target achievement, and clinical outcomes is not well defined.

Methods: We conducted a systematic review to synthesize available data for the association between serum cystatin C and drug pharmacokinetics, dosing, and clinical outcomes in adults (≥18 years). PubMed, Ovid MEDLINE, Ovid EMBASE, EBSCO ICNAHL, and Scopus were systematically searched from 1946 to September 2017 to identify candidate studies. Studies of cystatin C as a predictor for acute kidney injury (AKI) or for management of contrast-associated AKI were excluded. Also, studies were excluded if drug concentrations were unavailable and if a reference standard for drug dosing (e.g., serum creatinine) was not concurrently reported. The outcomes of interest included drug clearance (L/h), concentrations (mg/L) target level achievement (%), therapeutic failure (%), and drug toxicity (%).

Results: We included 28 manuscripts that evaluated 16 different medications in 3455 participants. Vancomycin was the most well studied drug. Overall, cystatin C-based estimated glomerular filtration rate ($eGFR_{Cystatin\ C}$) was more predictive of drug levels and drug clearance than $eGFR_{Creatinine}$. In only one study were target attainment and outcomes compared between two drug dosing regimens, one based on $eGFR_{Creatinine\text{-}Cystatin\ C}$ and one dosed with the Cockcroft Gault creatinine clearance. In conclusion, compared with $eGFR_{Creatinine}$, use of $eGFR_{Cystatin\ C}$ to predict elimination of medications via the kidney was as accurate, if not superior, in most studies, but infrequently were data on target attainment or clinical outcomes reported.

Conclusions: Drug-specific dosing protocols which use cystatin C to estimate kidney function should be tested for clinical application.

Pharmacological Decision-Making in Gout: A Comparison Between Nephrologists and Other Specialists Using a Script Concordance Test

Sarah Gilligan,[1] Andrea M. Barker,[2] Michael J. Battistone,[1] Kalani L. Raphael.[1,2] *[1]University of Utah Health Sciences Center, Salt Lake City, UT; [2]VA Salt Lake City Health Care System, Salt Lake City, UT.*

Background: Gout commonly coexists with CKD and the presence of CKD often complicates gout management. Gout is treated by providers from many disciplines, hence pharmacotherapeutic heterogeneity may be common in CKD. The goal of this pilot study was to determine whether a validated script concordance test (SCT) for gout, which assesses clinical reasoning in short case scenarios, might detect interprofessional heterogeneity of pharmacological gout therapy.

Methods: Nephrologists (Neph), rheumatologists (Rheum), primary care providers (PCP), and pharmacists (Pharm) at University of Utah and Salt Lake City VA completed the gout SCT. The full SCT consists of 24 case scenarios and responses are obtained using a 5-anchor Likert scale. As we were interested in pharmacological treatment, we used the 10 case scenarios assessing pharmacological decision-making in this study. Response options ranged from the proposed therapy being "strongly indicated" to "strongly contraindicated." SCTs were scored using an aggregate method normed by an expert panel. Mean scores for each discipline were calculated and differences between each discipline and Neph were compared using 2-tailed t-tests.

Results: 29% of invitees (38 of 129) completed the SCT. The number of responses was similar across disciplines (Table). The overall mean (SD) score was 14.69 (2.03); for reference, the maximum score for the 10 case scenarios is 24.39. Rheum had the highest and Neph had the lowest SCT score; the difference approached statistical significance. SCT scores were similar between Neph, PCP and Pharm (Table).

Conclusions: In our study sample, clinical decision-making regarding gout pharmacotherapy was similar between Neph, Pharm, and PCP. In contrast, differences between Neph and Rheum were observed, though confidence is limited by sample size. The results of this pilot study can inform future use of the SCT to detect interprofessional heterogeneity of pharmacological gout therapy in a larger sample across multiple institutions.

Mean SCT score by discipline

Discipline (# of respondents)	Mean (SD) SCT Score	p vs. Nephrology
Nephrology (n=9)	13.77 (2.13)	–
Rheumatology (n=10)	15.67 (1.83)	0.05
PCP (n=10)	15.06 (2.26)	0.22
Pharmacy (n=9)	14.12 (1.48)	0.69

Maximum possible score is 24.39

PUB441

Autosomal Recessive Polycystic Kidney Disease Diagnosed in Adulthood

Kamal Nayyar, Nobuyuki (Bill) Miyawaki, Naveed N. Masani, James Drakakis. *NYU Winthrop Hospital, Mineola, NY.*

Introduction: Autosomal recessive polycystic kidney disease (ARPKD) belongs to a group of congenital hepatorenal fibrocystic syndromes. Renal cysts arising from collecting ducts and congenital hepatic fibrosis (CHF) are hallmarks, usually in infancy and associated with high mortality in first year of life. For those who survive the neonatal period, the probability of being alive at age 15 ranges from 50-80%, with the majority requiring renal replacement therapy. Approximately 50% of infants have evidence of liver involvement at time of diagnosis. This can lead to progressive portal hypertension. Here, we present a case of an adult female with known CHF believed to be idiopathic, until additional investigation into proteinuria revealed cystic kidney disease, confirmed on genetic testing to be ARPKD.

Case Description: A 38-year-old female with a history of hypertension, bipolar disorder (never on Lithium) and congenital hepatic fibrosis diagnosed at age 20 months presented for evaluation of long standing proteinuria. Albumin was preserved with proteinuria quantification ranging from less than 1 g/g to upwards 3.2 g/g. While a workup was being undertaken, angiotensin receptor blockade was initiated with significant improvement in proteinuria to values less than 200 mg/g. Renal ultrasound revealed relatively large kidneys with bilateral cysts. MRI abdomen confirmed innumerable left kidney cysts, along with several subcentimeter parapelvic cysts on the right kidney. Genetic testing was performed with results consistent with ARPKD. There was no known family history of renal cystic disorder or renal morbidity.

Discussion: The classic presentation for ARPKD is hypertension with progression to ESRD by age of 15. Typicaly a small number of those with ARPKD will live to adulthood with some kidney function, but significant deterioration in liver function. Due to its wide variability, the diagnosis of ARPKD may be made during any stage of childhood and only in rare cases does it present in adolescence or adulthood. A minority of affected individuals present as older children or young adults with evidence of hepatic dysfunction as the prominent feature. This case highlights the potential spectrum of presenting signs and symptoms associated with ARPKD and the possibility that the diagnosis may need be considered even in adulthood if the scenario seems appropriate.

PUB442

A Novel Presentation of Fabry Disease

Farid Arman,[1] Peter D. Lymberopoulos,[1] Niloofar Nobakht,[1] Mohammad Kamgar,[1] Ramy M. Hanna,[1] Carl E. Schulze,[1] Reza Khorsan,[1] Jean Hou,[2] Behnoud Beroukhim,[2] Anjay Rastogi.[1] *[1]University of California, Los Angeles, Los Angeles, CA; [2]Cedars- Sinai Medical Center, Los Angeles, CA.*

Introduction: Fabry disease (FD) is an X-linked genetic disease due to mutations in the *GLA* gene that lead to deficient or absent α-galactosidase A (α-Gal A) activity and consequent accumulation of globotriaosylceramide throughout the body. Various manifestations of FD include proteinuria, declining glomerular filtration rate (GFR), hypertrophic cardiomyopathy, hypohidrosis, heat intolerance, hearing loss, acroparesthesia, cryptogenic strokes, and cornea verticillata, among others. Renal presentations of FD in classic males typically begin with proteinuria in childhood, followed by a gradual decline in GFR, and ultimately results in end-stage renal disease (ESRD) over the course of a few decades if patients are left untreated. We present an unusual case involving a male patient who had normal GFR at the age of 40, but was diagnosed with ESRD by 42.

Case Description: Our patient was a 42-year-old male, who was first diagnosed with kidney disease when his annual physical lab tests revealed a creatinine of 11 MG/DL. This demonstrated a dramatic elevation from his labs 2 years prior, where the patient's creatinine was measured to be 1.1 MG/DL. At the time of diagnosis, the patient had no history of kidney disease. Meticulous review of the patient's history, in addition to physical examination and work-up did not identify any cause for the observed kidney failure. A kidney biopsy, however, was suspicious for FD. Subsequent screening of α-Gal A enzyme activity and genetic testing confirmed the diagnosis of FD with a P40S mutation. Thus, hemodialysis and enzyme replacement therapy were initiated.

Discussion: Although kidney disease is amongst the most important presentations of FD, this patient demonstrated a unique case with a rapidly progressive disease that has not been reported previously. A review of available natural history data from the Fabry Registry (NCT00196742; sponsor and provider of data: Sanofi Genzyme) showed 14 patients with the same mutation, including 7 males. No renal or cardiovascular events were reported in the male patients. In females, 1 stroke and 1 cardiac event have been reported, but no kidney events. Conclusion: This is a novel presentation of FD in a classic male that will require further investigation.

PUB443

Irreversible Electroporation Treatment of Renal Cell Carcinoma in Von-Hippel Lindau

Su-Ling Lai. *Alfred Health, Melbourne, NSW, Australia.*

Introduction: Irreversible electroporation (IRE) is a non-thermal nephron-sparing technique which offers an alternative treatment for renal tumors in patients previously deemed inoperable or unsuitable for other therapies. It is particularly useful in patients at risk for recurrent renal cell carcinoma (RCC), where it may help prolong renal function and delay requirement for dialysis.

Case Description: A 55 year old female with Von-Hippel Lindau presented in 2009 with a 19mm right midpole RCC, judged unsuitable for partial nephrectomy or thermal ablation due to central location. At time of presentation, the patient previously had one right sided and three left sided partial nephrectomies for confirmed RCCs. In the interests of preserving remaining renal function patient was treated with IRE.

Discussion: In 2009 the patient was enrolled in our department's IRE safety study and underwent two rounds of IRE to the right midpole RCC, which was completely ablated with no residual/recurrent tumor seen for a 6 year interval. In 2015 two further RCCs were detected within right kidney (16mm upper pole, 20mm lower pole), both of which were ablated with a single round of IRE. The inferior pole lesion was completely ablated post IRE while minimal contrast enhancing residual tumor was seen at the upper pole on post-procedural triphasic CT. Two further RCCs were detected within the right inferior pole in 2017, potentially amenable to IRE. However post Urology review patient proceeded to right sided nephrectomy. No major procedural complications of IRE were seen in this patient. This result was in line with results from a further 18 patients and 26 tumors treated. Success was highly correlated to tumor size, with 94% of lesions initially measuring <3 cm in diameter (15 of 16) successfully ablated after ≤2 rounds of IRE versus 63% in lesions ≥3cm (7 of 11). Complete ablation post ≤2 rounds of IRE was seen in 100% of patients at <5 years and 58% of patients at 5-7 years. Partial ureteric stenosis was seen in post-IRE in 1 patient, thought to be related to previous thermal ablation of the same tumor. No other major complications were observed. In conclusion, a previous study performed by our hospital has shown renal IRE is a safe alternative treatment for small renal tumors. IRE is especially useful in patients such as this case at risk for recurrent renal tumors, where a total delay of 8 years to right nephrectomy was achieved.

PUB444

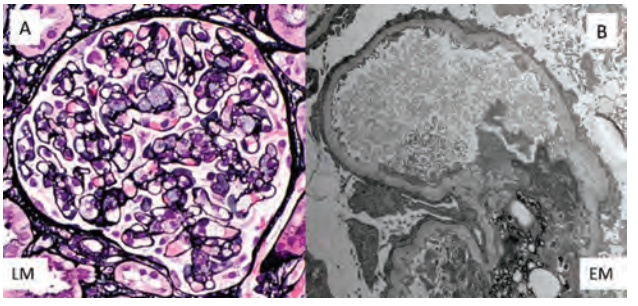
Nephrotic Syndrome in Familial Hyperlipoproteinemia: A "Two-Hit" Hypothesis

Harish Shanthanu Seethapathy, Ricard Masia, Alexander T. Sipilief, Jillian Rosenthal, Karen A. Laliberte, John Niles, Frank B. Cortazar. *Massachusetts General Hospital, Watertown, MA.*

Introduction: Familial hyperlipoproteinemia (FH) Type III is an autosomal recessive disorder caused by mutations of ApoE, which plays a crucial role in lipid metabolism. We discuss a patient with type III hyperlipoproteinemia who developed nephrotic syndrome.

Case Description: A 26 yo female presented with anasarca 2 weeks after pregnancy. She had a urine Protein:Cr ratio (UPCR) of 15 g/g with a serum albumin of 1.2 g/dL. Serum cholesterol (676 mg/dL) and triglycerides (1336 mg/dL) were markedly elevated. Renal biopsy showed diffuse deposition of large lipid droplets in macrophages, mesangial cells, renal tubular cells, and stromal cells (Fig A). Genetic testing revealed familial type III hyperlipoproteinemia (Apo E2/E2 genotype) and she was started on a fibrate. Her nephrosis was presumed to be mediated by FH Type III and thus not responsive to immunosuppression (IS). However, upon referral to our center, review of electron microscopy revealed diffuse foot process effacement suggestive of a primary podocytopathy (Fig B). Treatment with high dose glucocorticoids led to a complete remission (UPCR 0.3) with resolution of dyslipidemia (Cholesterol/Triglycerides). She relapsed twice with steroid tapering and received rituximab for steroid-dependent nephrotic syndrome. She is now in complete remission off glucocorticoids.

Discussion: While patients with FH Type III have lipid deposition in many organs, clinically relevant kidney disease is atypical. Patients with other rare ApoE mutations can develop lipoprotein glomerulopathy, which is a distinct pathologic entity mediated by abnormal deposition of lipoprotein and not responsive to IS. In our case, the patient developed minimal change disease, which unmasked the clinical phenotype of Type III FH. IS led to complete remission and resolution of dyslipidemia. The finding of diffuse foot process effacement serves as a surrogate for a primary podocytopathy. Immunosuppression should not be withheld in such patients, even in the presence of renal lipidosis.



PUB445

Alport Syndrome: A Case of Uncommon Inheritance Pattern

Sonia Nasery, Yasir Alfi, Sina Emami, Renu Regunathan-Shenk. *Division of Renal Disease and Hypertension, George Washington University, Wasington, DC.*

Introduction: In 1927, Arthur C. Alport first published his description of a triad of symptoms in a family with congenital hemorrhagic nephritis, deafness, and ocular changes. Alport syndrome still inevitably leads to end-stage renal disease (ESRD). It occurs as a consequence of structural abnormalities in type IV collagen, the major constituent of basement membranes. Six genetically distinct chains of type IV collagen have been identified. Mutations in the COL4A5 gene, encoding the alpha-5 chain, is responsible for X-linked Alport syndrome, the most common form of the disease. Mutations in COL4A3 or COL4A4, which encode alpha-3 and alpha-4 chains, are involved in the rarer autosomal recessive and autosomal dominant forms of the disease. Here we describe a female with Alport's syndrome that had an indolent presentation and an uncommon inheritance pattern.

Case Description: 42 year old El Salvadorian female with microscopic hematuria and proteinuria that were persistent for 2 years. Previous cystoscopy was negative. The subject's father and 2 out of 4 brothers had ESRD and passed away (with dialysis initiated at age 50, 45, and 47 respectively). One of these brothers had hearing impaired. Her other 2 brothers, sister, and mother are healthy. Physical examination was unremarkable. Labs revealed serum creatinine of 0.7, 1.3 g/g proteinuria, and urine sediment with 2-3 nondysmorphic RBCs/HPF without cellular casts. Serologic work-up was negative. The renal sonogram showed normal size kidneys. Renal biopsy performed. The light microscopy was notable for glomerulomegaly and routine immunofluorescence was unremarkable. The electron microscopy revealed thin glomerular basement membranes (241 nm) with segmental areas of basement membrane scalloping and microparticles, consistent with Alport syndrome. Staining for alpha 5 chain of type IV collagen was preserved.

Discussion: In this patient, preserved alpha 5 chain staining is consistent with either autosomal dominant or autosomal recessive forms of Alport syndrome. Given her family history she likely has autosomal dominant disease, which accounts for less than 5% of Alport cases. Autosomal dominant disease has a milder renal phenotype, with a median renal survival of 70 years. This case stresses the importance of obtaining an accurate family history and consideration of biopsy in patients with sub-nephrotic proteinuria and family history of ESRD.

PUB446

Late-Onset Bartter Syndrome Type II

Benjamin Gollasch,[2,3] Yoland marie Anistan,[4] Maik Gollasch.[1] *[1]Charité University Medicine, Berlin, Germany; [2]Charité Universitätsmedizin Berlin, Berlin, Germany; [3]Cardiology/Nephrology/Pulmonology, HELIOS Klinikum Berlin, Berlin, Germany; [4]Charité, Berlin, Germany.*

Introduction: Mutations in the ROMK1 potassium channel gene (*KCNJ1*) cause antenatal/neonatal Bartter syndrome (aBS) type II. Bartter syndrome type II is believed to represent a disorder of the infancy, but not in adulthood.

Case Description: We herein describe a female patient with a remarkably late-onset and mild clinical manifestation of BS. Laboratory tests showed hypokalemia (3.0 mmol/L),

low-normal total serum calcium (2.31 mmol/L), hyperaldosteronism (515 ng/L, 847 ng/L) (normal 30-340), hyperreninemia (43.1 ng/L, 25.6 ng/L) (normal 2.0-24.6) and increased calcium excretion in the urine (7.5 mmol/d or 0.13 mmol/kg body weight/day (normal range <6.2 mmol/d or <0.1 mmol/kg body weight/day)). Serum sodium (139 mmol/L), chloride (104 mmol/L), magnesium (0.87 mmol/L) and phosphate (0.9 mmol/L) levels were normal. In arterial blood, pH was high but bicarbonate levels were normal (pH 7.498, HCO3- 25.7 mmol/L, pCO2 30.5 mmHg, PO2 118 mmHg). Fractional excretion of potassium (FEK 22%, 29%) and chloride were increased (FECl 2.52%). The trans-tubular potassium gradient (TTKG 21) was high in our patient considering the presence of hypokalemia, indicating renal potassium wasting. Serum creatinine was 1.10 mg/dL (eGFR [MDRD] 58 mL/min). After 14 hours of water deprivation, our patient had a reduced urine osmolality (392 mOsmol/kg; normal 915±91 mOsmol/kg at a plasma osmolality of 294 mOsm/kg), indicating that our patient cannot concentrate her urine well. Antidiuretic hormone (AVP) in plasma was high. We implemented and evaluated the performance of two different bioinformatics based approaches of targeted massively parallel sequencing (NGS) in defining the molecular diagnosis. Both analyses detected heterozygous *KCNJ1* missense mutations, consisting of a novel c.197T>A (p.I66N) and a previously reported c.875G>A (p.R292Q) *KCNJ1* mutation in our patient. Family analysis revealed compound heterozygosity.

Discussion: Our results demonstrate that aBS II may be suspected in patients with a late-onset phenotype. Our experimental approach of NGS-based mutation screening combined with Sanger sequencing proved to be a reliable molecular approach for defining the clinical diagnosis in our patient. Our results can have a significant impact on diagnosis of other patients with clinical unclassified phenotypes of nephrocalcinosis and congenital renal electrolyte abnormalities.

PUB447

A Case of Autosomal Recessive Alport's Syndrome

Farid Arman, Misak Harutyunyan, Gurpreet Singh, Kevin C. Donohue, Maha Al-Baghdadi, Rohit Singhal, Niloofar Nobakht, Anjay Rastogi. *University of California, Los Angeles, Los Angeles, CA.*

Introduction: Alport Syndrome (AS) is a genetic disorder caused by mutations in Type IV Collagen, which plays a major role in the structural integrity of the glomerular basement membrane. Mutations to the *COL4A3*, *COL4A4*, and *COL4A5* genes can all result in defects to Type IV Collagen. People with AS typically experience a progressive loss of kidney function, and often present with proteinuria and hematuria. Gradual scarring of the kidney eventually leads to ESRD in many people with AS. Type IV collagen is also expressed in important components of the inner ear as well as the eye, thus patients tend to develop extra-renal complications such as hearing loss and visual impairments. Over 80% of AS is inherited in an X-linked pattern due to mutations in *COL4A5*, however AS can also be inherited in an autosomal recessive or autosomal dominant pattern due to mutations in *COL4A3* or *COL4A4*. Compared to autosomal dominant AS, patients with X-linked or autosomal recessive inheritance patterns typically have a more severe disease progression leading to earlier onset of ESRD and extra-renal manifestations

Case Description: Our patient is a 17-year-old male who first presented with persistent 'tea colored' urine, proteinuria, and hematuria at the age of five. His creatinine at the time was measured at 0.27mg/dL and a urinalysis showed protein ≥300mg/dL. At the time there was no family history of renal disease, recurrent hematuria, or hearing loss, therefore a renal biopsy was performed. Renal biopsy showed abnormal basement membrane and an amino histochemistry assay for Type IV collagen was also abnormal, suggesting diagnosis of AS. Genetic testing confirmed the diagnosis of the homozygous autosomal recessive AS. Currently, the patient has a stable renal function with creatinine of 0.57mg/dL, Schwartz estimate 118.7ml/min/1.73m^2, and uACR 1449mg/g.

Discussion: Although our patient is confirmed to have two mutations in the *COL4A4* genes, representing a true autosomal recessive inheritance, his health has been relatively stable. About 50% of untreated males with X-Linked AS develop kidney failure by age 25, increasing to 90% by age 40 and nearly 100% by age 60. Although our patient presents with proteinuria and hematuria, he has stable kidney function, does not present with hypertension, and has no extra-renal complications seen in AS.

PUB448

Two Brothers with ESRD Due to C3 Glomerulopathy – A Case Report

Abbas Raza,[2] Jaime A. Baynes-Fields,[2] Michael L. Levin,[1] Sandeep Aggarwal,[3] Muhammad O. Hanif,[5] Karthik M. Ranganna.[4] *[1]Metropolitan Nephrology Associates, PC, Lafayette Hill, PA; [2]Drexel University College of Medicine, Philadelphia, PA; [3]Drexel University College of Medicine, Philadelphia, PA; [4]Drexel University, Philadelphia, PA; [5]Drexel University, PHILADELPHIA, PA.*

Introduction: C3 glomerulopathy includes several rare forms of glomerulonephritis (GN) with underlying defects in the alternate complement cascade. The two major subgroups of C3 glomerulopathy are dense deposit disease (DDD) and C3 GN—are distinguished by electron microscopy (EM). DDD is diagnosed at an earlier age than C3 GN. DDD is defined by the EM findings of intramembranous glomerular basement membrane dense deposits. C3 GN encompasses the remainder of the C3G lesions and is defined by some combination of mesangial, sub-epithelial, sub-endothelial, and/or less dense, discontinuous intramembranous deposits. Clinically C3 glomerulopathy presents with proteinuria, hematuria and some degree of renal insufficiency. 35-50% of DDD and 25% C3 GN progresses to ESRD over a 10 year period.

Case Description: Here we describe two brothers who are in their early 20s with ESRD on hemodialysis secondary to MPGN with dominant C3 deposition. Both presented with elevated creatinine and proteinuria. One of them was diagnosed with MPGN at 14 years of age and the other one at 20 years of age. Biopsies revealed electron dense deposits in the mesangium and sub-endothelial space with segmental duplication of basement membrane with mesangial hyper-cellularity and granular C3 staining in the mesangium, and the tubular basement membrane. There were significant interstitial fibrosis and tubular atrophy. See table 1 for results of genetic, functional assay and the biomarkers.

Discussion: There are only few case reports of family members having C3 glomerulopathy. Both of our patients are awaiting kidney transplant. Their genetic analysis revealed variants of unknown significance in genes ADAMTS 13, CFH, SERPINC1 and VWF. There are no effective targeted treatment options for C3 glomerulopathy and there is high recurrence of disease and allograft loss after transplantation. Plasma exchange has been tried with limited success in patients with C3Nefs and greater success in patients with mutations in CFH. Eculizumab has been studied in C3G and DDD with partial response. There needs to be more research into effective treatment as this disease affects younger members of our society.

Altered Function of TRPC6 May Contribute to Pregnancy-Associated aHUS

Johannes Muench,[2] Stephanie Häfner,[1] Marie L. Weber,[3] Ria Schönauer,[2] Tom H. Lindner,[2] Carsten Bergmann,[4] Holger Stepan,[3] Jan Halbritter.[2] *[1]Rudolph-Boehm-Institute of Pharmacology und Toxicology, University of Leipzig, Leipzig, Germany; [2]Department of Nephrology, University Hospital Leipzig, Leipzig, Germany; [3]Department of Obstetrics, University Hospital Leipzig, Leipzig, Germany; [4]Center for Human Genetics, Bioscientia, Ingelheim, Germany.*

Introduction: Pregnancy-associated atypical hemolytic uremic syndrome (p-aHUS) has recently become a well-recognized differential diagnosis of aHUS. Postpartal deficiency of complement system inhibitors is suspected trigger endothelial damage and formation of thrombotic microangiopathy (TMA), leading to hemolytic anemia and kidney failure. The presence of preeclampsia is thought to constitute a risk factor for p-aHUS, as the production of soluble Fms-like tyrosinkinase-1 (sFLT-1) promotes TMA formation (Erpenbeck, *JASN* 2016) by inhibiting the angiogenic effect of vascular endothelial growth factor (VEGF). However, since sFLT-1 production normally ceases with delivery and genetic defects in complement regulators can only be found in half of the cases (Bruel, *CJASN* 2018), further mechanisms need to be considered.

Case Description: In a 41 year-old female, delivery by caesarean section was performed in the 25th gestational week, due to preeclampsia (proteinuria 3,4 g/g creatinine, sFLT-1/PIGF 231). Ten days postpartum, she presented with coombs-negative hemolytic anemia (Hb 3.2 mmol/l, platelets 32 Gpt/l, schistocytes 4.3%, LDH >30 mmol/l, haptoglobin <0.1 mmol/l), and acute renal failure (s-creatinine 472 µmol/l). Kidney biopsy revealed glomerular TMA. Genetic testing for mutations of known aHUS genes was unremarkable. However, a previously reported heterozygous 12bp insertion in exon 2 of *TRPC6* was detected (c.253_264dup, p.(Ala85_Phe88dup)) (Weber, *Ped. Neph.* 2015). *TRPC6* encodes an ubiquitously expressed calcium-permeable channel that also plays a crucial role in human podocytes, where defects have been associated with genetic FSGS by mechanisms of both, gain and loss of function (Riehle, *JASN* 2016). Patch clamp analysis and calcium influx assays upon overexpression of wildtype versus Ala85_Phe88dupare ongoing.

Discussion: P-aHUS is a major postpartal condition that takes several triggers in order to develop. We suggest that altered TRPC6 function may constitute an alternative trigger for development of acute TMA-related kidney failure, similar to the proposed mechanism in DGKE-related aHUS/TMA (Ozaltin, *JASN* 2013). As podocytic TRPC6 expression is also influenced by VEGF (Thilo, *NDT* 2012), sFLT-1 mediated VEGF inhibition in the setting of preeclampsia might further provoke an alteration in podocyte and platelet function.

PUB450

Vitamin D Drops Leading to Kidney Failure

Bourne L. Auguste,[1] Joanne M. Bargman.[2] *[1]University of Toronto, Toronto, ON, Canada; [2]Toronto General Hospital, Toronto, ON, Canada.*

Introduction: Vitamin D toxicity is rare but early recognition may limit complications related to hypercalcemia including acute and chronic renal failure. Hypervitaminosis D can be treated with glucocorticoids, ketoconazole or hydroxychloroquine.

Case Description: A 54-year old man is seen for AKI after his creatinine increased to 376 µmol/L from 132 µmol/L (baseline 100) over a 4-week period despite holding ACEi and diuretic. Medications included perindopril, rosuvastatin, amlodipine, indapamide and febuxostat. Medical history was significant for hypertension and gout. On exam, blood pressure was 149/98 mm Hg with no urgent clinical indications for dialysis. Renal ultrasound was normal. Urine microscopy was normal. Ionized calcium was 1.48 mmol/L and PTH was 0.5 pmol/L. Serum and urine protein electrophoresis studies were negative. Renal biopsy showed tubular atrophy with microcalcifications. He later revealed to be taking 12,000 IU of Vitamin D drops daily for 2.5 years. Measured vitamin D levels were elevated and continued to rise despite stopping supplements (Table 1). He was started on hydroxychloroquine given rise in vitamin D, which only normalized after initiation of hydroxychloroquine. Unfortunately, he is now left with Stage 3B CKD from nephrocalcinosis.

Discussion: Hypervitaminosis D treatment must focus on reducing dietary sources. Alternative strategies to reduce levels by inhibiting conversion to active 1,25-$(OH)_2$D3 must also be considered. If asymptomatic then levels can be monitored expectantly, but may take time to normalize as vitamin D is fat soluble. Glucocorticoids, ketoconazole and hydroxychloroquine have been used to treat hypercalcemia related to sarcoidosis. These medications reduce 1 α-hydroxylase activity and in turn decrease 1,25-$(OH)_2$D3 levels. Given that our patient was reluctant to use glucocorticoid treatment, we successfully used hydroxychloroquine as an alternative to treat his hypervitaminosis D.

Serial clinic labs

Lab Value	Week 1	Week 5	Week 10	Week 16	Week 20	Week 24	Normal Range
Ionized calcium (mmol/L) corrected for pH 7.4	1.48	1.54	1.63	1.47	1.26	1.27	1.12-1.32
Serum calcium (corrected for albumin)	3.04	3.21	3.28	2.87	2.57	2.57	2.20-2.62

Dipilumab Induced Acute Interstitial Nephritis

Fatima Sheikh,[1] Kenar D. Jhaveri,[1] Vanesa Bijol,[2] Khurram Mehtabdin.[1]
[1]Nephrology, Zucker School of Medicine at Hofstra/Northwell, Great Neck, NY; [2]Pathology, Zucker School of Medicine at Hofstra/Northwell, Great Neck, NY.

Introduction: Dupilumab, sold under the trade name Dupixent, is a monoclonal antibody designed for the treatment of allergic diseases, such as eczema. It binds to the alpha subunit of the interleukin-4 receptor (IL-4Rα). Through blockade of IL-4Rα, dupilumab modulates signaling of both the interleukin 4 and interleukin 13 pathway. To our knowledge, renal adverse effects were not reported with this agent.

Case Description: A 59 year old male with achalasia and eczema presented with an elevated serum creatinine of 2.2mg/dl and a bland urine sediment. A few weeks prior to presentation, he was initiated on dupilumab, dosed q2 weeks. His baseline serum creatinine was normal in the past. He was not on any other nephrotoxic agents such as NSAIDs, proton pump inhibitors or antibiotics. Furthermore, he denied any herbal medications. A kidney biopsy was performed which revealed acute moderate allergic interstitial nephritis (AIN) with minimal fibrosis. No other significant pathological findings were noted on biopsy. The patient was started on steroids and dipilumab was subsequently held. The serum creatinine responded to treatment and improved to 1.5mg/dl.

Discussion: AIN is commonly associated with monoclonal antibody agents used for cancer treatment. This is the first reported case of dipilumab-induced AIN discovered during its use for the treatment of eczema. Dermatologists and nephrologists need to be aware of this serious complication associated with IL-4R antagonists.

PUB452

Almond Milk: A Potential Cause of Oxalate Nephropathy?

Felix E. Santiago,[2] Pang-Yen Fan.[1] *[1]University of Massachusetts Medical School, Worcester, MA; [2]UMass Medical School, Worcester, MA.*

Introduction: After Roux-en-Y gastric bypass (RYGB), luminal fatty acid and bile salts increase oxalate absorption. Fecal fat binds calcium that would otherwise bind oxalate. Luminal bile salts enhance colonic epithelial oxalate permeability. These changes cause hyperoxaluria and increase the risk for oxalate nephrolithiasis, although the incidence of oxalate nephropathy remains poorly defined.

Case Description: 62 y.o. woman s/p RYGB in 2012 received DDKT for ESRD from diabetic nephropathy in 3/2014. Her creatinine slowly rose to 2.2 from 8/17 to 11/17. She presented with AKI in 12/17 (Fig. 1). She was asymptomatic except for chronic diarrhea. She also "started to eat healthy", drinking 32 oz. of almond milk a day since 10/17. Biopsy revealed oxalate nephropathy (Fig. 2). The patient was treated with low oxalate diet and citrate supplements. Her creatinine improved to 2.7. Urinary oxalate excretion is now 85 mg/day.

Discussion: This case shows the impact of dietary changes for patients at risk for oxalate nephropathy. We initially suspected almond milk as the source of oxalate that caused AKI. Almond milk is made by filtering water through ground almonds. Many almond milk products contain minimal amounts of almond, though specific data on oxalate content are not available. It is unclear whether consumption of almond milk significantly increases oxalate intake. Therefore, we concluded that the patient's AKI may have been due to other factors such as hypovolemia from diarrhea and RYGB. It's important to note the patient later reported that she had increased her consumption of nuts, hot chocolate, and spinach though the amounts consumed were quite small. In summary, relatively modest increases in oxalate intake may precipitate AKI in patients with RYGB. However, it remains uncertain whether almond milk is a source of dietary oxalate. We hope to arrange formal chemical testing to determine the oxalate content of this popular beverage.

PUB453

Thrombotic Microangiopathy Associated with Gastric Adenocarcinoma Causing AKI

Brad Long,[1] Josephine Abraham,[1] Laith Al-Rabadi.[2] *[1]University of Utah, Salt Lake City, UT; [2]University of Utah hospital, Salt Lake, UT.*

Introduction: Gastric cancer is identified as a cause of thrombotic microangiopathy (TMA), a class of disease occurring with thrombocytopenia and microvascular thrombosis-induced organ damage commonly affecting the kidneys. We present a case of acute kidney injury resulting from TMA due to metastatic gastric adenocarcinoma.

Case Description: The patient is a 46 year old woman complaining of weakness and weight loss admitted with L2 burst fracture and diffuse lymphadenopathy on CT. Blood pressure was elevated to 159/98. Labs showed anemia with hemoglobin of 7.1g/dL and platelets of 67K/uL. Renal function notable for creatinine of 1.45mg/dL and BUN of 38mg/dL. Biopsy of the spine lesion revealed CK7+/CK20+ carcinoma; EGD showed a fungating gastric cardia mass with biopsy showing poorly-differentiated adenocarcinoma. Colonoscopy showed a sigmoid ulcer with ischemic pattern of injury with microthrombi on histology. Additional tests were consistent with microangiopathic hemolytic anemia (MAHA), a feature of TMA. Haptoglobin was <10mg/dL, total bilirubin 2.1mg/dL, and schistocytes seen on blood smear. ADAMTS13 activity was normal at 91% and direct Coombs test was negative. PT and PTT were not prolonged and fibrinogen was normal. Kidney biopsy was felt to be too dangerous at the time. The patient started on chemotherapy but unfortunately her kidney function worsened due to oxaliplatin and she ultimately required hemodialysis.

Discussion: TMA is a recognized complication of gastric adenocarcinoma with kidney injury as a possible result. Kidney biopsy is often not necessary to make the diagnosis. TMA resulting from gastric adenocarcinoma is challenging to treat and is typically refractory to treatment with plasma exchange. Chemotherapy is felt to be the most effective treatment strategy though can itself be nephrotoxic.

"Zombie" at Home: Rhabdomyolysis Secondary to Synthetic Cannabinoid K2 Withdrawal

Mario R. Funes-Hernandez,[4] Shirin Poustchi,[2] Pablo Garcia,[4] Kartik Kalra.[4] *[2]Rutgers Robert Wood Johnson Medical School, Somerset, NJ; [4]Saint Peters University Hospital, New Brunswick, NJ.*

Introduction: Synthetic cannabinoid (SC) use as a marijuana alternative was first reported in the United States in 2008. Multiple variants have been developed that are not recognized as illegal substances, do not appear in routine toxicology screens, and are marketed under a variety of names, including K2, Spice, Joker, and Kronic. Recently, an acute intoxication outbreak was reported in New York City. There have been limited reports on rhabdomyolysis due to K2 withdrawal. We present a case of a 46-year-old African American male with rhabdomyolysis due to severe withdrawal symptoms after acute K2 cessation.

Case Description: A 46-year-old African American male with no PMH presented with a 5-day history of nausea, muscle cramps, irritability, insomnia, auditory and visual hallucinations. Patient's wife described his behavior as a "zombie". Patient had been smoking K2 daily for the past 3 months and symptoms were precipitated after abruptly stopping. Patient was afebrile, BP of 135/85, HR 120 beats per minute, RR of 22 and O2 Sat 100%. He was anxious, tremulous and restless. He was alert and oriented but unable to focus. Patient had dry mucous membranes, pupils < 2 mm, and horizontal nystagmus. Investigation revealed: WBC 22.7 x 10^9/L, Hgb 17.8 g/dL, sodium 126 mEq/L, potassium 3.2 mEq/L, chloride 88 mEq/L, bicarbonate 22 mEq/L, urea nitrogen 21 mg/dL, creatinine 2.16 mg/dL, calcium 10.6 mg/dL, albumin 5.1 g/dL and CPK 3981 U/L. Urinalysis showed a specific gravity of 1.015, trace blood, trace protein, 2-5 red blood cell per high-power field, 2-5 hyaline casts per low-power field. Urine toxicology was positive for THC. Patient was given 2 L of normal saline on admission followed by 200 mL/hr. Management included benzodiazepines due to insomnia and restlessness as well as intravenous hydration due to acute kidney injury. Patient's AKI resolved subsequently; creatinine decrease to 0.74 mg/dL after 72 hours and CPK decreased to 500 U/L at time of discharge.

Discussion: SC use is a public health concern as it has become popular due to low cost, easy availability, and lack of regulation. Acute withdrawal sequelae have not been studied nor understood yet. Rhabdomyolysis should be suspected in patients presenting with acute withdrawal, allowing for prompt initiation of adequate treatment and potentially avoiding acute renal failure.

PUB455

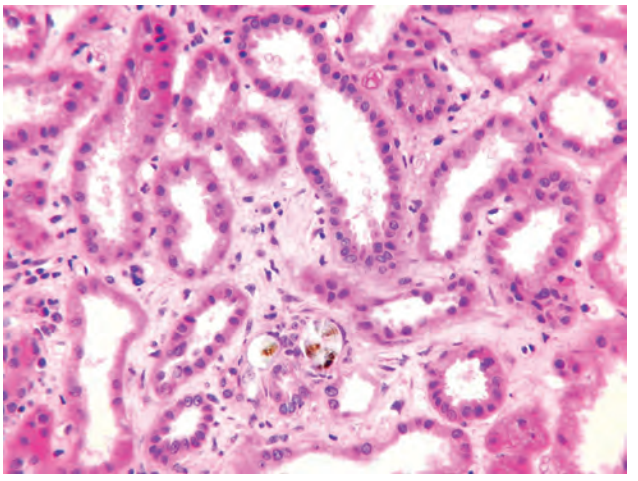
A "Crystal Clear" Case of AKI

Jennifer L. O'Brien, Jennifer B. Hanko. *Belfast City Hospital, Carrickfergus, United Kingdom.*

Introduction: A patient was transferred to nephrology with severe acute kidney injury (AKI) requiring dialysis and was subsequently diagnosed with crystal nephropathy (CN) from oral Aciclovir. Intravenous Aciclovir is a well described cause of CN. This case highlights the risk of CN with high dose oral Aciclovir in the setting of volume depletion.

Case Description: A 66 year old female with a medical history of Hodgkins Lymphoma; prior vasculitis with renal and skin involvement; and shingles, on oral Aciclovir prophylaxis; presented with a 1 month history of shortness of breath and palpitations and a 2 day history of gastric upset. She was clinically dehydrated, in rapid atrial flutter and had transient hypotension. She was treated with IV Metoprolol. Over 4 days, she developed anuric AKI; serum creatinine increased from 0.97 mg/dl to 7.68 mg/dl. Oral Aciclovir 200mg three times daily was administered until day 5 of admission when she transferred for haemodialysis. Admission was complicated by an unstable duodenal ulcer bleed, acute confusion and transient inflammatory thrombocytopenia. A renal biopsy was performed after 3 weeks; she remained dialysis dependent but urine output was increasing. Biopsy showed crystals within the tubules and recovering acute tubular necrosis (ATN). By week 4, she was independent of dialysis.

Discussion: The severity of her AKI was out of keeping with the degree of volume depletion and hypotension. Renal biopsy was delayed due to other acute medical issues. Despite the delay, crystals remained within the renal tubules. Oral Aciclovir in this setting contributed to severe anuric AKI. For patients at risk of AKI or with established AKI, physicians should have a low threshold to review Aciclovir indication; if indicated, ensure that the dose is adjusted for the level of renal function.



Renal biopsy showing a crystal within a tubule and recovering ATN

PUB456

Metformin Associated Lactic Acidosis: Identifying Rare Clinical Presentation

Sai mounica Maddu, Gabriella R. Gomez, Rabih Nasr. *Bronx Care Health System, Bronx, NY.*

Introduction: Metformin is the one of the most frequently used oral agent in the treatment of Type 2 Diabetes Mellitus. The major toxicity associated with metformin is lactic acidosis, which carries a high morbidity and mortality. While Metformin poisoning can be challenging to diagnose, it requires high index of suspicion. We present one such case.

Case Description: 78 year old Hispanic Female patient with Type 2 Diabetes Mellitus, Hypertension presented to the ER with generalized body aches, diarrhea and flank pain since 3 days associated with severe watery non bloody diarrhea. Patient was initially hypertensive in the triage. Labs reported severe metabolic acidosis with pH of 6.785 with elevated lactic acid 18.0 mmol/L, bicarbonate of 2.0 mmol/L and anion gap of 56. Patient was also noted to have acute kidney injury – with serum creatinine of 6.1 mg/dL (baseline 0.7 mg/dL). Patient was drowsy, providing limited history - said she was taking all of her diabetes and medications including metformin. Pre-dialysis metformin levels were obtained due to high clinical suspicion. Patient was started on IV Bicarbonate replacement, emergency dialysis was arranged with elevated Bicarbonate bath with 40meq/L done in the ER. Pre-dialysis metformin levels later on were found to be 13mcg/mL (theraupetic range 1-2 mcg/mL). Post dialysis metformin levels were noted to be: 5.6 mcg/mL. Patient's septic workup later came back negative pointing that this was a case of Metformin Associated Lactic Acidosis. Patient's renal function and clinical status improved and she was discharged home with serum creatinine of 1.3 mg/dL

Discussion: Metformin poisoning carries a high mortality and morbidity rate. It remains a challenging clinical entity which requires high index of clinical suspicion. Recognizing metformin associated lactic acidosis early on and implementing appropriate therapy would increase patient survival. Dialysis would remain best intervention in patients with Acute kidney Injury with serum creatinine >2 mg/dL and elevated serum lactate levels >15 mmol/L.

PUB457

Mycobacterium Chimaera Infection – A Rare Case of Interstitial Nephritis

Sadichhya Lohani,[1] Marco Delsante,[1] S.M. Bagnasco,[2] Avi Z. Rosenberg,[3] Blaithin A. McMahon.[1] *[1]Johns Hopkins Hospital, Baltimore, MD; [2]The Johns Hopkins School of Medicine, Baltimore, MD; [3]Johns Hopkins University, Baltimore, MD.*

Introduction: Outbreaks of *Mycobacteria chimaera* with cardiac and extra-cardiac manifestations have been reported post cardiac surgery with the use of heater-cooler units in heart-lung machines. Nephritis is a rare presentation of this iatrogenic infection with few reported cases.

Case Description: A 62-year old male developed *Mycobacterium chimaera* spinal infection a year after coronary artery bypass graft and aortic valve replacement. He was started on azithromycin, Rifabutin, Gatifloxacin, and Ethambutol. He developed acute kidney injury that initially improved with IV fluid (figure 1). Gatifloxacin was stopped.10 months later, he presented with altered mental status. Creatinine was 7.1 mg/dl, protein/creatinine ratio of 0.53g/g, urinalysis without pyuria or cellular casts, and a normal WBC count without eosinophilia. Blood cultures grew *M. chimaera*. Mycobacterial urine cultures were negative. Azithromycin, Rifabutin, and Ethambutol were continued. Clofazimine (added 1 month prior to presentation) level was subtherapeutic. Renal biopsy revealed diffuse interstitial inflammation and one small interstitial granuloma with multinucleated giant cells, but AFB stain was negative. Clofazimine was titrated to a therapeutic dose. Mycobacterial blood cultures were subsequently negative. He had a partial improvement in his renal function with Cr of 4.1 mg/dl at the time of discharge.

Discussion: Diagnosis of granulomatous interstitial nephritis in our patient was likely related to the *M. chimaera* infection. Renal function improved with the clearance of bacteremia. Drug-induced interstitial nephritis was less likely since renal function improved despite continuing the 4-drug antimicrobial therapy. *M. chimaera* related interstitial nephritis is a rare condition with poor outcomes. Renal biopsy is crucial to rule out other etiologies of renal dysfunction. Timely initiation of antimicrobial therapy on appropriate doses can prevent deterioration of renal function.

PUB458

All Fired Up: The Angry Macrophage

Divyanshu Malhotra,[1] Ravi Kodali,[2] Ursula C. Brewster.[3] *[1]Yale New Haven Hospital, New Haven, CT; [2]Yale University, New Haven, CT; [3]Yale University School of Medicine, New Haven, CT.*

Introduction: Hemophagocytic Lymphohistiocytosis(HLH) is an aggressive and life-threatening syndrome of excessive immune activation characterized by activation and proliferation of uncontrolled macrophages and lymphocytes, culminating in an unrelenting cytokine storm and subsequent tissue infiltration and multi-organ system failure. Here we present a case of a patient who had a dramatic presentation of HLH with severe renal failure and was ultimately found to have a surprising diagnosis.

Case Description: 48 y/o male originally from Ghana, living in US for years with HTN not on treatment who presented with 3 weeks of a variety of symptoms including fever, headache, abdominal pain, poor appetite and a bad taste leading to a weight loss of 20-25 lbs. Also noticed yellowness of his eyes. No sick contacts or travel. Had significant laboratory abnormalities including pancytopenia, severe renal failure with BUN 330 mg/dl and Cr 22 mg/dl, elevated liver enzymes but normal INR, K 7.8mmol/L, CO2 10mmol/L, PO4 17mg/dl,Lipase 4470U/L,lactate 3.2mmol/L,Ferritin 5466ng/ml,TG 451mg/dl and soluble IL-2 43800pg/ml. Imaging revealed pancreatitis, pulmonary edema and bladder calcification. Was started on dialysis. Met criteria for HLH after BM biopsy and was started on steroids. Kidney biopsy revealed ATN.Extensive search for a potential trigger for HLH including all blood/BM cultures was negative. After initial improvement, suffered a PEA arrest after 1 week and continued to rapidly deteriorate and died within hours. Autopsy was performed which showed miliary TB, Schistosomiasis(likely inactive) and HLH.This was very surprising given negative AFB blood and BM cultures and no clear radiological sign of TB.

Discussion: HLH is primarily a pediatric syndrome but is being increasingly recognized in adulthood. Divided into primary and secondary forms, typically associated with a trigger(most commonly infection). Caused by lack of normal downregulation of activated macrophages and lymphocytes leading to a cytokine storm and multi-system injury. Renal manifestations include ATN(most common), pre-renal injury or glomerulopathy(MCD, TMA and collapsing FSGS). High mortality if untreated. No randomized trials to guide treatment, regimens based on HLH-94 protocol with etoposide and steroids. Alternate regimens used especially in the setting of cancer. Triggers should be treated aggressively. TB, a great mimic, has rarely been associated with HLH with a subsequent high morbidity/mortality.

PUB459

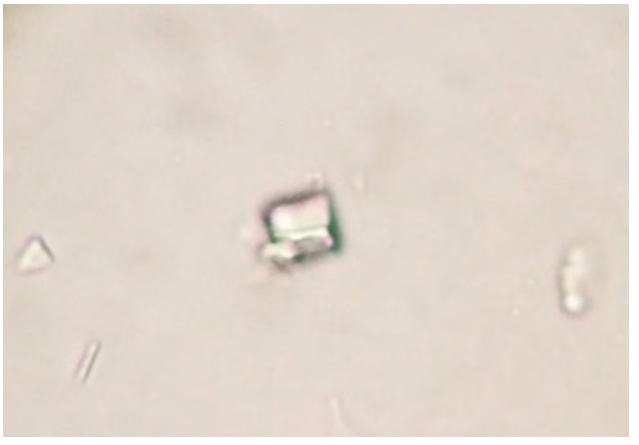
Sulfamethoxazole Crystal-Induced AKI

Franklin D. Ponce-Herrera, Vipulkumar Bhalara, Joshua Kaplan. *UMDNJ/NJ Medical Center, Newark, NJ.*

Introduction: In the HIV/AIDS population, TMP/SMX is a frequently used in prophylactic doses, should these patients present with acute illness due to PCP pneumonia, they may require higher dosing, the potential for nephrotoxicity due to sulfa-induced crystalluria is high and vigilance is required for prevention and recognition.

Case Description: We report a 55 year-old woman with PMHx of AIDS, CKD stage III, who presented to the hospital with shortness of breath, cough, CT Chest without contrast showed nodular opacities. The patient was admitted with a suspected diagnosis of PCP pneumonia and was treated with high doses of TMP/SMX, followed by development of anuric renal failure most likely secondary to IV TMP/SMX. Patient was started on IV Lasix to which she was initially not responsive until day 5 when she began making urine, patient's urine was analyzed under microscopy and found to have pleomorphic crystals present. At this point patient's creatinine began to return to baseline and she entered the diuretic phase of AKI, producing 7 liters of urine on days 6 and 7.

Discussion: There are several major risk factors for Sulfadiazine crystalluria and acute kidney injury: volume depletion, administration of higher doses of oral and intravenous formulations, hypoalbuminemia, urine pH <5.5, use of an ACE-inhibitor and the presence of previous underlying kidney disease. In these respects, our patient was exposed to a high IV dose of TMP/SMX (15 mg/kg/day, Patient's weight 110kg), had decreased GFR at baseline and acidic urine (pH = 5.0), along with volume depletion. Management of sulfa-induced kidney injury mainly involves discontinuing the offending drug and aggressive intravenous fluid administration. Urinary alkalization may also play a role; as urine pH increases the crystals more readily dissolve and the obstruction is relieved. It seems prudent to hydrate aggressively during treatment with high dose TMP/SMX to reduce the risk of crystal nephropathy, with increased natriuresis



PUB460

Should You Wait? Taking a Patient with AKI for TAVR Resulting in Dialysis Dependence

Deep Phachu,[2] Hassan B. Attique.[1] *[1]Uconn Health, Farmington, CT; [2]University of Connecticut Health, Hartford, CT.*

Introduction: Aortic stenosis (AS) is one of the most common cardiac valvular diseases, with a prevalence of 1.3% in patients between 65 and 74 years and ~3% in patients >75 years of age. Trans-catheter aortic valve replacement (TAVR) has shown comparable survival rates in high-risk patients not eligible for open-heart surgery. Given the well-documented complication of AKI in patient's undergoing TAVR, the question arises, in CKD patients with AKI, should you take them for TAVR or try alternative temporizing measures to address the AS and wait for the AKI to resolve?

Case Description: 62 year old female with HTN, T2DM, CKD 3B, CAD status post CABGx4 and history of AS presented with shortness of breath and syncope. She was found to have severe AS and due to her prior cardiac surgeries, deemed a candidate for TAVR. As a part of TAVR workup, she underwent left-heart catheterization and cardiac CT with contrast complicated by Oliguric AKI from a baseline creatinine of 1.7 mg/dL to 3.3 mg/dL. She was initiated on high-dose furosemide bolus, then furosemide infusion without improvement. The following day, she was taken for TAVR. 48 hours post-TAVR, her AKI worsened with creatinine of 6.5 mg/dL and urine output <10ml/hr. Echocardiogram revealed inoperable peri-valvular leak around her new aortic valve. Decision was made to initiate dialysis, and over the following 2 weeks, there was no evidence of renal recovery and patient was discharged with plans for long-term dialysis.

Discussion: Temporary alternatives to aortic valve replacement do exist for patients with AS and have shown to be fairly effective in temporarily improving cardiac function. Since one of the hypothesized etiologies of AKI in patients with AS is decreased renal perfusion, balloon dilation could theoretically provide the time required to resolve any pre-existing kidney injury. Furthermore, spacing out contrast load one week apart from TAVR may potentially be beneficial. Given the mean incidence of AKI post-TAVR to be ~22%, one would assume that CKD patients with a pre-existing AKI prior performing TAVR would be at increased risk for further worsening of their renal function. Further studies should be performed to compare the degree of renal failure in patients with pre-existing renal injury that received temporizing measures versus those that were taken immediately for cardiovascular procedures.

PUB461

AKI Secondary to Enoxaparin Induced Pelvic Hematoma

Samrah Zaigham,[1] Ahmad M. Sharayah,[1] Geeta Bhagia,[1] Mihir K. Maniar.[2] *[1]Monmouth Medical Center, Long Branch, NJ; [2]Private Physician, Long Branch, NJ.*

Introduction: Pelvic Hematomas have been recognised secondary to pelvic trauma or as a complication of obstetric surgeries and rarely secondary to use of anticoagulation therapy. It is a rare cause of abdominal pain which is often missed and a rarer cause of acute kidney injury.

Case Description: 78 year old female was admitted with shortness of breath and palpitations. A diagnosis of rapid atrial fibrillation was made, and she had AV node ablation after failure of medical therapy. Patient was anticoagulated with enoxaparin injected into the left side of the abdominal wall, as her CHADVASC score was 5. Four days after

admission, she complained of lower abdominal pain and anuria for one day. Physical examination revealed mild abdominal distention and tenderness in the suprapubic region. Labwork showed a sharp rise in serum creatinine and a drop-in hematocrit one day after onset of symptoms. Computed tomography scan of the abdomen revealed a 15x15cm hematoma within the paracolic gutter and pelvis causing bladder compression and left-sided hydronephrosis, patient was diagnosed to have post renal acute kidney injury secondary to pelvic hematoma. Patient was initially managed conservatively with serial physical exams, monitoring of haematocrit, imaging studies and avoidance of anticoagulants. But persistence of abdominal pain and anuria, warranted for a repeat scan which showed expansion in the size of hematoma and new development of right sided hydronephrosis, and hence bilateral nephrostomy tubes were placed. Patient was discharged few days later after removal of nephrostomy tubes and spontaneous reduction in the size of her hematoma.

Discussion: Spontaneous pelvic hematomas are usually missed as a cause of abdominal pain in patients on anticoagulation therapy. They usually develop within 5 days of initiating therapy, symptoms vary depending on the location of the hematoma and are best diagnosed with computed tomography scans. Conservative management should be reserved for patients who are stable, intra-arterial embolization or stent grafting is the treatment of choice when conservative measures fail. In conclusion subcutaneous injections into the abdominal wall increase the risk of hematoma, especially in elderly and thin patients. Healthcare professionals, patients and their relatives using enoxaparin should be advised to avoid deep injections into the abdomen; deltoid region could be a safer alternative.

PUB462

Atypical Hemolytic Uremic Syndrome Overlapping with Antiphospholipid Antibody Syndrome: A Case Report with Four Years Follow Up

Emmanuel A. Adomako,[1] Eseosa Edo-Osagie,[1] Evan Leibowitz.[2] *[1]Englewood Hospital and Medical Center, Englewood, NJ; [2]Prospect Medical Offices Valley Medical Group, Midland PArk, NJ.*

Introduction: Overlapping presentation of atypical hemolytic uremic syndrome (aHUS) and antiphospholipid antibody syndrome (APS) is a rare phenomenon. We present a case with four year follow up.

Case Description: A 57-year-old Caucasian female with a history of APS first diagnosed 10 years prior, presented with a year's history of recurrent abdominal pain and cognitive dysfunction. Laboratory evaluation showed evidence of microangiopathic hemolytic anemia with schistocytes, significant thrombocytopenia and renal insufficiency. Her laboratory studies are summarized below in Table 1. MRI of the brain showed chronic cerebellar and cerebral infarcts. She underwent plasmapheresis for one week without significant improvement in her symptoms or laboratory abnormalities. Given the presentation of thrombotic microangiopathy, the ADAMTS13 activity was > 5%, significant renal insufficiency and the lack of significant response to plasmapheresis, a diagnosis of aHUS was made. She was started on eculizumab infusions, initially 900mg weekly and subsequently maintained on 1200mg every two weeks. After 2 weeks of treatment, her creatinine decreased to 1.2 and hemoglobin stabilized at 9.8g/dl. She has had consistent follow up for 4 years during which period her creatinine has remained stable without the need for renal replacement therapy.

Discussion: aHUS is a condition associated with alternative pathway complement dysregulation. It is characterized by thrombotic microangiopathy(TMA), thrombocytopenia and end organ damage. Clinical presentation of aHUS is difficult to distinguish from other causes of TMA and laboratory differentiation does not always have a quick turnaround time. With an incidence of 1-2 per million, diagnosing aHUS requires a high index of suspicion and the exclusion of thrombotic thrombocytopenic purpura (TTP). APS is a recognized cause of secondary aHUS but may mask its presentation. Timely recognition of aHUS in such cases and the initiation of eculizumab is essential towards modulation of the course of the disease including onset of ESRD and dialysis dependence.

Rhabdomyolysis Secondary to Hypothyroidism

Alvaro Cornejo Cobo,[1] Ayan De.[2] *[1]Saint Peters University Hospital, Somerset, NJ; [2]Saint Peter's University Hospital, New Brunswick, NJ.*

Introduction: The relationship between Hypothyroidism (HT-H) and Rhabdomyolysis (Rhabdo) is not well-known. This is a case report of a patient that presented with ARF secondary to increased levels of CK and elevated TSH. The connection between both has been mentioned in few case reports but the mechanism is yet to be completely understood.

Case Description: A 71-year-old female with PMH of DM, HTN, and HT-H presented to the ED referred from her primary doctor for a raised Crea of 4.89 mg/dL. The patient was asymptomatic and did not report any changes to medication. On admission, her VS were stable. Repeat Crea in the ED was 4.57 and a BUN of 31. CK was 5403, with a CK MB fraction of 19.7 and a negative Trop. Rest of the labs where normal. UA was consistent with Rhabdo and negative for infection.

Discussion: This case is an example of an asymptomatic patient who presented with Rhabdo and Renal failure secondary to undertreated HT-H. HT-H is a common endocrine with a broad variety of symptoms ranging from asymptomatic to the most serious myxedematous coma. Rhabdo is a syndrome characterized by muscle necrosis and the release of intracellular muscle content into plasma. Most of the time it presents with severe muscle pain, weakness, hematuria, but in some cases, it could be asymptomatic. Diagnosis is made by laboratory results which elicit elevated levels of CK. Different causes for non-traumatic Rhabdo are known such electrolyte imbalances, infections heat exposure. Some endocrine disorders like DM, including DKA and nonketotic hyperglycemia, have also been reported to cause Rhabdo. Other electrolyte imbalances such as hypophosphatemia may also be the cause. There have been very few cases of Rhabdo caused by HT-H, and in most cases, there is an association with precipitating factors like exercise, trauma, drugs, most commonly statins and alcohol. The cause of Rhabdo secondary to HT-H is unclear. Various hypotheses including impaired mitochondrial oxidative metabolism, induction of insulin-resistant state, and decrease muscle carnitine levels including autoimmune mechanism, have been proposed. Thyroxine affects energy metabolism and its deficiency leads to abnormal glycogenolysis, mitochondrial oxidative metabolism and triglyceride turnover, which impair muscle function by causing a switch of fast-twitching type 2 muscle fibers to slow-twitching type 1 fibers, low myosin ATP-ase activity and low ATP turnover in skeletal muscle.

PUB464

Sulfadiazine Related Obstructive Nephrolithiasis and Acute Renal Failure

Usman A. Pirzada. *Bronx Lebanon Hospital, Bronx, NY.*

Introduction: Renal stones are a known complication of Sulfadiazine but not seen commonly. We report a case of nephrolithiasis and acute renal failure secondary to sulfadiazine.

Case Description: A 73 year old male was evaluated in the Emergency room with complains of hematuria and abdominal pain. He has a past medical history of a cerebello-pontine brain lesion/mass/ abscess and seborrheic keratosis. The patient was admitted in the hospital a month back with ataxia, balance problems and left sided facial weakness/ facial droop. He had extensive workup done including Pan-CT, tumor markers, PSA, blood cultures, Echo - all of which were unrevealing. Toxoplasma IgG was positive, HIV negative. The family refused for a biopsy of the brain lesion based upon location and the risk of procedure. Patient was treated empirically with Ceftriaxone, Metronidazole, Leucovorin, Bactrim and sulfadiazine and discharged on same. One month later, he presented to the ER with abdominal pain and hematuria. In the Emergency room, BUN/Cr was 44/6.4 (baseline serum creatinine 0.8). CT abdomen and Pelvis showed mild left sided hydroureteronephrosis caused by 2mm calculus at the left ureterovesical junction and trace right sided hydroureter caused by a punctate calculus at the right uretero-vesical junction. CT abdomen and Pelvis done one month back was negative for renal stones. He was treated conservatively with intravenous fluids and alkalinization of urine and the BUN/Cr trending down from 44/6.4 to 18/1.3 over the next 6 days. Atovaquone was substituted for sulfadiazine and the patient was advised to continue the meds as MRI showed interval decrease in size of the primary lesion and significant improvement in vasogenic edema and mass effect

Discussion: Sulfadiazine induced nephrolithiasis leading to renal failure is a potentially serious complication that can be managed conservatively in most cases. In our patient BUN/Cr improved dramatically within 1 week. Physicians should be aware of the complication and give their patients a trial of intravenous fluids and controlled alkalinization of urine if clinically warranted.

PUB465

Role of Eculizumab in Postpartum Atypical Hemolytic Syndrome in a Kidney Transplant Recipient

Hassan M. Awan,[1] Manish Talwar,[1] Aravind Dasari,[1] Sandeep K. Rajan,[1] Barry M. Wall.[2,1] *[1]UTHSC, Memphis, TN; [2]Veterans Affairs Medical Center, Memphis, TN.*

Introduction: Pregnancy-associated atypical hemolytic uremic syndrome (aHUS) is a rare, potentially lethal condition that can complicate pregnancy in upto 1 in 25000 cases. Given the broad spectrum of conditions that can present similarly in the peripartum period, it is difficult to establish the correct diagnosis in a timely manner. The C5 complement cascade inhibitor eculizumab has been used with considerable success in non-pregnancy aHUS; however, its use in pregnancy associated aHUS is limited to isolated case reports. We present a case of pregnancy associated aHUS in a kidney transplant recipient that was successfully treated with eculizumab with recovery of renal function and safe reintroduction of transplant medications.

Case Description: 33 year old female with history of end stage renal disease due to IgA nephropathy who received a cadaveric kidney transplant 7 years prior, presented at 25 weeks gestation with severe hypertension and acute kidney injury. Immunosuppression included tacrolimus, azathioprine and prednisone. Her baseline Cr was <1.0 mg/dl and was 4.7 mg/dl at presentation. She had thrombocytopenia (58 K/ul, down from baseline normal) and hemolytic anemia with high LDH of 1810 U/L, depleted haptoglobin (< 8mg/dl) and presence of schistocytes. She underwent cesarean section for suspected pre-eclampsia with a non-viable fetus. She remained hypertensive, anemic with high LDH, thrombocytopenic, and had worsened renal function with Cr of 7.7 mg/dl. Schistocytes persisted and ADAMTS13 was normal. Tacrolimus was held with concern of drug induced thrombotic microangiopathy (TMA); however, no improvement occurred. Kidney biopsy, initially avoided due to low platelets, was done at week 4 and confirmed the presence of TMA with no evidence of rejection.

Discussion: After exclusion of other etiologies, a diagnosis of aHUS was made and eculizumab initiated. Patient had rapid improvement in renal function by day 4 of induction (Cr of 3.5 mg/dl), platelets increased to 255 K/ul, and LDH decreased to 200unit/L. While on consolidative phase of eculizumab, azathiorine and prednisone were continued. Tacrolimanus was also safely restarted and subsequently switched to belatacept, which she has been tolerating well. This case provides additional support for the role of eculizumab in the treatment of life threatening post-partum aHUS.

PUB466

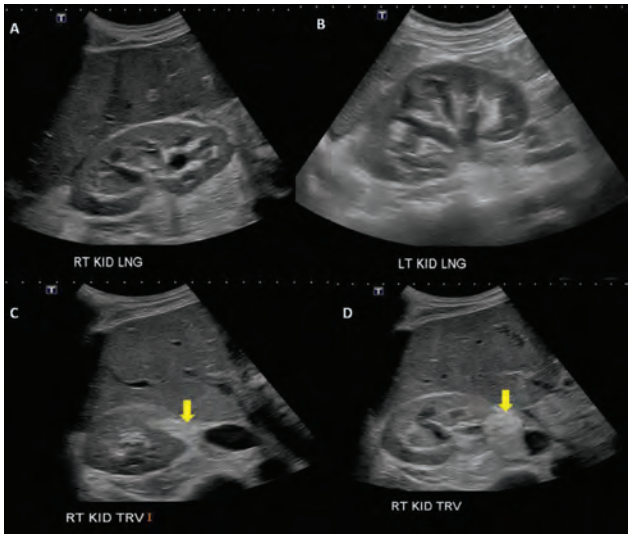
Ultrasonography: Another String to Nephrologists' Bow

Justin Lee Loy, Abhilash Koratala. *University of Florida Gainesville, Gainesville, FL.*

Introduction: Pyonephrosis is a rare purulent infection of the upper urinary tract, which can lead to rapid clinical deterioration. While contrast enhanced CT scan is a sensitive test, point-of-care renal sonography can serve as a quick and valuable bedside tool for diagnosis, especially when iodinated contrast use is contraindicated.

Case Description: A 57-year-old woman presented with fever, abdominal pain and nausea for 6 days. She was hypotensive at presentation and laboratory data demonstrated leukocytosis, pyuria, acute kidney injury requiring renal replacement therapy (RRT) and lactic acidosis. Non-contrast CT scan of the abdomen revealed mild bilateral hydronephrosis with no perinephric stranding or fluid collection. Vasopressors and broad-spectrum antibiotics were initiated. Exploratory laparotomy to identify a possible bowel source of sepsis was unremarkable. A renal ultrasound demonstrated moderate bilateral hydronephrosis with echogenic debris in right renal pelvis, suggestive of pyonephrosis [Figure]. She underwent emergent bilateral nephrostomy tube placement. Her blood and urine cultures were positive for *E coli* and antibiotics were adjusted accordingly. Follow-up ultrasound showed resolution of hydronephrosis. Patient subsequently showed rapid clinical improvement and RRT was discontinued.

Discussion: Pyonephrosis is a rare purulent renal infection due to ureteric blockage, which can lead to septic shock and death. Contrast-enhanced CT scan is commonly used for diagnosis, which may show findings of obstruction with renal pelvic wall thickening and layering of contrast material around the purulent fluid. However, the diagnosis can be missed on unenhanced CT and ultrasonography is a valuable bedside tool for rapid diagnosis as in our case.



PUB467

Amphotericin as Treatment for AKI

Mengyao Tang,[1] Jerald Cherian,[1] Thomas A. Golper,[2] Juan Pablo Arroyo.[2] *[1]Medicine, Vanderbilt University Medical Center, Nashville, TN; [2]Nephrology, Vanderbilt University Medical Center, Nashville, TN.*

Introduction: Histoplasma capsulatum is a fungus endemic to the southeastern United States. Immunocompromised patients are at increased risk for disseminated infection, often presenting with fever, pulmonary disease, hepatosplenomegaly or central nervous system involvement. We report an unusual case of disseminated histoplasmosis presenting with acute kidney injury (AKI), acute liver injury and thrombocytopenia, which resolved upon initiation of amphotericin.

Case Description: A 57-year-old woman with rheumatoid arthritis (on methotrexate and etanercept) presented with 1-month of upper respiratory symptoms and malaise. On admission, she had a creatinine of 11 mg/dL (0.7 mg/dL prior), BUN 127 mg/dL, AST 325 unit/L, ALT 477 unit/L, alkaline phosphatase 313 unit/L, total bilirubin 10 mg/dL, PLT 42 x10^3/mcL. Urine microscopy showed WBC 27/hpf and RBC 129/hpf. Spot urine protein creatinine ratio was 2.42. Ground-glass opacities, as well as mediastinal and right hilar adenopathy were visualized on CT; no hepatosplenomegaly or hydronephrosis was seen. Renal biopsy was deferred due to risk of bleeding. A liver biopsy, performed simultaneously with transjugular dialysis catheter placement, revealed necrotizing granulomas with narrow based budding yeast consistent with histoplasma. Urine histoplasma antigen was 5.98 ng/mL, which confirmed the diagnosis of histoplasmosis. The patient was started on liposomal amphotericin at 3mg/kg daily, and within 5 days the patient no longer required hemodialysis. She was transitioned to itraconazole on discharge, and after 2-months, her renal function, liver function, and platelets had normalized.

Discussion: Our case highlights that, given the right clinical context, nephrotoxic drugs can be given to treat AKI. In this case, although kidney biopsy was not performed, it is hypothesized that either direct damage by histoplasma or the liver failure associated histoplasmosis contributed to the AKI, given that it improved shortly after initiating amphotericin. Although autopsies have shown renal involvement in up to 40% of patients with disseminated histoplasmosis, clinically significant renal disease is rare. In patients with renal failure, renal biopsies have demonstrated several etiologies, including renal papillary necrosis, granulomatous interstitial nephritis, glomerulonephritis, and urinary obstruction. Renal function may recover in such cases with prompt treatment of histoplasmosis.

PUB468

Delayed Bleeding Following Renal Biopsy

Pascale Khairallah, Jacob Stevens, Jai Radhakrishnan. *Columbia University Medical Center, New York, NY.*

Introduction: Renal biopsy is considered a safe procedure with less than 1% of patients having significant bleeding. Post-procedural bleeding typically occurs within 2-24 hours. Risk factors for bleeding include older age, female gender, renal failure, and bleeding diathesis. There is no consensus on when to resume anticoagulation following renal biopsy, particularly among high-risk patients.

Case Description: We report the case of a 70 yo male with cirrhosis, diabetes and CKD stage 3 admitted for recurrent diffuse alveolar hemorrhage of unknown etiology. On admission, creatinine was at his baseline of 1.7mg/dL. Urine sediment was bland and ANCA titers were negative. A few weeks into his hospitalization, he developed non-oliguric AKI with hematuria, pyuria and 0.8g/day of proteinuria. Repeat PR3 ANCA titers were positive at 26AU/mL (negative<19). A left-sided renal biopsy with CT guidance was performed to evaluate for pulmonary-renal syndromes. At the time of biopsy, the platelet count was $100x10^3$/uL and INR was 1.5. Biopsy results showed diabetic glomerulosclerosis and acute tubular injury. Prophylactic heparin was started 3 days after the biopsy. The patient developed hemorrhagic shock 14 days after the biopsy requiring massive transfusion protocol and pressor support. CT of the pelvis showed left intraparenchymal renal hemorrhage. Angiogram identified left renal artery bleeding pseudoaneurysms that were successfully coiled.

Discussion: Delayed bleeding following renal biopsy is very rare. We report a case of life threatening bleeding that occurred 14 days after the biopsy. This is to our knowledge the second reported case of a bleed occurring more than 10 days post biopsy. Our patient had several bleeding predisposing risk factors including older age, renal failure, coagulopathy, and use of heparin. The benefit as well as timing of initiating anticoagulation must be carefully weighed against the risk of post-procedural bleeding, particularly in high-risk patients who can present with delayed bleeding.

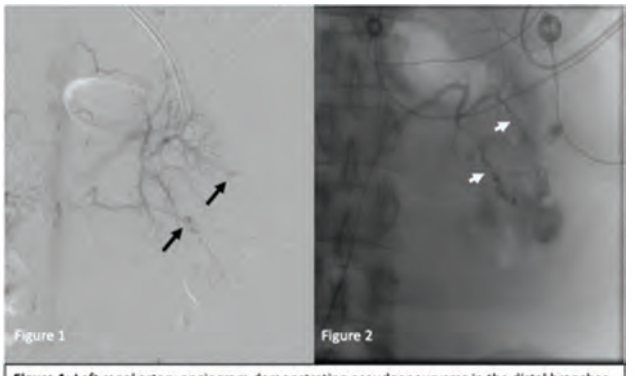


Figure 1: Left renal artery angiogram demonstrating pseudoaneurysms in the distal branches supplying the left mid and lower poles. Black arrows point to the pseudoaneurysms.
Figure 2: Coil embolization of the lower pole pseudoaneurysm and mid pole pseudoaneurysm. White arrows point to the coils.

PUB469

A Unique Approach of Combined Peritoneal Dialysis and Haemodialysis in a Case of Cardiorenal Syndrome

Kamlesh N. Parikh.[1,2] *[1]Shreenath Clinic, Vadodara, India; [2]Nephrology and Transplant Department, Bhailal Amin General Hospital, Vadodara, India.*

Introduction: This is a case of renal dysfunction in a pt. with dilated cardiomyopathy(DCM) & cardiac arrythmia. Author was challenged by therapeutic dilemma of DCM, hypotension, acute renal dysfunction needing dialysis & haemodynamic disturbance arising due to haemodialysis(HD). Peritoneal dialysis (PD) & HD were done. It provided efficient solute extraction in volume overloaded pt & corrected diminished renal function.

Case Description: 50-year-old male, k/c/o hypothyroidism, ischaemic heart disease with DCM and CRT-D in-situ came with complaints of palpitations, breathlessness on exertion(NYHA IV), nausea, oliguria and anasarca. Admitted in ICU, systolic BP(SBP) 100 mmHg & temp 100° F; pt. had atrial fibrillation with rapid ventricular rate(RVR). 2D echo showed biventricular systolic dysfunction and EF 30%; Sr. creat1.2 mg/dL. Diuretic and BiPAP ventilator started. Amiodarone dose optimized. Persistence of RVR & hypotension, requiring increasing dose of inotropes. After 48 hrs, sr. creat 5.4. Due to low BP, lung congestion and AKI decision of dialysis was taken Tenckhoff catheter placed in LA. PD exchange with Icodextrin done with ultrafiltration(UF). Azotemia worsened. 4 sessions of short HD & PD over 10 days done. SBP was ≥90 with inotropes which were tapered. Pt. had VAP which was treated. Oliguria persisted 3 wks Pt. was managed in 4 wks with HD & PD. Gradual recovery of renal function with good UOP occurred. CRT-D reprogrammed.

AV Node ablation done & palpitation improved. Sr. Creat was 1.6. Catheter was removed. SBP ≥100 without inotropes. Pt. was fully ambulatory at discharge

Discussion: Cardiac and renal dysfunction often occur together as they share common pathogenic mechanism, known as CRSs. In such case of poor cardiac function & arrythmia, there is risk of intradialytic hypotension & renal hypoperfusion causing worsening of azotemia, which was obviated by combining PD & HD. With a multidisciplinary collaboration between cardiologist and nephrologist, we could achieve symptomatic improvement, improved exercise tolerance, euvolemia, recovery of renal function, and reduction in NYHA class with improvement of EF. It represents a pathophysiologically and conceptually relevant option by simultaneously addressing renal and cardiac dysfunction. The case is first of its kind reported from Indian subcontinent demonstrating safety and efficacy of this therapeutic modality for CRS.

PUB470

A Case of Granulomatous Interstitial Nephritis Likely Associated with Lisinopril

Jobira A. Woldemichael,[1] Thomas E. Rogers,[2] Sarah A. Johnson.[3] *[1]Emory university, Atlanta, GA; [2]Emory University, Atlanta, GA; [3]Emory University School of Medicine, Atlanta, GA.*

Introduction: Granulomatous interstitial nephritis (GIN) as a cause of acute kidney injury (AKI) is a rare clinical condition. Drugs, infections and immune processes are among the most common causes.

Case Description: A 61 year old African American female with a history of hypertension and hypothyroidism was admitted with nausea, cough and easy fatigability of 2 weeks duration with decreased urine output. She was found to have a serum creatinine (Scr) of 15 mg/dl from a baseline of 0.8 mg/dl six months prior and was admitted for further workup. She denied NSAID use, did not have any recent contrast studies, illnesses or travel. Her home medications include atenolol, levothyroxine and lisinopril with no new medications. Clinically the patient was uremic with no rashes or edema. She had mild hypertension and was initiated on hemodialysis. Her urinalysis revealed 3+ blood and her sediment review showed many WBC, granular casts and rare RBC. Spot urine protein to creatinine ratio was 2.5 gm/gms. Renal ultrasound showed a 14 cm right kidney and 12.5 cm left kidney but otherwise was normal. Serologies for hepatitis B and C and HIV were negative. Antinuclear antibody, anti-glomerular basement membrane antibodies and ANCA were negative. Complements C3 and C4 were normal. The patient underwent a renal biopsy which showed GIN, so an infectious workup was initiated. A CT scan of the chest was normal, and serum ACE and calcium were normal, largely ruling out sarcoidosis and pneumonia. Blood cultures were negative. Tuberculosis was ruled out with PPD and sputum cultures. Serum protein electrophoresis was negative. The patient's symptoms significantly improved with initiation of HD but her renal function did not recover initially. In total, she received 7 sessions of HD. As infection was ruled out, she was started on 40 mg of oral prednisone and tapered quickly as her Scr improved to 2.1 mg/dl within 3 days of steroid initiation and eventually improved to 1.2 mg/dl. Lisinopril was discontinued on admission and now appears the most likely culprit for the GIN and severe AKI.

Discussion: Although GIN has not been linked with ACEI, captopril has been previously described as a cause of interstitial nephritis. This case opens further discussion for ACEI being a possible inciting agent for GIN among other etiologic association reported thus far.

PUB471

An Unexpected Cause of Hypercalcemia in a Cancer Patient

Gajapathiraju Chamarthi,[1] Judith E. Sallustio,[2] Justin Lee Loy,[1] Abhilash Koratala.[1] *[1]University of Flroida, Gainesville, FL; [2]VAMC Gainesville, FL, Gainesville, FL.*

Introduction: Primary hyperparathyroidism and malignancy are the most common causes of hypercalcemia, though the differential diagnosis is usually broad. Determining the etiology of hypercalcemia is key to its management and it can be difficult in the presence of multiple confounding factors. We present a case of hypercalcemia in a cancer patient, which was likely secondary to Sarcoidosis.

Case Description: A 59-year-old man with CKD stage 4, hypertension, and prostate cancer on androgen deprivation therapy was admitted to the hospital for worsening renal function and hypercalcemia. Serum creatinine at presentation was 4 mg/dL (baseline 2.8) and calcium was ~12 mg/dL. On chart review, he had varying degrees of hypercalcemia for at least a year that was associated with nephrolithiasis. He was not taking any calcium or vitamin D supplements. Serum parathyroid hormone (PTH) was suppressed and PTH-related peptide, serum protein electrophoresis, free light chain ratio and 1,25-dihydroxy vitamin D level were within normal limits. However, 25-hydroxy vitamin D level was low. Positron emission tomography–CT was negative for bony metastasis but showed lymphadenopathy in mediastinum and abdomen. Inguinal lymph node biopsy surprisingly revealed non-caseating granulomas with asteroid bodies and Schaumann bodies, consistent with sarcoidosis. Corticosteroid therapy was initiated and his calcium and creatinine gradually improved.

Discussion: Sarcoidosis is a multisystem granulomatous disease characterized by non-caseating granulomas. It can affect any organ including kidney. However, granulomatous interstitial nephritis alone is rarely implicated in CKD. Instead, chronic hypercalcemia and hypercalciuria causes tubulointerstitial inflammation with associated calcium deposits leading to nephrocalcinosis, and fibrosis and CKD. Though CKD in our patient was originally attributed to hypertension, hypercalcemia could have contributed. Take-home point from our case is that hypercalcemia in a cancer patient is not always from bone metastases and alternative etiologies should be sought when appropriate. Interestingly, 1,25-dihydroxy vitamin D level was normal in our patient, which is thought to be the main mechanism of hypercalcemia in sarcoidosis. However, 25-hydroxy vitamin D, which is the substrate for the formation of 1,25-dihydroxy vitamin D was low, which could explain this unexpected finding.

PUB472

A Case of Likely Bile Cast Induced Nephropathy

Syed A. Ali. *UCLA, Los Angeles, CA.*

Introduction: An important non vasomotor (as opposed to hepatorenal syndrome in cirrhosis) mechanism of Acute Kidney Injury in liver dysfunction is the nephro-toxicity of cholephiles (i.e.bilirubin and bile acids). This entity is defined by histologic lesions which include tubular bile cast formation and tubular epithelium injury, associated with jaundice. I describe the case of suspected bile cast induced nephropathy in a patient with obstructive cholestasis caused by stones in the common bile duct, without any prior history of liver disease.

Case Description: This was a seventy two year old male with a history of coronary artery disease s/p coronary artery bypass graft surgery, heart failure with reduced ejection fraction, atrial flutter, atrial fibrillation, diabetes mellitus, hypertension, hyperlipidemia, chronic kidney disease stage IIIA, who presented with epigastric pain. His work up revealed a creatinine of 1.4 at the time of admission and it rose upto a peak of 2.93 with the total bilirubin peaking at 23.13. He had a CT scan of the abdomen/pelvis without contrast done which showed a suspected stone in the common bile duct after which an ERCP was done which confirmed the suspicion and after relief of the obstruction, both the total bilirubin and creatinine trended down simultaneously. This happened concurrently with the fall in bilirubin in the urine analysis.

Discussion: Kidney injury in the setting of severe cholestasis can result from precipitation of cholephiles in renal tubules with subsequent toxicity to the epithelial cells. In our case, although we did not perform a renal biopsy, but the temporal correlation, as seen in the accompanying table, between the total and direct serum bilirubin levels and the serum creatinine/eGFR and the level of bilirubin in the urine analysis suggest that cholestasis was strongly contributing to the renal injury.

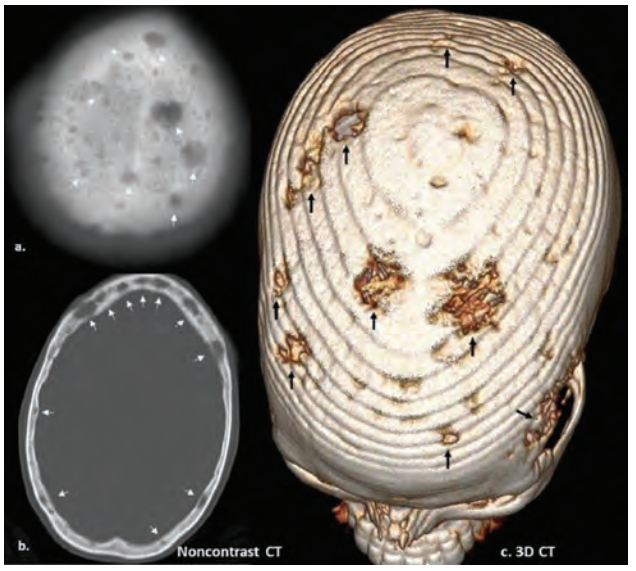
Temporal Mass and AKI as a Presentation of Multiple Myeloma

Muhannad Leghrouz, Abhilash Koratala. *University of Florida, Gainesville, FL.*

Introduction: Solitary bone Plasmacytoma is a rare malignancy characterized by malignant proliferation of monoclonal plasma cells. It constitutes less than 5% of malignant plasma cell tumors. Herein, we report a case of multiple myeloma that presented with temporal plasmacytoma and found to have acute kidney injury.

Case Description: A 70-year-old female with a history of endometrial cancer s/p hysterectomy, maintained on tamoxifen was brought to our institution for altered mental status of acute onset. She previously told her family about a left temporal mass ~3 weeks ago. Head CT demonstrated left temporal mass centered in the calvarium with intracranial as well as extracranial extension into the left lateral orbit and with associated osseous destruction. In addition, more than 20 calvarial lucent lesions were identified [Figure 1]. Laboratory data demonstrated AKI with a serum creatinine of 13 mg/dL, hypercalcemia with a serum calcium level 11.6mg/dL, anemia with a hemoglobin of 9 g/dL. SPEP showed two distinct monoclonal spikes in the IgA (0.7g/dL) and IgG (1.2g/dL) regions. Serum free kappa light chain (LC) was 1.49mg/dL (Ref: 0.33-1.94) and lambda LC 1339.3mg/dL (significantly elevated). She required initiation of hemodialysis and mental status gradually improved. Temporal mass biopsy demonstrated plasmacytoma with positive kappa LC and bone marrow biopsy was consistent with multiple myeloma. Chemotherapy was initiated with cyclophosphamide, bortezomib and dexamethasone and she is currently dialysis dependent.

Discussion: Plasmacytoma may involve the cranial vault, base or brain parenchyma and rarely, the temporal bone as in our patient. It is important to keep this differential in mind when evaluating a patient for acute kidney injury and cranial mass as not all such patients get appropriate imaging at presentation, especially if the lesion is small.



PUB474

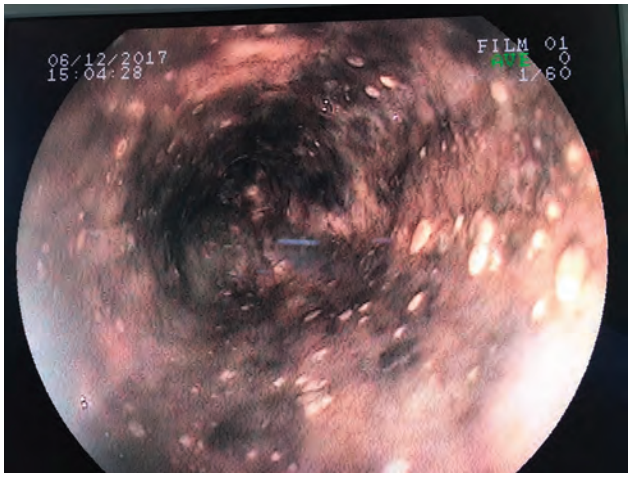
Acute Esophageal Necrosis in a Patient with AKI Due to Acute Pancreatitis

Marcelo V. Silva,[1,2] Paulo H. Amor divino,[3] Francisco A. Maia,[3] Joao vitor T. Motta.[4] Faculdade de Medicina da USP *[1]FMUSP, São Paulo, Brazil; [2]Santa Casa de Misericórdia de São Paulo, São Paulo, Brazil; [3]Santa Casa de Misericórdia de São Paulo, São Paulo, Brazil; [4]Santa Casa de Misericordia de Sao Paulo, Sao Paulo, Brazil*.

Introduction: The acute esophageal necrosis (AEN), also known as black esophagus, is a rare esophagic complication of many acute criticial illness. Since it has been described by Goldenberg et al in 1990, it has been linked to many critical clinical conditions, like descompensated diabetes mellitus, hypovolemic shock and acute kidney injury (AKI). In this report we aim to describe a case of AEN in a patient with AKI due to acute pancreatitis (AP)

Case Description: A 61 male patient with medical history of severe alcoholism, presented to the emergency department with a history of abdominal pain associated with nauseas and hematemesis for 2 days. He presented with hypotension, tachycardic, diaphoretic, pale and anxious. Labs showed amilasis 780 UI/L, urea 505 mg/dL and a Hb 5,5 g/dL. The patient was promptly resuscitated with saline and received transfusoin of 3 packs of red cells. Posteriorly the patient realized a CT of the abdomen, which confirmed acute pancreatitis, and an upper endoscopy which showed an acute esophagic necrosis. The patient was treated with broad-spectrum antibiotics, was placed on 'nil per os' and received renal replacement therapy. After 3 weeks the patient remained hemodynamically stable, the kidney function restored so that the patient no longer needed renal replacement and was progressively fed back, with good acceptance.

Discussion: Acute esophagic necrosis is a rare complication of many criticall illness. Although imprecise, some studies believe it has a prevalence of 0,2%. AEN is linked with many critical clinical illness, like diabetes mellitus, trauma, any cause of shock and AKI. We presented a case of AEN after a severe AP witch evolved with a AKI requesting renal replacement therapy. Acute GI bleeding is not rare in patients with AKI, normally occurring due to gastric or duodenal ulcer. In the present report we show that AEN is a potential cause of GI bleeding in patients with AKI



PUB475

Primary Renal Lymphoma: An Unusual Cause of Bilateral Nephromegaly

Khai Ping Ng,[1] Mark E. Thomas.[2] *[1]Birmingham Heartlands Hospital, England, Birmingham, United Kingdom; [2]Heart of England Foundation Trust, Birmingham, United Kingdom*.

Introduction: Primary renal lymphoma is a rare disease, which account for only 0.7% of all extra-nodal lymphoma in North America. Amongst the 70 cases reported in the literature to date, it was often reported as unilateral renal involvement in adults. We describe a case of primary renal diffuse large B-cell lymphoma, presenting with acute kidney injury (AKI) and bilateral nephromegaly.

Case Description: A 63 year-old female was admitted with two weeks history of vomiting, legs swelling and weight loss. She has bilateral ballotable kidneys on examination. Initial blood tests showed stage 3 AKI (serum urea: 45.7 mmol/L, creatinine 828 μmol/L) and pancytopenia. Haemolytic, clotting, virology and haematinic screens were unremarkable. Her lactate dehydrogenase was 341 U/L. She had nephrotic syndrome with serum albumin of 27 g/L and random urine protein-creatinine ratio of 413 mg/mmol. Her kappa/lambda ratio was normal with mildly low IgG (5.57 g/L). Ultrasound scan reported bilateral enlarged kidneys (right 14.0cm, left 14.6cm) and homogenous appearance of cortex and medulla. She was started on haemodialysis. Renal biopsy was performed, which showed renal tissue with scattered tubules extensively infiltrated by medium-sized blastoid cells. Bone marrow aspirate showed only slight hypocellularity. Immunophenotyping of the renal biopsy found a diffuse large B-cell lymphoma. She was commenced on CHOP regime with 50% reduction of cyclophosphamide. She had further readmission with pulmonary oedema and hyperkalaemia, which required increased haemodialysis and ultrafiltration. There was no evidence of myocardial infarction, however, the echocardiogram reported severely impaired systolic function. Her chemotherapy regime therefore was altered to R-CEOP. She reported blurred vision following the 2nd cycle of chemotherapy. Though CT and MRI head were unremarkable, cerebrospinal fluid flow cytometry showed evidence of lymphoma infiltration. She was commenced on intra-thecal methotrexate. She has had good response to chemotherapy and is showing signs of potential renal recovery.

Discussion: Although primary renal lymphoma is a rare condition, it must be considered in the differential diagnosis of nephromegaly and AKI. Comparable to previous published cases, our case demonstrated encouraging haematological and renal outcomes following R-CEOP treatment.

PUB476

Methotrexate Crystal Nephropathy in Patients with Rheumatoid Arthritis: An Underrecognized Cause of AKI

Tomonori A. Oyadomari,[1] Himabindu Yerneni,[3] Martin Sedlacek.[2] *[1]Dartmouth Hitchcock Medical Center, Lebanon, NH; [2]Dartmouth-Hitchcock Medical Center, Lebanon, NH; [3]Dartmouth Hitchcock medical center, Hanover, NH*.

Introduction: Renal dysfunction following administration of high-dose Methotrexate, defined as 1,000-3,000mg/m², has been well described. However, the incidence of nephrotoxicity with low-dose therapy, typically 7.5mg to 25mg weekly prescribed for patients with rheumatoid arthritis, remains largely unknown. Risk factors for nephrotoxicity include high serum Methotrexate level, low urine pH, low urine output and concomitant use of agents known to reduce GFR such as NSAIDs. Crystallization of Methotrexate in the renal tubules, seen as clumps of gold brown needle-like crystals on light microscopy, is urine pH-dependent and occurs in acidic urine. Literature surrounding renal dysfunction from low-dose Methotrexate administration is scarce and crystal formation leading to AKI in this cohort has not been described.

Case Description: We describe a case of a 56 year-old woman with a 10-year history of rheumatoid arthritis on Prednisone 20mg weekly who was referred to our clinic for a rise in serum creatinine from her baseline 0.9 to 1.4 during a 6-month period. Her medical history included hypertension treated with Triamterene-HCTZ and a remote history of asymptomatic nephrolithiasis that was found incidentally on ultrasound. Patient had been on daily Sulindac for many years, which was discontinued only with a transient improvement in creatinine. There was no proteinuria. Patient denied any urinary symptoms. Patient had no history of herbal supplement, smoking, alcohol, or recreational drug use. There was no family history of renal disease. Renal ultrasound was negative for obstruction. Urine dipstick showed specific gravity of 1.015 and pH of 7.0, otherwise negative. Surprisingly urine microscopy showed multiple clumps of brown weakly birefringent crystals, similar to published images of Methotrexate crystals. Upon further questioning, the patient admitted to frequent consumption of Coca Cola.

Discussion: Our case confirms that Methotrexate crystal nephropathy exists even in patients treated with low doses. We postulate that the use of NSAIDs and diuretics led to reduced Methotrexate clearance and consumption of urine pH-lowering foods facilitated crystal formation. The patient recovered renal function after discontinuing Methotrexate. Clinicians must be aware of this clinical entity and be thorough in their history taking including diet and medications.

PUB477

I'm Feeling Swell, and That Is a Complement (Mediated Disease)!

Derian Lai, Nicole Canon, Prejith P. Rajendran. *Baylor College of Medicine, Houston, TX*.

Introduction: Angioedema is a severe manifestation of complement dysregulation. Hereditary Angioedema (HAE) patients have deficient or non-functional C1 esterase inhibitor (C1-INH). Acquired Angioedema (AAE) patients have autoantibodies or hyper catabolism of C1-INH. Systemic lupus erythematosus (SLE) has a wide array of

complement derangements and angioedema is a rare complication. SLE has been associated with both the hereditary and acquired forms of angioedema. Here we describe a patient with recently diagnosed SLE who presented with a severe case of angioedema and class 3 lupus nephritis.

Case Description: A 33-year-old female with recently diagnosed SLE calls emergency services for tongue swelling, stridor and respiratory distress. She was intubated at the scene and later transferred to the nearest hospital in stable condition. No skin rashes were noted. Initial labs notable for elevated serum creatinine and active urine sediments. She was treated with pulse dose steroids on day of presentation. The next morning, the patient developed respiratory distress after being extubated, so she was re-intubated and then transferred via airlift to our tertiary medical center. On arrival, she was awake, alert and stable on mechanical ventilation. Labs revealed elevated serum creatinine (1.7mg/dL), nephrotic range proteinuria with active sediments, anemia and thrombocytopenia. ANA, Anti-dsDNA titers were elevated, and her complements were low. C1-INH levels were collected but unfortunately the samples never resulted. Imaging of the chest and abdomen were negative for lymphadenopathy. Renal biopsy was performed and revealed class 3 lupus nephritis. She was treated with methylprednisolone pulses and Cyclophosphamide. Patient's respiratory status and renal function improved with therapy and she was extubated after 2 days.

Discussion: Angioedema is a rare complication of lupus flares. Clinicians should be aware of this rare but potentially life-threatening association, to prevent any delay in management

PUB478

Typical Atypical Hemolytic Uremic Syndrome: A Pregnancy-Induced Story

Oluwadamilola O. Babaniji,[1] Roberto L. Collazo-Maldonado.[2] *[1]Methodist Hospital Dallas, Dallas, TX; [2]Dallas Nephrology Associates, Dallas, TX.*

Introduction: Pregnancy-associated atypical hemolytic uremic syndrome (p-aHUS) is a rare condition that can mimic other clinical conditions in the postpartum period. It is very important for clinicians to promptly recognize and manage this potentially fatal condition to reduce the catastrophic complications that could result if early diagnosis is not made.

Case Description: A 31 year old primigravida African American woman with past medical history of hypertension, asthma and obesity presented to her post-partum follow up clinic 2 weeks after her C-section delivery of a preterm live infant at 29 weeks. Her pregnancy was complicated by premature ROM and chorioamnionitis. She was found to be very hypertensive (220/120 mmHg) with new onset abdominal pain associated with frontal headache and new-onset bilateral lower extremity edema with no fever and normal mental status. She was immediately admitted to the hospital and her initial laboratories showed new onset acute kidney injury (creatinine 2.5mg/dL), new-onset thrombocytopenia (35000), presence of hemolytic anemia with schistocytes on smear, markedly elevated LDH levels (>2000), and undetectable haptoglobin levels. Urinalysis was notable for active sediment with nephrotic range proteinuria and hematuria. Nephrology was consulted and given her classic presentation, she was started on intravenous steroids and hematology was consulted for emergent plasmapheresis the same day of admission. Diagnosis of atypical hemolytic uremic syndrome was confirmed with normal ADAMTS-13 level. Hemodialysis was eventually initiated for worsening kidney function. She was started on Eculizumab 48 hours after being admitted. After 2 doses of Eculizumab, her blood pressure is controlled with normalization of her hemoglobin and platelets and recovery of her kidney function. Patient is currently undergoing genetic workup for identification of inherited complement abnormalities.

Discussion: p-aHUS is a challenging condition that has been known to present in the early postpartum period. It could easily be mistaken for other well-known postpartum complications such as preeclampsia and HELLP syndrome leading to delay in treatment. The bad outcomes of this entity may be mitigated with quick clinical recognition and treatment initiation.

PUB479

Renal Biopsy – Remains an Irreplaceable Tool for the Nephrologist

Lucy M. Esteve,[2,1] Manoj Bhattarai,[2,1] Muhammad Abdullah,[2,1] Jeet Gandhi,[2,1] Bahar Kapoor,[2,1] Fermin O. Tio,[1] Shweta Bansal.[2,1] *[1]South Texas Veterans Medical Center, San Antonio, TX; [2]University of Texas Health Science Center at San Antonio, San Antonio, TX.*

Introduction: In the absence of perfect biomarkers for acute kidney injury (AKI), renal biopsy remains an important diagnostic tool despite associated complications. We report a case of non-oliguric AKI with multiple risk factors masquerading the real diagnosis eventually requiring renal biopsy for definitive diagnosis and successful treatment.

Case Description: 63-year-old man with morbid obesity, hypertension, atrial fibrillation, chronic kidney disease and recurrent deep vein thrombosis on warfarin presented with 4 months of intermittent gross hematuria. His BP was 150/90 mmHg with an otherwise normal physical exam. Blood work revealed serum creatinine of 5.9 mg/dl (baseline 1.5 mg/dl). Urine microscopy showed many normal and a few dysmorphic red blood cells (RBCs). 24hr urine protein was 1.6 gm (baseline 1+ on dipstick). INR ranged from 1.5 to 5 in the recent past. He was treated with Ciprofloxacin for presumed urinary tract infection a month prior to presentation with stable creatinine 2 weeks later. He had normal cystoscopy a week prior to presentation. No other exposure to new medications or contrast was noted. Serology work up was negative. CT abdomen was unremarkable except for findings suggestive of liver cirrhosis. Diagnoses of Warfarin related nephropathy (WRN) and IgA nephropathy (IgAN) were entertained and Warfarin was held. Renal biopsy was initially deferred due to morbid obesity and need for anticoagulation but performed a few days later when renal function failed to improve. Despite prophylactic Desmopressin, the biopsy was complicated by a retroperitoneal hematoma requiring embolization of the interlobar artery and blood transfusions. It showed numerous tubules packed with RBCs, severe lymphocytic and eosinophilic interstitial infiltrate, and mesangial expansion with immunofluorescence positive for IgA. The findings were consistent with WRN, acute interstitial nephritis (AIN) and non-crescentic IgAN. He was started on oral steroids and an IVC filter was placed. His serum creatinine was 3.4 mg/dl on discharge, which stabilized around 1.5 mg/dl on follow up. Anticoagulation was resumed with no worsening of renal function.

Discussion: This is a rare case of acute renal failure with a combination of AIN, WRN and IgAN and highlights that renal biopsy remains an essential tool for definitive diagnosis and initiation of timely treatment.

PUB480

Eculizumab: Atypical Treatment of Typical Hemolytic Uremic Syndrome

Maggie Meier, Pablo D. Dayer. *Saint Luke's Hospital, Chesterfield, MO.*

Introduction: Typical hemolytic uremic syndrome (HUS) with neurological involvement is a life threatening disease. HUS is caused by E.Coli producing Shiga-toxin damaging endothelial and activating the complement cascade. In atypical HUS, a monoclonal antibody Eculizumab has been effective in treating complement pathway abnormalities. We present a case of typical HUS with severe neurological involvement treated effectively with Eculizumab.

Case Description: An 18 year old Caucasian female was transferred from a Dominican Republic hospital with multiorgan failure including renal failure. She developed bloody diarrhea and was initally hospitalized with presumed acute gastroenteritis. She was started on antibiotics. Her condition worsened as she became anuric despite aggressive fluid resuscitation. She developed seizures and acute encephalopathy requiring ventilatory support. Upon arrival to our hospital, she was in acute renal failure with severe metabolic acidosis. Lactate dehydrogenase was elevated at 9000 with associated anemia and thrombocytopenia. Blood smear showed shistocytes. A clinical diagnosis of HUS was made based on acute renal failure, thrombocytopenia and hemolytic anemia. Stool PCR was positive for Shiga toxin 2. She was initiated on hemodialysis and treated with Eculizumab. Antibiotics were stopped. After 2 weeks in the intensive care unit, her overall condition improved. Her seizures resolved, and she did not require continued treatment with anti-seizure medications. Her renal function started to improve and she came off hemodialysis after 5 weeks. Her renal function though has remained decreased with a GFR around 30.

Discussion: An 18 year old without past medical history presented with a severe form of typical HUS. Shiga toxin as a causative agent was identified. However, neurological manifestations are unusual in typical HUS and thrombotic thrombocytopenia purpura was also considered. She was treated with hemodialysis but plasmapheresis was not offered in this case. Eculizumab was associated with full neurological recovery. After two doses of eculizumab, our patient's seizures resolved and she did not require long term anti-seizure medications. In life threatening cases of HUS with severe neurological symptoms, Eculizumab may be consdered as first line therapy.

PUB481

Postpartum Ruptured Sub-Capsular Liver Hematoma with Dialysis-Dependent AKI and Intracranial Bleed with Delayed Recovery: Is It HELLP or aHUS?

Sanjeev Gupta,[1] Savneek S. Chugh,[2] Aromma Kapoor.[1] *[1]Westchester County Medical Center, Valhalla, NY; [2]New York Medical College, Hartsdale, NY.*

Introduction: HELLP, a known complication of preeclampsia, can rarely result in ruptured sub-capsular liver hematoma (SLH) and very rarely dialysis-dependent AKI. We present a case of preeclampsia complicated by postpartum ruptured SLH and dialysis-dependent AKI with delayed recovery after delivery.

Case Description: A 33-year-old lady with prior two 1st trimester miscarriages admitted for emergent C-section due to fetal bradycardia and preeclampsia. During surgery hemoperitoneum and ruptured SLH was found. The patient developed AKI and anuria the following day. CVVHD was initiated. Lab workup showed low Hb & platelet counts with elevated LFTs & S.ammonia, resulting in a presumed diagnosis of HELLP syndrome. The patient showed minimal recovery post-delivery with supportive treatment. CVVHD was continued. A CT head was performed due to AMS which revealed sub-arachnoid hemorrhage. Due to persistent thrombocytopenia and anemia, further workup for TTP/aHUS, and APLS were ordered. Schistocytes were seen on peripheral blood with low complement levels and normal ADAMTS 13 activity. A renal biopsy wasn't done due to thrombocytopenia, however, given high suspicion of aHUS treatment with Eculizumab was considered. Just before the treatment initiation, her platelet count and other lab parameters started to improve so the drug was withheld.

Discussion: HELLP syndrome, APLS, TTP, and aHUS, can clinically mimic each other and it can be very challenging to differentiate, although expedited delivery usually improves HELLP and APLS. ADAMTS 13 is low in TTP but the diagnosis of aHUS is solely based on the clinical picture. Our patient didn't respond to expedited delivery and ADAMTS 13 was normal. Given delayed recovery, our patient likely had aHUS which fortunately resolved spontaneously. Henceforth, it is important to exclude aHUS when there is minimal or delayed recovery in patients with severe preeclampsia/ HELLP even after the delivery.

PUB482

Who Did It? An Unusual Case of an AKI MM and CLL in a Patient with Multiple Myeloma and Chronic Lymphocytic Leukemia

Francisco J. Alvarado,[2] Kayla Shirley,[3] Fadee Abu Al Rub,[1] Claude Bassil.[1] *[1]Department of Nephrology and Hypertension, University of South Florida, Tampa, FL; [2]Internal Medicine, University of South Florida, Tampa, FL; [3]Internal Medicine, Univeristy of South Florida, Tampa, FL.*

Introduction: Multiple Myeloma (MM) is a notorious malignancy known to cause kidney damage. The range of renal pathology induced by MM range from the effects of tumor lysis syndromes to various types of glomerulonephritis's. It is quick to assume that a patient with MM with an Acute Kidney Injury is likely induced in some way or another from that disease process. However in this case report this particular patient also had Chronic Lymphocytic Leukemia (CLL), a malignancy that is rarely known to cause renal damage.

Case Description: This is a 60 y/o gentleman with a history of MM and CLL. The diagnosis of CLL was made after patient came to the ED for evaluation of chest tightness and palpitations that was attributed to an exacerbation of his known atrial fibrillation. His labs noted to include a WBC count of 175 k, an Absolute Lymphocyte Count of 171 k, with mild anemia and thrombocytopenia. Flow cytometry was ordered and it was consistent with CLL and FISH showed trisomy 12. Patient was asymptomatic so treatment was deferred. 2 months later patient presented with an AKI with a Cr of 3.6, baseline Cr was 1.1. SPEP and UPEP showed 6.3 grams of lamba light chain. Bone marrow biopsy one month later showed CLL with plasmocytic differentiation and plasma cell myeloma. Patient then received a renal biopsy and it showed 3 out of 12 sections that were globally sclerotic. There was prominent but patchy infiltration of the interstitium with lymphocytes (had positive immunoperoxidase staining for CD5, CD20 and CD23). Stainings were negative for kappa and lambda light chains.

Discussion: CLL is a disease entity that is not commonly know to cause an AKI. However going through the literature there are various case reports of CLL induced AKI. What is even more uncommon is AKI secondary to leukemic infiltration but this too is a known entity. In the setting of multiple myeloma one would expect that this disease process would be the etiology of this patient's AKI but the biopsy showed that this was not the case. In a patient with CLL and an AKI, it is important to consider that this disease process could be the cause of a patient's renal damage.

PUB483

Hydralazine Induced ANCA Vasculitis Causing Acute Interstitial Nephritis

Tanuja Yalamarti,[1] Pooneh Alborzi.[2] *[1]Internal medicine, Pennsylvania hospital, Philadelphia, PA; [2]Pennsylvania Nephrology Associates, PC, Philadelphia, PA.*

Introduction: This case describes a patient with hydralazine induced autoimmune disease who presented with pulmonary hemorrhage and rapid decline in GFR secondary to biopsy proven acute interstitial nephritis(AIN)

Case Description: A 74-yo male with hypertension on hydralazine for 3 years. He presented with a history of malaise, dark urine and shortness of breath. He had pancytopenia and AKI. Serological tests were positive for anti-histone, anti-MPO antibody and low complements. Bone marrow biopsy was normal. Renal biopsy showed acute interstitial nephritis(AIN) without any glomerular pathology. He was treated with pulsed steroid, and rituximab with the impression of hydralazine associated autoimmune disease. One week later, he had further hemoptysis, significant decline in renal function with proteinuria, RBC, granular casts in the urine. Chest CT revealed new bilateral pulmonary ground-glass infiltrates. He was given pulsed steroids with four plasma exchanges and rituximab. His respiratory status improved but he remained dialysis dependent at the time of discharge with full recovery of AKI at four months.

Discussion: Hydralazine induced lupus glomerulonephritis(GN) causes deposition of immune complexes and complement. Hydralazine induced ANCA associated(AAV) vasculitis cases reported till date have biopsy proven pauci immune crescentic GN. Our patient's history of malaise, pancytopenia, positive anti-histone antibodies and low complements lend weight to lupus syndrome but the rapidly increasing serum creatinine, features of diffuse alveolar hemorrhage(DAH) along with absence of immune deposits at renal biopsy make it most consistent with AAV. However, the presence of only AIN is interesting in this case. Despite adequate sampling, it is still possible that rare crescentic lesion were missed. Alternatively, the findings in our case may represent a drug hypersensitivity-associated AIN. In hydralazine induced lupus, cessation of the drug is sufficient to reverse disease activity. Although there was no histopathological evidence of GN, the patient responded to immunosuppressive therapy that is often used in the treatment of AAV. The uniqueness of this case lies in the development of AIN due to hydralazine induced ANCA vasculitis which recovered fully with immunosuppression. Hence, it is important to recognize the absence of the expected characteristics associated with hydralazine induced autoimmune disease.

PUB484

Calcium Channel Blocker Overdose Revisited: From Insulin to Methylene Blue

Prejith P. Rajendran,[1] Ahmed A. Awan,[2] Shalini Makawita,[1] David Sheikh-Hamad.[1] *[1]Baylor College of Medicine, Houston, TX; [2]Baylor college of medicine, Houston, TX.*

Introduction: Calcium channel blockers (CCB) are commonly prescribed anti-hypertensive agents. CCB's are highly protein bound in the serum with a large volume of distribution and hence not easily dialyzed. Amlodipine, a dihydropyridine CCB, has predominant action on the vascular smooth muscle; overdose of Amlodipine can lead to circulatory shock and may be fatal. Several management strategies have been employed including calcium, insulin and lipid emulsion among others. We describe a case of refractory shock due to Amlodipine overdose, unresponsive to calcium/vasopressors/insulin/lipid emulsion, but stabilized after a single dose of methylene blue (vascular endothelium NO-cGMP inhibitor).

Case Description: A 53-year-old obese male with major depressive disorder and prior suicide attempts brought to the hospital by emergency services after having consumed 15 pills of Amlodipine (75 mg), 5 pills of Valproate and 30 pills of Aspirin (~2500 mg). On arrival, the patient was awake and alert. Following treatment with activated charcoal, he became progressively hypotensive, altered and hypoxemic. He was transferred to the ICU, where he was intubated and started on calcium, Dopamine and Norepinephrine infusions, followed by high dose Insulin infusion (up to 10 IU per kg per hour). CVVHD was started due to oliguric AKI (Cr 1.8) and severe acidosis (pH 7.02 and bicarb of 12). The following day, vasodilatory shock worsened requiring 4 vasopressors while receiving 1000 IU/hr of Insulin infusion. He was given a single dose of methylene blue, along with calcium chloride infusion and a dose of IV Lipid emulsion (aids in the clearance of lipophilic drugs). His mean arterial pressure (MAP) stabilized above 70 soon after, and his vasopressor requirement decreased. Hospital course was complicated by pulmonary edema and hypoxemia due to volume overload, which was successfully managed with CVVHD and ultrafiltration.

Discussion: Summary: Methylene blue (a selective inhibitor of guanylate cyclase, a second messenger for nitric oxide–mediated vasodilation) should be considered in the management of CCB overdose complicated by shock refractory to therapy with calcium, vasopressor and insulin therapy

PUB485

Unique Case of Urinoma After Laminectomy Presenting with Elevated Serum Creatinine

Pavela Saha,[1] Chelsea C. Estrada.[2] *[1]Stony Brook University Medical Ctr., Stony Brook, NY; [2]Stony Brook University Medical Center, Stony Brook, NY.*

Introduction: Close to 70% of all ureteral injuries are iatrogenic and occur most commonly subsequent to gynecologic or urologic surgeries. Despite the location of the ureter just lateral to the transverse processes of the lumbar vertebrae, such injury is rare after spinal procedures. If iatrogenic ureteral injury occurs, it usually does not cause acute kidney injury (AKI) in patients with normal baseline renal function. We present a unique case of iatrogenic urinoma after laminectomy which presented with a sustained elevation in serum creatinine.

Case Description: A 64 year old male with Diabetes Mellitus and HTN presented for elective L5-S1 laminectomy. On the first post-operative day, patient complained of back pain and nausea. Physical exam revealed BP of 118/73 mmHg, heart rate of 95-115 beats/minute and normal temperature. Chest was clear and there was no edema. Foley catheter was in place and draining large amounts of yellow urine. Laboratory data showed serum creatinine of 1.5 mg/dL, elevated from pre-operative baseline of 1.0 mg/dl and BUN of 44, elevated from 17 pre-operatively. Rest of the laboratory data including serum potassium and bicarbonate as well as urinalysis were normal. Rise in serum creatinine was attributed to intraoperative hypotension with mean arterial pressures between 50-60 mmHg. Over the subsequent week serum creatinine ranged between 1.5 and 1.8 mg/dL and on postoperative day eight, patient developed abdominal pain. CT abdomen revealed large left sided retroperitoneal collection consistent with urinoma with left sided hydroureteronephrosis. He underwent cystoscopy with ureteral stent placement; after which, serum creatinine normalized to 0.90 mg/dL. Abdominal pain resolved and patient was discharged with urology follow up.

Discussion: Ureteral injury is rare after laminectomy however must be considered in the case of sustained increased serum creatinine post-operatively. As AKI subsequent to unilateral ureteral injury is uncommon in patients with normal baseline renal function, the rise in serum creatinine observed might not reflect a true decline in GFR but rather increased reabsorption from urinoma.

PUB486

Utility of RRT in Reducing Mortality and Morbidity in a Heart Transplant Recipient with Idiopathic Hyperammonemic Encephalopathy

Muhammad Azhar,[1] Sameer Hirji.[2] *[1]Brigham and Women's Hospital, Boston, MA; [2]Brigham and Women's Hospital, Boston, MA.*

Introduction: Development of Hyperammonemic encephalopathy is extremely rare in solid organ transplant recipients. Only 3 such cases have been reported in the literature, all due to idiopathic causes [3,4] Since continuous RRT with iHD plays a major role in improving ammonia levels, we hypothesized that similar improvements will be observed in a heart transplant recipient with HAE.

Case Description: A 44-year old male who was POD3 from a heart transplantation for congenital heart disease developed generalized tonic-clonic seizures in the setting of hyperammonemia syndrome. MRI showed diffuse cerebral edema while MR Spectroscopy showed reduced glutamine synthetase activity, N-acetyl aspartate and myo-inositol levels, all of which reflected glial and neuronal dysfunction. All labs were normal except for ammonia levels of 1400 umol/L. Liver and renal studies were also unremarkable. The patient was promptly started on levetiracetam, sodium benzoate, arginine. The patient's ammonia levels on POD4 still remain elevated (1350 umol/L) but decreased to 900 umol/L two days after initiating CVVH with iHD. CRRT was continued for additional 10 days along with sodium benzoate, arginine. Within 2 weeks, ammonia levels had completely normalized (**Table**) and while cerebral edema significantly improved on repeat scans, the

patient still had cognitive impairment (including impulsivity and memory impairment) which was slowly improving.

Discussion: HAE is a rare complication following solid organ and bone marrow transplantation, with an estimated risk of 0.5% and very high mortality. [1,3,4]. Hyperammonia levels can occur in the setting of cirrhosis, inborn errors of metabolism, type 1 RTA, and drugs. Furthermore, metabolic encephalopathy is driven by the effects of glutamate on the brain. Extracellular glutamate activates NMDA receptors and leads to alterations in nitric oxide metabolism and a shortage of ATP. This causes a cascade of events that eventually lead to free radical accumulation and the formation of nitric oxide. As a result, astrocyte swelling and disruption of the blood-brain barrier occurs, along with cerebral vasodilation due to prostaglandin release which causes loss of autoregulatory control in cerebral blood flow and vasogenic edema.

Post-op day	3	4	5	6	7	8	9	10	11
Ammonia level (umol/L)	1392	1250	920	450	344	208	110	45	33

PUB487

Double Whammy - IgM Lambda Multiple Myeloma and Normotensive ATN Abetting AKI

Joseph Edmund,[2] Arun Rajasekaran,[1] Zhabiz Solhjou,[3] Lazaro Delgado.[4] *[1]University of Central Florida College of Medicine, Kissimmee, FL; [2]UCF College Of Medicine, Kissimmeee, FL; [3]UCF, Orlando, FL; [4]Nephrology Associates of Central Florida, Orlando, FL.*

Introduction: Multiple Myeloma (MM) is a plasma cell disorder characterized by the neoplastic proliferation of plasma cells in the bone marrow producing monoclonal immunoglobulins. We present a case of IgM light chain lambda predominant MM resulting in acute kidney injury (AKI) necessitating long term hemodialysis.

Case Description: A 50 year old male with arterial hypertension and diabetes presented with complaints of nausea, vomiting and fatigue. Vitals signs were stable, and clinical exam was unremarkable. Labs revealed normocytic anemia with hemoglobin 8 g/dl, elevated BUN (78 mg/dl) and creatinine (6.8 mg/dl, baseline 0.9 mg/dl three months back). Serum electrolytes, including calcium, magnesium and phosphorus levels were within normal limits. UA revealed isosthenuria with increased hyaline casts, and absence of hematuria, proteinuria or pyuria. Serum total protein (5.1 mg/dl) and albumin (1.1 mg/dl) levels were low. ESR (87 mm/hr.) and serum viscosity levels were markedly elevated. A 24-hour urine collection revealed proteinuria (848 mg). No osteolytic lesions were noted in a skeletal survey. Quantitative immunoglobulins were significant for elevated IgM levels, with concurrent suppression of IgG and IgA levels. Quantitative serum light chain measurement revealed elevated levels of lambda (6925 mg/L) and kappa (22.56 mg/L), with a Kappa:Lambda ratio of less than 0.01. SPEP, UPEP and serum immunofixation revealed IgM-Lambda Myeloma (MM). Renal biopsy was performed - moderate interstitial fibrosis and tubular atrophy, diffuse acute tubular injury; numerous large intraluminal casts that stained strongly against lambda (3+); diffuse GBM thickening with widespread epithelial foot process effacement was noted. Bone-marrow biopsy with flow cytometry revealed intracytoplasmic lambda-restricted monoclonal plasma cells that occupied 80% of the marrow. He underwent multiple plasma exchanges, and was started on a chemotherapeutic regimen consisting of Bortezomib, Cyclophosphamide, and Dexamethasone. His renal function has not improved, and is dependent on dialysis.

Discussion: Only 10- 20% of all MM are due to light chain disease. Lambda light chain disease is extremely rare, and carries a poor prognosis. Despite aggressive plasma exchange, dialysis, and chemotherapy, our patient did not attain remission. Further research on this rare entity is warranted.

PUB488

ACE Levels – An Unreliable Predictor of Disease Activity in Isolated Renal Sarcoidosis

Arun Rajasekaran,[1] Elpidio Abreu,[2] Pran M. Kar.[3] *[1]University of Central Florida College of Medicine, Kissimmee, FL; [2]Nephrology Associates of Central Florida, Ocoee, FL; [3]VA Medical Center Orlando, Orlando, FL.*

Introduction: PTH independent intrarenal calcitriol production by activated macrophages in isolated renal sarcoidosis is an extremely rare cause of hypercalcemia. We describe hypercalcemia with mildly increased serum ACE levels in a patient with isolated renal sarcoidosis.

Case Description: A 63 year old male presented with worsening weakness and polyuria. He was mildly hypotensive, and had no lymphadenopathy. Labs revealed normal hematological indices, moderate hypercalcemia (13 mg/dl), normal total protein and albumin levels, with a preserved hepatic synthetic function. Serum BUN (86 mg/dl) and creatinine (6.9 mg/dl, baseline 1 mg/dl) were elevated. UA revealed no proteinuria, pyuria, or hematuria. Even after aggressive fluid resuscitation with intravenous crystalloids, azotemia persisted with minimal recovery in renal function despite attaining adequate diuresis). Further investigations revealed low serum PTH (9 pg/ml) and 25-hydroxy Vitamin D (14 ng/ml) levels, and mildly elevated ACE (28 IU/L) and 1,25-dihydroxy Vitamin D (38 pg/ml) levels. Serum PTH-related peptide levels were undetectable. SPEP, UPEP, serum complements and immunoglobin levels were normal. RF, ANA, ANCA, anti-dsDNA, anti-MPO, anti-GBM and anti-proteinase-3 antibodies were negative; as were serologies for Hepatitis B & C, cryoglobulins, HIV panel, and RPR. Tuberculin skin test, and cultures for mycobacterium tuberculosis were negative. Chest and abdomen imaging were unremarkable. Renal biopsy demonstrated normal glomeruli with no hypercellularity, mesangial proliferation, necrosis or crescents. Numerous tubulointerstitial granulomas comprising of noncaseating epithelioid and multinucleated giant cells, surrounded by marked infiltration of mononuclear cells were seen. A diagnosis of isolated renal sarcoidosis was made. He was started on Prednisone 60 mg/day with subsequent improvement of hypercalcemia and renal function.

Discussion: Measurement of serum ACE levels is valuable in diagnosing and following disease activity in sarcoidosis. ACE levels in isolated renal sarcoidosis is typically lower than that seen in pulmonary sarcoidosis, likely secondary to reduced numbers of ACE-producing epitheloid cells isolated to the kidney. We illustrate that ACE level elevations may not be a dependable parameter in the diagnosis or evaluation of sarcoid disease activity in those with isolated renal sarcoidosis.

PUB489

Isolated Renal Sarcoidosis Presenting with Granulomatous Interstitial Nephritis

Arun Rajasekaran,[1] Elpidio Abreu,[2] Pran M. Kar.[3] *[1]University of Central Florida College of Medicine, Kissimmee, FL; [2]Nephrology Associates of Central Florida, Ocoee, FL; [3]VA Medical Center Orlando, Orlando, FL.*

Introduction: Sarcoidosis is a chronic, inflammatory disorder that affects multiple organs, characterized by noncaseating epithelioid granuloma formation. However, granulomatous interstitial nephritis in the absence of extrarenal sarcoidosis is extremely rare.

Case Description: A 59 year old black male with no significant past medical history presented with acute kidney injury (AKI). Vital signs were stable on admission, and no lymphadenopathy was noted. Labs revealed normal hematological indices, electrolyte levels (including calcium, magnesium and phosphorus levels), total protein and albumin levels, with a preserved hepatic synthetic function. Serum BUN (78 mg/dl) and creatinine (7.6 mg/dl, baseline 1.1 mg/dl) were elevated. PTH (7 pg/ml) and 25-hydroxy Vitamin D (15 ng/ml) levels were suppressed, while Angiotensin Converting Enzyme (69 IU/L) and 1,25-dihydroxy Vitamin D (42 pg/ml) levels were significantly elevated. Serum PTH-related peptide levels were undetectable. Urinalysis revealed no proteinuria, pyuria, or hematuria. ESR was elevated at 80 mm/hr. SPEP, UPEP, serum complements and immunoglobin levels were normal. RF, ANA, ANCA, anti-dsDNA, anti-MPO, anti-GBM and anti-proteinase-3 antibodies were negative. Serologies for Hepatitis B & C, cryoglobulins, HIV panel, and RPR testing were negative. Tuberculin skin test, and cultures for mycobacterium tuberculosis and systemic fungi were negative. CT chest-abdomen-pelvis, renal ultrasound, and pulmonary function tests were unremarkable. Despite aggressive intravenous crystalloid resuscitation, renal function did not significantly improve. Early renal biopsy demonstrated normal glomeruli with no mesangial proliferation, capillary wall abnormalities, or crescents. Numerous tubulointerstitial granulomas comprising of noncaseating epithelioid and multinucleated giant cells, surrounded by marked infiltration of mononuclear cells were seen. Based on laboratory and renal biopsy findings, a diagnosis of isolated renal sarcoid GIN was made. He was started on Prednisone 40 mg/day and renal function normalized to baseline within a month.

Discussion: Isolated renal sarcoidosis is extremely rare and is seen in elderly males unlike systemic sarcoidosis. Our patient did not have hypercalcemia that is frequently associated with this entity. Early diagnosis and prompt steroid therapy lead to normalization of kidney function.

PUB490

From Heart Failure to Light Chain Deposition Disease and Cast Nephropathy in Multiple Myeloma

Sana J. Shaikh,[3] Christian C. Nwankwo,[1] Alexandre Lacasse,[3] Steven C. Cheng.[2] *[1]Nephrology, SSM St. Mary's Hospital - St. Louis, St. Louis, MO; [2]Nephrology, Washington University School of Medicine, St. Louis, MO; [3]Internal Medicine, SSM St. Mary's Hospital - St. Louis, St. Louis, MO.*

Introduction: Light chain deposition contributes to renal failure in multiple myeloma (MM) via 3 main patterns of injury: cast nephropathy (CN), MIDD with light chain deposition disease (LCDD) being a variant, and amyloidosis.

Case Description: 64-year-old man with HFpEF and CKD-3 presented with leg swelling and weight gain. Jugular venous distention and bilateral pitting pedal edema were noted. Labs included creatinine of 5 mg/dl (baseline 1.4), proteinuria, hematuria, glycosuria, raised BNP and anemia of chronic disease. On ultrasound, both kidneys were 16 cm in size. Admission diagnosis was acute cor pulmonale. Further workup revealed abnormal restricted peak in the gamma region on SPEP, elevated κ-FLC and κ- to λ-FLC ratio, and IgG κ monoclonal protein on immunofixation. Renal biopsy detected LCDD-CN and bone marrow analysis confirmed MM.

Discussion: Alternative diagnosis was pursued due to nephrotic-range proteinuria, normoglycemic glycosuria and enlarged kidneys, and MM was diagnosed without albuminocytologic dissociation, hypercalcemia or bony lytic lesions. LCDD-CN is rare and requires detailed microscopy. In contrast to pure LCDD or MIDD, mean age and incidence of AKI and dialysis are higher. Treatment is the same as that of MM and goals include improvement of renal function and prevention of extrarenal deposits.

Literature review of LCDD-CN

Reference	Sample size	LCDD-CN	Comments
Gokden et al	23 with LCDD-CN	100%, 23 cases	13% NGS on LM, 100% positive IF (18 κ & 5 λ), 65% EDD on EM, 35% IF-positive & EM-negative
Lin et al	34 with MIDD	32%, 11 cases	18% NGS on LM, 100% positive IF (10 κ & 1 λ), 36% IF-positive & EM-negative
Pozzi et al	63 with LCDD	16%, 10 cases	NGS on LM unlikely, frequent discrepancy between IF & EM (80% versus 18% with pure LCDD)
Pirani et al	47 with plasma cell dyscrasias	9%, 4 cases	-
Paueksakon et al	121 with monoclonal gammopathy and/or renal biopsy diagnosis related to paraprotein	0.8%, 1 case	-
Qian et al	(CR)	(CR)	MM with CN + heavy and LC deposition disease
Lorenz et al	(CR)	(CR)	MM with LCDD + CN + amyloidosis
Lam et al	(CR)	(CR)	IgD-λ myeloma with λ-LCDD + CN. Post autopsy kidney sections detected amyloid deposits around renal medullary vessels. 2 other specimens showed LCDD + CN and CN + LCDD + amyloidosis

CN - cast nephropathy, CR - case report, EDD - electron-dense deposits, EM - electron microscopy, IF - immunofluorescence, LC - light chain, LCDD - light chain deposition disease, LM - light microscopy, MIDD - monoclonal immunoglobulin deposition disease, MM - multiple myeloma, NGS - nodular glomerulosclerosis, κ - kappa, λ - lambda

TMA in Antisynthetase Syndrome

Raad B. Chowdhury,[1] Christopher Valentine.[2] *[1]Internal Medicine, Ohiohealth: Riverside Methodist Hospital, Columbus, OH; [2]Riverside Nephrology Associates, Columbus, OH.*

Introduction: Thrombotic Microangiopathy (TMA) is a syndrome characterized by microangiopathic hemolysis, thrombocytopenia, and kidney injury. Primary causes include Thrombotic Thrombocytopenic Purpura or complement mutations. Secondary causes are due to autoimmune diseases, malignancy, and transplantation. Overall, autoimmune disease causing TMA is extremely rare. A study from Taiwan retrospectively reviewed 2461 cases of SLE in a 10-year span and reported only 25 cases of TMA. This abstract presents a case of an autoimmune phenomenon, Antisynthetase syndrome, causing TMA. As per our literature review, one case of TMA was reported in a patient with Polymyositis. In that case however, the patient also had underlying RA and was on a calcineurin inhibitor which may predispose to TMA.

Case Description: A 64-year-old female with recently diagnosed polymyositis and pulmonary embolism presented for worsening dyspnea. In a prior admission, she presented with arthritis and soft tissue edema. Serology showed elevated JO-1, aldolase, and CPK at the time. Computed tomography of the lungs showed diffuse pneumonitis, due to interstitial lung disease attributed to her autoimmune disease. Her overall presentation and imaging was suggestive of antisynthetase syndrome. During the current admission, her dyspnea was worsening and she had new onset kidney injury. Urinalysis was remarkable for protein and hematuria and she subsequently developed hemolytic anemia and thrombocytopenia. Due to her unexplained proteinuria, renal biopsy was performed revealing thrombi in glomerular capillaries and arterioles, suggestive of TMA. Primary causes of TMA such as TTP, HUS, and drug induced TMA were ruled out. Secondary causes such as malignancy were ruled out with additional CT of abdomen and pelvis. Other secondary autoimmune disorders were ruled out serologically. The only positive test was the >100 JO-1 antibody titers on ENA.

Discussion: TMA is an often fatal disease process. It has been reported in the context of HUS, TTP, autoimmune diseases and malignancy. This case is extremely novel in that the patient met criteria for antisynthetase syndrome by having both autoimmune polymoysitis and interstitial lung disease. Subsequently she developed AKI with biopsy proven TMA. Of note, patient's symptoms and renal function improved following treatment with prednisone. Having ruled out most, if not all causes of TMA, the only culprit was the antisynthetase syndrome.

PUB492

A Catastrophic Sequela of Cryoglobulinemia: Was Bedside Ultrasound Useful?

Christian Castillo latorre,[1] Luis O. Gerena Montano,[1] Roberto Borrero-Lugo.[2] *[1]San Juan City Hospital, San juan, PR; [2]Hospital Municipal de San Juan, Carolina, PR.*

Introduction: Intravenous drug usage has a strong correlation with renal failure, as well with chronic viral infections Hepatitis C and HIV respectively. With this risk factors other complications had been describes such as cryoglobulinemia, rhabdomyolysis, disseminated intravascular coagulation (DIC) that in cases could developed Purpura Fulminans as a deadly complication. Several factors had been implicated with renal function deterioration, and one of them is deposition of immune complexes as in cryoglobulinemia. This systemic disease could give rise to distinct clinical manifestations such as hyperviscosity syndrome that could be evidenced by sonography at initial presentation. Hyperpigmented lesions due to direct damage and diffuse anasarca, are early signs of deteriorated renal function. Skin changes could present as well with catastrophic limb gangrene. Here we report a rare case of hepatitis C with HIV related cryoglobulinemia which presented with generalized seizures de novo, rhabdomyolisis, rapidly progressing renal failure, disseminated intravascular coagulation, and purpura fulminant.

Case Description: Case of a 37 year old male with history of intravenous drug usage that presented to the emergency department after having a seizure event in the streets. He developed acute respiratory failure requiring mechanical ventilation within next few hours. Over a period of 24 hours severe renal failure developed, with mucosal bleeding as well bleeding from intravenous sites with bilateral acrocyanosis with pregangrenous changes. During this course, HIV came positive as well Hepatitis C infection.

Discussion: Based on the clinical picture with lab evidence of positive cryoglobulins and association of HCV, we made the diagnosis of HCV related mixed cryoglobulinemia with multi organ failure, glomerulosclerosis, vasculitis in the form of purpura and symmetric distal gangrene of limbs and nose, consistent with Purpura Fulminans. At intial evalaution patient had a bedside echocardiogram, that was relevant for severe hyperviscosity of blood, that is a clinical characteristic othat can be found in cryoglubulinemia. This early sign gave us a clue about patients underlying condition causing this catastrophic presentation, that was later comfirmed with laboratory results. Cryoglobulinemia is a catastrophic event associated with hepatitis C and HIV, early recognition is key.

PUB493

Close Encounters of the Peritoneal Kind: Case Series of Uroperitoneum and Renal Pseudofailure

Sam Kant,[1] Derek M. Fine.[2] *[1]University of Maryland Medical Center, Baltimore, MD; [2]Johns Hopkins University School of Medicine, Baltimore, MD.*

Introduction: Uroperitoneum, usually a consequence of bladder rupture, can occur after blunt trauma and surgical procedures or in association with pelvic irradiation, alcohol abuse and bladder anatomic abnormalities. As a result of exchange of solutes across the peritoneal membrane- a reverse autodialysis- an electrolyte milieu mimicking AKI can result

Case Description: Case 1: 74 year old male, day 10 status post robotic assisted radical prostatectomy for prostate cancer presented with increasing abdominal distension. These symptoms progressively worsened since removal of urinary catheter 4 days earlier. He had gross abdominal distension on exam. Labs showed Na 132, K 6.3, Bicarbonate 19, Urea 64 and Creatinine 9.7 mg/dL. Peritoneal fluid creatinine was 9.4 mg/dL. CT abdomen revealed gross ascites continuous with focal fluid at the surgical bed concerning for leak. Subsequent insertion of urinary catheter led to normalization of metabolic disarray in 24 hours Case 2: 32 year old female para 0, 40 weeks pregnant, presented to obstetric unit with reduced fetal movements. Induction was commenced and converted to a cesarean section 2 days later due to failure of descent. On postoperative day 4, patient was noted to have progressively increasing abdominal distension with labs: Na 134, K 3.8, Urea 13, Creatinine 2.4. Peritoneal fluid revealed creatinine of 8.4. A CT abdomen showed evidence of bladder leak and gross ascites. Insertion of urinary catheter led to normalization of creatinine next day Case 3: 37 year old male, with a history of alcohol abuse, presented with increasing abdominal pain and vomiting for 1 week. Labs revealed Na-120, K 6.2, Bicarbonate 20, Urea 151 and creatinine 11.8. Presence of gross ascites on CT led to large volume paracentesis, with subsequent reaccumulation in 8 hours. In light of the same and history of recent fall, a suspicion for bladder rupture was confirmed via cystogram. Insertion of urinary catheter led to correction of renal indices in 24 hours

Discussion: These cases underscore that in the presence of inciting event (trauma/surgery), unexplained ascites, classic electrolyte abnormalities(particularly hyponatremia) and urine:serum creatinine ratio of >1 – uroperitoneum should be suspected. The ensuing elevated creatinine is a consequence of reversed intraperitoneal autodialysis and does not represent a renal injury, thus termed renal pseudofailure

PUB494

Rare Spontaneous Renal Infarction of Unknown Etiology

Ifedolapo O. Odebunmi, Eric Y. Chang, Taiwo A. Ajose, Anam Umar, Khalid Bashir. *Morehouse School of Medicine, Atlanta, GA.*

Introduction: Spontaneous renal infarction is rare, especially in the absence of thromboembolism secondary to atrial fibrillation. Other potential causes include hypercoagulable states, infective endocarditis, previous endovascular intervention, renal artery dissection, and oral contraceptive use. We report a rare case of spontaneous renal

infarct in a patient with no known risk factors presenting with abdominal pain mimicking a previous endometriosis flare.

Case Description: A 36 y/o African American female with a history of hypertension, possible congenital right renal atrophy, and endometriosis presented with a two-day history of severe left flank and abdominal pain like her prior endometriosis flares. On physical examination, her systolic blood pressure was 160mmHg and she was in significant distress. However, her exam was negative for peritoneal signs or costovertebral angle tenderness. Initial blood work up and urinalysis was unremarkable. Urine pregnancy test was negative. EKG revealed normal sinus rhythm. CT abdomen/pelvis without intravenous contrast was negative for obstructive uropathy but revealed an enlarged left kidney and an atrophic right kidney. MRA of the abdomen/pelvis revealed a previously unknown lower pole infarct in the left kidney without any significant infrarenal atherosclerosis, or aneurysms. Renal ultrasound was significant for an atrophic right kidney (3.3 cm) and an enlarged left kidney (13.5 cm) with decreased echogenicity of the lower pole consistent with known infarction. Left renal artery duplex scan was negative for significant renal artery stenosis. Hypercoagulable and venous thromboembolic work up was negative. Patient was medically managed and discharged home without chronic anticoagulation after symptomatic improvement.

Discussion: Spontaneous renal infarction is rare in the absence of predisposing risk factors such as thromboembolic disorders or hypercoagulable states. Due to non-specific manifestations, diagnosing renal infarction is a challenge and may lead to delayed diagnosis and intervention. Physicians must maintain a high index of suspicion so that timely interventions can be performed to properly assess and maintain kidney function

PUB495

AKI Associated with Acinar Cell Pancreatic Cancer

Kevin D. Marquez,[1] Kuang-Yu Jen,[3] Brian Y. Young.[2] *[1]University of California Davis School of Medicine, Sacramento, CA; [2]UC Davis Medical Center, Sacramento, CA; [3]University of California, Davis, Sacramento, CA.*

Introduction: The kidney plays a large role in the elimination of pancreatic enzymes from the circulation. Acinar cell carcinomas are rare pancreatic cancers associated with lipase hypersecretion. We present a patient with metastatic pancreatic cancer with recurrent acute kidney injury potentially linked to her acinar subtype.

Case Description: A 49 year-old woman was diagnosed with acinar cell cancer and underwent chemotherapy with gemcitabine and abraxane for biopsy-proven metastatic disease with symptomatic ascites. One week after initiating chemotherapy, she developed painful raised bumps on both of her legs. She was hospitalized twice over two months for IV antibiotics for presumed cellulitis. Nephrology was consulted for worsening renal function as her creatinine steadily rose from 1.3 to 2.4 mg/dl. She had 2.8 grams of proteinuria, which was largely tubular, with only 2% of the total being albumin. Urine microscopy showed abundant coarse granular casts and no dysmorphics RBCs. Serologic workup showed no paraproteins, normal complement, and negative screens for hepatitis, ANA, ANCA, and GBM antibodies. Renal imaging showed no evidence of obstruction. A kidney biopsy was performed which showed ATN without any evidence of TMA or GN. Clear cause for ATN could not be identified; there were no hypotensive or nephrotoxic exposures. Without other exposures, she continued to have a rising creatinine to greater than 5 mg/dl along with worsening leg lesions. Another kidney biopsy 5 weeks after her initial one found only progressive ATN. Dermatology skin biopsy of the leg showed necrosis of adipocytes compatible with pancreatic panniculitis. Her serum lipase was 810 U/L (high) with normal serum amylase. She had no symptoms of pancreatitis. A urine lipase was checked and was markedly elevated at 1,112 U/L (Normal < 4).

Discussion: We present a patient with ATN who has acinar cell pancreatic cancer and pancreatic panniculitis. Studies have implicated lipase as pathogenic in panniculitis by its identification in areas of subcutaneous necrosis. 20% of pancreatic enzymes are excreted by the kidneys, with animal studies showing that lipase undergoes filtration, tubular reabsorption, and subsequent intrarenal degradation. We propose a potential novel cause of ATN due to supraphysiologic levels of serum and urinary lipase that should be investigated, similar to that of pancreatic panniculitis.

PUB496

Massive Creatinine Increase in the Setting of Protein Malnutrition

Stephanie Colon Lopez, Ileana E. Ocasio Melendez, Fatima B. Cintron-Rosa, Krystahl Z. Andujar, Carlos G. Rivera-Bermudez. *Nephrology, University of Puerto Rico - Medical Sciences Campus, San Juan, Puerto Rico.*

Introduction: Serum creatinine (SCr) is a marker of kidney function and its elevation is usually associated with a concomitant rise in the blood urea nitrogen (BUN). An isolated rise in SCr has been described with the use of drugs that decrease the secretion of creatinine, with increased muscle mass and interference with its assay. We present the case of a patient with ulcerative colitis (UC) and acute kidney injury (AKI) characterized by an isolated rise in SCr.

Case Description: A 63-year-old man with UC on chronic prednisone and a previous colectomy was admitted to surgery ward after an ileal pouch-anal anastomosis (IPAA) with upstream ileostomy. After IPAA was performed, vancomycin and piperacillin-tazobactam were started for recorded episodes of fever. He was consulted to Nephrology service due to AKI. On evaluation, the patient was hypotensive, tachycardic, with high ileostomy output and decreased urine output. No skin rash was noted. Laboratories showed an elevation in SCr to 6.18 mg/dL from 1.3 mg/dL with associated metabolic acidosis without increase in BUN, electrolyte disturbances or eosinophilia. Albumin levels were 2.8 g/dl. Urine sediment was bland. He had no medications that could alter the secretion of creatinine. Due to signs of volume depletion, he was repleted with intravenous (IV) isotonic saline. SCr continued to rise to 9.44 mg/dL and since he was hemodynamically stable, IV fluids were changed to 0.45% NSS to replace ileostomy losses. Loperamide was added to achieve a solid consistency of ileostomy output. Imaging revealed fluid collections adjacent to IPAA, which identified an infectious focus. Vancomycin and piperacillin-tazobactam were discontinued and meropenem was started. SCr continued to increase up to 13.65 mg/dL while BUN remained at 35 mg/dL without hypervolemia or other electrolyte disturbances, hence dialysis was not considered. SCr levels returned to baseline three weeks later.

Discussion: Reduced muscle mass in patients with UC is associated with inflammation and glucocorticoid treatment. In this setting, BUN is expected to increase at least proportionally to SCr. In our patient, hypovolemia was not associated to an elevated BUN; and despite correction, SCr continued to rise. Severe and prolonged protein malnutrition may explain this unusual presentation.

PUB497

A Rare Presentation of Cocaine Induced Kidney Injury

Ifedolapo O. Odebunmi, Titilope Olanipekun, Nnamdi K. Nwaohiri. *Morehouse School of Medicine, Atlanta, GA.*

Introduction: An estimated 1 out of every 20 young adults in the US abuse cocaine. Case reports have described cocaine related renal impairment manifesting as acute tubular necrosis (ATN), infarction, pigment induced kidney injury and acute interstitial nephritis (AIN). However, hematuria in the setting of cocaine use without evidence of commonly seen cocaine induced renal pathologies has rarely been reported.

Case Description: A 29-year-old female with a medical history of hypertension, cocaine abuse, chronic hepatitis C virus infection and cryoglobulinemic vasculitis (diagnosed 2 weeks prior) was admitted for right lower extremity cellulitis. She was noted to have 1-week history of bloody urine necessitating nephrology team evaluation. She admitted to IV cocaine use few days before presentation. She had mildly elevated blood pressure - 158/69 mm/hg and the rest of her physical exam was unremarkable. Laboratory blood investigations revealed elevated serum creatinine - 3.1 mg/dl and low hemoglobin - 8.6g/dl. Her urinalysis revealed 3+ hemoglobin and 1+ protein. UDS was positive for benzodiazepines and cocaine. Other pertinent lab work up including creatine phosphokinase, urine chemistry and eosinophils, HIV and hepatitis B virus tests and serology for autoimmune disorders was negative. Renal ultrasound scan showed normal kidney size without hydronephrosis or stones. Renal biopsy revealed tubular lumen filled with red blood cells (RBC) and casts with no evidence of fibrosis, sclerosis or tubular atrophy. She was managed supportively with IV normal saline, antibiotics for cellulitis and her outpatient prednisone treatment. Her hematuria resolved, and serum creatinine level improved to her baseline (1.0 mg/dl). She was counseled on cocaine use.

Discussion: Cocaine causes kidney injury by different mechanisms; ATN and renal infarction through severe vasoconstriction and rhabdomyolysis and AIN through idiosyncratic allergic response. Also, chronic cocaine use has been linked to glomerulopathies. Our patient had cocaine related renal injury with RBCs and RBC casts in the tubular lumen without findings to suggest renal abnormalities frequently associated with cocaine abuse and toxicity. This is quite unusual and to our knowledge, has not been reported in the literature. Nephrologists and clinicians should be aware of the various renal manifestations of cocaine use.

PUB498

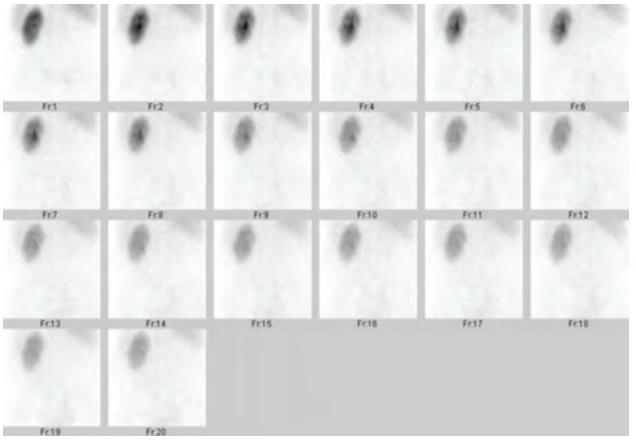
Suspected Pyelovenous Backflow Causing Acute Anuric Renal Failure (ARF)

Pace Romney,[1] Kalani L. Raphael,[2] Aylin R. Rodan,[3] Martin C. Gregory.[1,2] *[1]University of Utah Medical Center, Salt Lake City, UT; [2]VA Salt Lake City Health Care System, Salt Lake City, UT; [3]University of Utah, Salt Lake City, UT.*

Introduction: The following is a case of ARF requiring dialysis in a man with normal cystatin C and β-2 microglobulin (B2M) levels without evidence of urine leak on imaging.

Case Description: A 72 year-old-man with normal renal function and solitary left kidney after donor nephrectomy 30 years ago underwent prostatectomy for prostate cancer. Surgery was uneventful with EBL 800 mL and intraop SBP remaining over 60. A routine abdominal drain was placed. The patient said he felt well after the surgery, however urine output diminished and he became anuric and creatinine (Cr) increased in the following days. IV fluids had no effect. There was no evidence of hydronephrosis, urine retention, or intra-abdominal fluid collection on CT or US. Urine microscopy showed RBCs without casts. Fluid from the abdominal drain had Cr levels similar to serum. Serum Cr steadily climbed and hemodialysis was initiated on post op day 6 for hyperkalemia. Cystatin C was 1.0 mg/L with a simultaneous Cr of 10.2 mg/dL and two days later B2M was 2.3 mg/dL with Cr 7.8 mg/L. MAG3 renal flow scan showed normal renal perfusion with concentrated tracer in the renal pelvis but not in the ureter and no evidence of urine leak. 2 weeks after the onset of ARF, urine output spontaneously increased and creatinine fell. He was discharged without further dialysis.

Discussion: Although our uninephric patient had ARF, he had normal glomerular filtration as shown by normal cystatin C, B2M, and MAG3 scan. The scan confirmed that freshly-formed urine was reaching the pelvis but not transiting the ureter. There was no evidence of extravasation on MAG3 scan or by analysis of drain fluid. Urine left the renal pelvis by another route: renal veins or renal lymphatics. Most likely postop edema and acute UV junction obstruction caused forniceal rupture and pyelovenous reflux into the arcuate veins. A less likely possibility is pyelolymphatic reflux. Had he been binephric, renal failure would likely have passed unnoticed.



PUB499

Bilirubin Cast Nephropathy Diagnosed by "Liquid Biopsy"

Eduardo Del Orbe, Melissa C. Fajardo, Jeffrey D. Wallach, Sudhanshu Jain. *Harlem Hospital, Forest Hills, NY.*

Introduction: AKI can occur in liver disease through numerous mechanisms; one of them is bilirubin cast nephropathy. Most cases have been diagnosed with kidney biopsy. We present a case of bilirubin cast nephropathy, diagnosed by urine microscopy, in a patient with obstructive cholestasis.

Case Description: A 59 year old woman with past medical history of morbid obesity, type 2 DM, HTN, and CAD was hospitalized for progressive weight loss, nausea, vomiting, itching, and yellow skin. Her vital signs were stable. Physical exam was significant for icteric sclera, jaundice, and scattered excoriations of skin. No ascites or abdominal pain was present. Baseline liver and renal function were both normal. Investigations were remarkable for serum creatinine of 4.7 mg/dL, which later peaked at 8.1 mg/dL. Hepatic panel was significant for total bilirubin of 18.8 mg/dL with direct bilirubin of 14.8 mg/dL, alkaline phosphatase was 568 U/L, ALT was 66 U/L, and AST was 88 U/L, suggesting cholestasis. UPCR was 1.0 g/g. Urine microscopy showed bilirubin-stained granular casts. Abdominal imaging showed cholelithiasis, dilated common bile duct, with normal kidneys and liver. Kidney biopsy was held due to possible renal recovery from planned intervention with ERCP. During ERCP periampullary tumor was found, and CBD stent was placed. Creatinine improved to 2.2 mg/dL afterwards with simultaneous improvement in bilirubin levels. Seven weeks after ERCP with CBD stent placement, creatinine and total bilirubin had returned to baseline.

Discussion: Cases of bilirubin cast nephropathy in the setting of obstructive cholestasis have been underreported. Most reported cases have been diagnosed with kidney biopsy. However, in our case this was a patient with obstructive jaundice, renal failure, and bilirubin-stained granular casts on urine microscopy who then underwent ERCP with CBD stent placement to relieve obstruction, and then had a subsequent improvement in her renal failure. Kidney biopsy was never performed, and may not be necessary to establish a clinical diagnosis of bilirubin cast nephropathy.

PUB500

Role of Eculizumab in Dialysis Dependent AKI Secondary to Atypical Hemolytic Uremic Syndrome

Katherine R. Robinson,[1] Kayla Shirley,[1] Fadee Abu Al Rub,[1] Claude Bassil,[1] Liying Fu.[2] *[1]University of South Florida, Lutz, FL; [2]Tampa General Hospital, Tampa, FL.*

Introduction: Thrombotic microangiopathies represent 3 syndromes: hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura, and atypical HUS (aHUS). While microvessel wall thickening and intraluminal thrombosis characterizes the pathology, the pathogenesis and prognosis for each disorder is variable. HUS is defined by a triad of microangiopathic hemolytic anemia (MAHA), thrombocytopenia and AKI. aHUS is then divided into two groups, typical (diarrheal) and atypical (non-diarrheal) HUS.

Case Description: A 65-year-old female with HTN, MDS and MGUS, presented to the ED with fatigue. Refer to Table 1 for lab findings. For the past 6 months, serial peripheral smears demonstrated increasing number of schistocytes. Renal ultrasound ruled out obstruction. Urine studies showed microscopic hematuria and 24h urine protein of 1.1g. As testing ruled out disseminated intravascular coagulation and suggested MAHA, therapeutic plasma exchange was given empirically until ADAMTS13 activity returned normal. Hemodialysis (HD) was then started for volume overload. Renal biopsy showed acute and severe chronic thrombotic microangiopathy-type injury, acute tubular necrosis and focal tubulointerstitial nephritis. Given lack of prodromal diarrhea, aHUS was diagnosed and she received corticosteroids followed by eculizumab. Her renal function and platelet counts recovered requiring 6 weeks of HD although she will require lifelong eculizumab therapy. Genetic testing for abnormal complement factors is pending.

Discussion: aHUS is an uncommon type of microangiopathy with incidence of 1 per million. Dysregulation of complement activation in the alternate pathway secondary to abnormal complement factors, with subsequent endothelial injury, typifies the pathogenesis of aHUS. As more genetic mutations are recognized it is becoming an increasingly understood clinical entity. Previously, standard first-line therapy consisted of plasma exchange followed by immunosuppression. The monoclonal antibody eculizumab has gained popularity in aHUS treatment by binding complement C5. Although eculizumab has been used more often for aHUS our case reflects the efficacy of this agent in a dialysis dependent patient if started immediately after the diagnosis has been made.

Creatinine	BUN	Hemoglobin	Platelets	INR	PTT	LDH	Haptoglobin
7.5 mg/dL	62 mg/dL	10.3 g/dL	69 x 10^3/uL	0.9	30 sec	890 u/L	<8 mg/dL

PUB501

Role of Steroids in Relapsing Light Chain Myeloma Patient with Dialysis Dependent Acute Renal Failure and Interstitial Nephritis

Katherine R. Robinson,[1] Gautam krishna Koipallil,[3] Onyekachi C. Obi,[1] Claude Bassil,[1] Liying Fu.[2] *[1]University of South Florida, Lutz, FL; [2]Tampa General Hospital, Tampa, FL; [3]University of South Florida Morsani College of Medicine, Tampa, FL.*

Introduction: Cast nephropathy and hypercalcemia are the major contributors to renal failure in multiple myeloma patients (MM). Casts result when large amounts of free light chain (FLC) interact with Tamm-Horsfall protein in the urine, blocking glomerular outflow. Conversely, acute interstitial nephritis (AIN) is a rare manifestation of acute kidney injury (AKI) in MM patients. To our knowledge, there are few cases of a MM patient with concomitant cast nephropathy and AIN - here we present one such rare case. Our patient AKI response to steroids highlights the possibility of multiple etiologies for renal failure in MM, and the importance of thorough patient history, workup, and kidney biopsy when caring for these patients.

Case Description: A 61-year-old male with past medical history of IgG kappa MM (relapsed on multiple lines of treatment, most recently Revlimid, not currently on therapy) presented with fevers, generalized fatigue and confusion. He was found to be in acute renal failure (ARF) with an admission creatinine of 4.4 mg/dL, peaking at 6.3 mg/dL. He was empirically given antibiotics, despite negative infectious workup. Urinalysis showed moderate hemoglobin and eosinophil presence. Kappa FLC and kappa:lambda ratio was elevated (1419 mg/L; ratio 61) but had been higher previously (1480 mg/L; ratio 167). Renal ultrasound had no acute findings. His creatinine remained greater than 5 mg/dL without signs of improvement, until he eventually required hemodialysis (HD). Kidney biopsy was pursued; pathology confirmed cast nephropathy with concomitant AIN. As a result of biopsy findings, he was placed on a prednisone taper starting with 60mg QD. He required HD for 6 weeks, but kidney function improved, and his creatinine has since remained 2-3 mg/dL.

Discussion: This case allows us to witness an alternate origin of renal failure in multiple myeloma, in contrast to the classic cast nephropathy. Rapid improvement with steroids reveals AIN as the underlying cause of his renal failure. Without kidney biopsy and diagnosis of AIN, further MM treatment may not have successfully recovered kidney function. Thorough patient history, workup, and kidney biopsy are crucial to prevent oversight of the possible alternate sources of renal failure in MM.

PUB502

A Case of AKI by an Unusual Cause of Rhabdomyolysis

Luis O. Gerena Montano, Christian Castillo latorre. *San Juan City Hospital, San Juan, PR.*

Introduction: Rhabdomyolysis is a syndrome characterized by muscle necrosis and the release of intracellular muscle constituents into the circulation. Creatine phosphokinase (CPK) levels are typically markedly elevated, muscle pain and myoglobinuria may be present. The severity of illness ranges from asymptomatic elevations in serum muscle enzymes to life-threatening disease characterized by extreme enzyme elevations, electrolyte imbalances, and acute kidney injury (AKI). AKI is an abrupt and usually reversible decline in the glomerular filtration rate (GFR). This results in an elevation of serum blood urea nitrogen (BUN), creatinine, and other metabolic waste products that are normally excreted by the kidney.

Case Description: We present the case of a 29 year old man with no past medical history that came to our urgency room complaining of muscle pain, malaise and gross hematuria. Pain was more prominent in proximal muscle of upper and lower extremities, cramping, 7/10 in intensity, not radiating, aggravated by movement and affects ambulation due to pain, of 3 days of evolution. Denied any recent medications, toxic habits, fever, nausea, vomiting, diarrhea, chills, seizures, SOB, cough, chest pain, recent travel, sick contacts, sore throat, rhinorrhea, animal contact. He started a new job that demands more physical activity than his usual and have to be prolonged time standing up. He remembers a similar episode when he was 13 year old. Work-up was done at the time as an inpatient elsewhere including muscle biopsy but he doesn't remember any diagnosis. Now initial pertinent laboratory work-up results showed a very high CPK levels, myoglobinuria and GFR of 40 mL/minutes. After history, physical examination and studies a metabolic myopathy was very high in the differential diagnosis. After muscle biopsy and genetic testing were done the diagnosis of McArdle's disease was confirmed.

Discussion: McArdle's disease is a glycogen storage disease affecting the muscle due to muscle phosphorylase deficiency affecting 1:167,000 of the population. It is a type of metabolic myopathy that may cause rhabdomyolysis. Metabolic myopathies represent a very small percentage of cases of rhabdomyolysis with consequent myoglobinuria in which AKI could develop. We as physicians have to be aware about these uncommon conditions that may cause recurrent rhabdomyolysis and therefore recurrent AKI.

PUB503

Cytomegalovirus PCR Levels and Collapsing Glomerulopathy

Ifeoma Okadigbo, John W. O'Bell, Basma O. Merhi. *Brown Nephrology, Port Jefferson, NY.*

Introduction: Collapsing glomerulopathy is a form of focal and segmental glomerulosclerosis (FSGS) which leads to very severe nephrotic syndrome and quickly progresses to end-stage renal disease is usually associated with HIV. We present a case of collapsing glomerulopathy most likely caused by Cytomegalovirus (CMV) as patient had renal function return to baseline during valganciclovir therapy.

Case Description: 21 yo healthy Hispanic patient presented with nausea, headache, myalgia and 8lbs weight gain and noted to have acute kidney injury with serum creatinine of 1.5 mg/dl. Urinalysis revealed 1+ blood and > 500 protein with numerous nondysmorphic RBCs on urine sediment and urine protein/ creatinine ratio of 12.66g/g. CBC showed WBC 12, 14% bands, 15% atypicals, ALT 181 and AST 156. Serologies including complements C3/C4, ANA, anti-DS DNA, HIV, Hepatitis B and C and EBV PCR viracor were negative. CMV PCR viracor was 9,000. Renal ultrasound showed right kidney at 12.5 cm and the left at 12.3 cm. Ct scan abd/pelvis revealed splenomegaly with spleen at 20.1 cm. Kidney biopsy was consistent with collapsing glomerulopathy with moderate to severe interstitial inflammation and negative staining to CMV DNA. He was treated with valganciclovir 900 mg daily, prednisone 60 mg daily and tacrolimus. After 21 days of treatment, CMV PCR viracor was undectected with marked improvement of proteinuria to 0.97 g/g. Prednisone has been tapered down, and tacrolimus was stopped and patient still demonstrated improved serum creatinine a month after undectable CMV PCR viracor.

Discussion: This case describes a patient who was started on valganciclovir which resulted in normalization of serum creatinine. He was also started on tacrolimus and prednisone in addition to the valganciclovir as recommended treatment plan for collapsing FSGS. CMV was more probable cause as there was a correlation with decreased CMV viracor levels and improved serum creatinine even when patient was off tacrolimus. It is still not clearly understood what the proposed mechanism for CMV induced FSGS. The lesion has been proposed to be related to podocyte injury and attachment upon a size from the glomerular basement membrane. This case presented demonstrated rapid improvement in renal function with valcyte administration and decreased CMV PCR viracor levels.

PUB504

Chronic Interstitial Nephritis Associated with e-Cigarette Cannabinoid Consumption

Emmanuel I. Bahamonde. *Cleveland Clinic Florida, Coral Springs, FL.*

Introduction: Synthetic cannabinoids (SCBs) are psychoactive designer drugs that bind to the cannabis receptors in the brain more potently than marijuana. Cases reported in the literature with SCBs use have been associated with reversible *AKI* characterized by *ATN* and *AIN*. Here we describe a case of a patient who developed chronic interstitial nephritis associated with habitual synthetic cannabinoid use via vaping.

Case Description: A 37 year old African American male with PMH of Diabetes and Obesity s/p gastric sleeve surgery was referred by PCP due to increased in creatinine from baseline of 1.45. His Social History is significant for frequent use of synthetic cannabinoids and marijuana via e cigarette devices. His creatinine on admission was 6.89 mg/dL and BUN 89 mg/dL and urine was remarkable for + eos in urine and muddy brown casts with minimal proteinuria. Initial serological work up was negative and ultimately underwent renal biopsy and dialysis with a creatinine was 10.86 mg/dL and BUN 110 mg/dL. Results of renal biopsy were consistent with patchy acute tubular injury associated with moderate to severe tubular atrophy and interstitial fibrosis, with chronic inflammation. There was also some evidence of mild changes consistent with diabetic nephropathy.

Discussion: Chronic interstitial nephritis (*CIN*) is a histological entity characterized by progressive scarring of the tubulointerstitium, with tubular atrophy, cellular infiltration, and interstitial fibrosis. There have been multiple case reports in which the use of synthetic cannabinoid (*SCBs*) has been associated with *AKI* via *ATN* or *AIN* but none *CIN*. Many of these cases are attributed to synthetic cannabinoid metabolites XLR-11, AM-2011, UR-144, which are present in these synthetic analogs and are found in e-liquids commercially available. This case illustrates the importance of increased awareness to the potential health risks associated with marijuana use via e-cigarettes, whether synthetic or plant derived.

PUB505

The Deceptiveness of Creatinine as a Measure of Renal Function in Rhabdomyolysis: A Case Report

Amanda A. Karasinski,[1] Jaime A. Baynes-Fields,[1] Muhammad O. Hanif,[2] Sandeep Aggarwal,[1] Karthik M. Ranganna.[1] *[1]Drexel University, Philadelphia, PA; [2]Drexel University, PHILADELPHIA, PA.*

Introduction: Rhabdomyolysis associated acute kidney injury (AKI) differs from other etiologies of AKI, as serum creatinine(sCr) represents the measurement of increased generation from muscle lysis and reduced excretion from pigment induced nephropathy. We present a case of dialysis dependent AKI due to rhabdomyolysis with persistently high sCr and eventual normalization of eGFR as demonstrated in a diethylenetriaminepentacetate (DTPA) scan.

Case Description: A 42 year old African American male with no prior medical history presented with progressive weakness and generalized muscle aches which began after phencyclidine use. On initial presentation he was found to have a creatinine of 10.4mg/dL (unknown baseline), potassium 6.9 mmol/L with peaked T waves on EKG, calcium 4.8 mg/dl (5.4, corrected), phosphate 13.4 mg/dl, sodium 127 mEq/L, bicarbonate 20 mEq/L, CK >200,000 IU/L and pH of 7.1. Urine dipstick had 3+ blood and 1-5 erythrocytes on direct microscopy. Renal ultrasound revealed normal renal size and echogenicity. The patient was managed with forced saline diuresis, but was eventually dialyzed for persistent hyperkalemia. After 6 dialysis sessions the patient had increased urine output, normalization of electrolytes and rapid decline of BUN with persistently elevated sCr, see Table 1. Given the patients' clinical improvement a DTPA scan was performed to determine eGFR due to persistently elevated sCr which revealed a GFR of 106 mL/min/1.73m2. Despite cessation of dialysis patient continued to have renal recovery with a sCr of 5.1mg/dL at the time of discharge.

Discussion: Our case demonstrates that sCr is not a reliable marker to monitor recovery of renal function in patients with severe rhabdomyolysis requiring hemodialysis. Nuclear renal imaging such as a DTPA scan is a helpful tool in assessing renal function in similar clinical scenarios. Larger studies are required to assess utility of non creatinine based measurement of GFR in such populations.

Table 1: Lab trend during hospitalization

	Initial labs	HD #1	HD #2	HD #3	HD #4	HD #5	HD #6	Discharge labs
Potassium (mmol/L)	6.9	6.7	4.9	4.5	4.4	4.5	4.6	5.3
BUN (mg/dL)	109	108	104	97	79	47	45	36
sCr (mg/dL)	10.4	11.1	12.8	14.7	14.4	12.0	13.2	5.1
CK (IU/L)	>200,000	>200,000	155,500	7,298	1,865	–	-	-

From One Page to the Next...

John Ahn,[2] Sandeep Padala,[1] Azeem Mohammed.[1] *[1]Augusta University, Augusta, GA; [2]Medical College of Georgia, Augusta, GA.*

Introduction: Page kidney represents a rare cause of renal dysfunction and secondary hypertension that results from external compression of the kidney immediately after a traumatic or iatrogenic sub-capsular hematoma. We present a unique case of an abnormally delayed development of page kidney after a renal biopsy.

Case Description: A 41year old female with a past history of systemic lupus erythematosus, CKD Stage 3b (baseline serum creatinine of 2.5 mg/dL) and hypertension was admitted for acute kidney injury. After undergoing a percutaneous kidney biopsy that revealed Class IV lupus nephritis, the patient developed hematuria and flank pain. Laboratory results indicated a drop in hemoglobin from 10.2 to 8.6 gm/dL and a rise in creatinine from 2.91 to 4.26 mg/dL. CT scan of the abdomen and pelvis revealed a large right retroperitoneal and sub-capsular hematoma measuring 8.1 x 5.3 cm. CT-guided drainage of 1.2 liter of sanguineous fluid resulted in renal function returning to baseline with minimal residual perinephric fluid on repeat imaging. Patient was discharged on immunosuppression for lupus nephritis. About seven months after the kidney biopsy, the patient presented to the clinic with no specific complaints but noted to have a large right lower quadrant mass. Laboratory results revealed acute kidney injury with serum creatinine at 4.03 mg/dL. Imaging revealed a sub-capsular abscess around the right kidney measuring 15.5 x 13.0 x 14.4 cm, presumed to have developed from the preexisting hematoma. The patient was diagnosed with acute renal failure from page kidney. Percutaneous drainage of the abscess resulted in 1.6 liter of purulent fluid that grew many gram-positive cocci on culture. Repeat imaging showed, the sub-capsular fluid had decreased in size to 5.3 x 2.4 x 5.6 cm with a concomitant decrease in serum creatinine to 3.2 mg/dL. The patient was discharged on oral clindamycin.

Discussion: Page kidney usually results in acute renal failure, pain and hypertension caused by activation of the renin-angiotensin-aldosterone system secondary to a sub-capsular hematoma. The present case is unique since this phenomenon was secondary to an abscess that developed in a preexisting hematoma. The patient's immunosuppressive regimen may have been responsible for her indolent course. Furthermore, in an age of abundant imaging modalities, this case highlights the importance of a physical exam.

PUB507

Acute Renal Failure in a Patient with Acute Lymphoblastic Leukemia (ALL): An Unexpected Combination of Etiologies

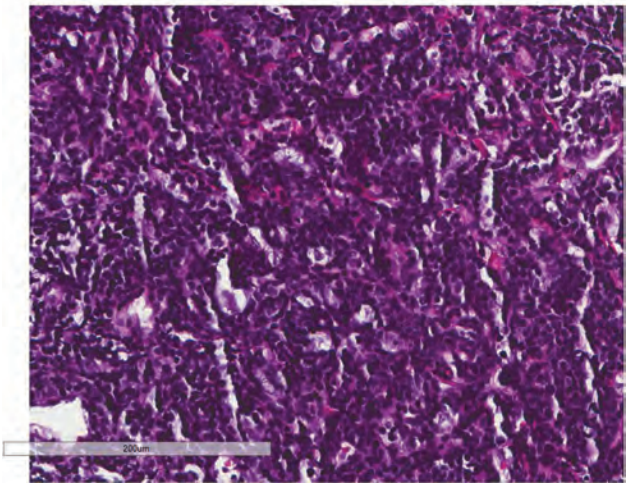
Azza Abdel Hak, Rakesh Gulati. *Thomas Jefferson University Hospital, Philadelphia, PA.*

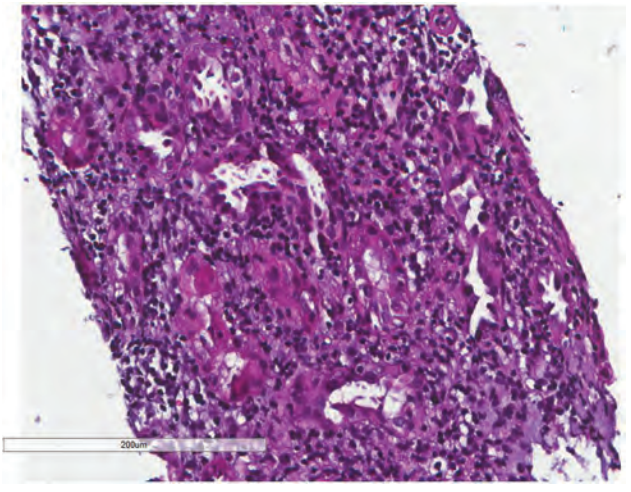
Introduction: We present a case of acute renal failure in an adult patient with relapsed ALL due to lymphomatous infiltration of the kidneys and Blinatumomab induced acute interstitial nephritis (AIN)

Case Description: A 23 year old African male, with relapsed B-cell ALL and chronic Hep B carrier on Entecavir was admitted with acute oliguric renal failure. He was started on Blinatumomab 2 months prior in preparation for stem cell transplant. Outpatient abdominal imaging was concerning for multiple bilateral renal lesions suspicious for secondary Lymphomatous involvement resulting in mass effect. Admission creatinine was 8.4 mg/dl. Renal Ultrasound showed mild bilateral hydronephrosis. Kidney biopsy contained portions of dense interstitial inflammatory infiltrate of CD10-positive and TDT-positive leukemic cells (Figure 1) and a less dense, diffuse interstitial inflammatory infiltrate of CD10-negative and TDT-negative lymphocytes with occasional plasma cells and eosinophils (Figure 2). This was consistent with leukemic infiltration and AIN. Renal failure resolved in a week with supportive measures. Blinatumomab was discontinued.

Discussion: Blinatumomab is a monoclonal antibody used for treatment of relapsed or refractory ALL in adults. It was felt that the most likely etiology of AIN was the recent introduction of Blinatumomab. In addition, ultrasound was concerning for hydronephrosis caused by ALL infiltration which may have contributed to his renal failure To our

knowledge, this is the first reported case of AIN secondary to Blinatumomab. Medications should be considered as a cause of unexplained renal failure.





PUB508

Rapidly Progressing Renal Failure: A Diagnostic Dilemma

Neelambuj Regmi,[1] Sulaiman J. Barkho,[3] Yadav Pandey,[5] Yahya M. Osman Malik,[4] Zeenat Y. Bhat.[2] *[1]Wayne State University/Detroit Medical Center, Detroit, MI; [2]Wayne State University, Detroit, MI; [3]Detroit Medical Center, St Clair Shores, MI; [4]Wayne State University Medical School, Detroit, MI; [5]University of arkansas for medical sciences, Little Rock, AR.*

Introduction: AKI though a common diagnosis can pose a diagnostic challenge especially so when it is rapidly progressing like our case

Case Description: A 52-year old lady with recent diagnoses of hypertension, new onset heart failure, cardiomyopathy preserved EF, pericardial effusion and AKI (Creatinine 2mg/dl; last Cr from 2012 – 0.9) presented with complains of generalized weakness and fatigue for a week. Her meds, all recently started were Atorvastatin, Carvedilol, aspirin and Furosemide. Pt denied fever, chills, sputum production, chest pain, orthopnea, palpitations or syncope. She has recent hospitalization with above problems, discharge Cr was 1.4mg/dl. Bone marrow biopsy had shown plasma cells <5% for diagnosis ?cardiac amyloid / pericardial effusion work up, On physical examination vital signs were unremarkable, She was lethargic but oriented to time, place and person. only positive finding was B/L crackles on lung bases and b/l lower extremity swelling. Abnormal Laboratory data : BUN 64mg/dl and creatinine of 2.02mg/l., Urinalysis showed 3+ blood and 2+ protein, Up/UC 0.8, Urine immunofixation revealed Bence Jones kappa protein. Ration of Kappa/Lambda- 1.99. Troponins 1.23, CPK 942 which downtrended. EKG showed T wave inversions in anterior leads. ECHO showed increased left ventricle thickness with ejection fraction of 65-70%. No regional wall motion abnormalities were noted, Moderate circumferential pericardial effusion is noted. CXR for opacity in left lower side of the lung. Renal Ultrasound showed no hydronephrosis with kidney sizes of 10.3 R and 11.1 cm L. Pt required dialysis and Kidney biopsy was done, it was consistent with myoglobin cast nephropathy- acute tubular injury with myoglobin laden casts. Immunoflorescence and electron microscopy identified small amounts of IgG, OgA, C3 and lambda light chain within the mesangium. No evidence of amyloid deposition were noted.

Discussion: In our patient, probable cause of rhabdomyolysis could be immobilization, infection (pneumonia) or the use of statin, hypokalemia(furosemide),. The CPK for the patient was not significantly increased but could have the on the recovering phase at the time of presentation to our hospital

PUB509

Bouquet of Flowers-Deep Inside the Great Pyramids - A Case of Medullary Sponge Kidney in the Elderly

Gabriela A. Ciofoaia,[1] Nkechi C. Mbaebie.[2] *[1]Berkshire Medical Center, Pittsfield, MA; [2]Berkshire medical center, Pittsfield, MA.*

Introduction: Medullary Sponge Kidney (MSK) is a congenital malformation characterized by dilatation of the collecting ducts of Bellini associated with defective urine acidification and concentration. MSK typically affects papillae in both kidneys. The usual clinical manifestations of hematuria, urinary tract infection and nephrolithiasis are delayed and emerge over a wide age range. 20% of patients with urolithiasis have MSK.

Case Description: 68 years old female admitted with worsening left thigh pain and left lower quadrant abdominal pain of 2 days duration. Past medical history significant for chronic UTIs and kidney stones for 10 years. Labs showed Cr of 1.78 (baseline of 1.2), Urinalysis revealed positive esterase with pyuria. CT showed bilateral renal stones in the calyces without obstruction and small calcifications compared to previous imaging. Bouquets of flowers pattern on CT was characteristic of MSK.Blood and urine cultures grew E. Coli. Patient was treated with targeted antibiotics. Kidney stone analysis revealed calcium phosphate. Potassium citrate was initiated. Creatinine continued to be above her baseline, however urine output remained normal. Despite all efforts, patient continued to have recurrent UTIs. On follow up visits patient reported less episodes of passing stones.

Discussion: MSK is usually asymptomatic. The diagnosis is commonly made as an incidental finding during an imaging test performed for a different indication. Although considered benign, the associated complications of medullary sponge kidney (nephrolithiasis and urinary tract infections) may rarely lead to chronic kidney disease and even renal failure. To identify patients at greatest risk for complications, a grading system based on the number of affected calyxes has been proposed. Our patient was grade 4 on this scale making her most susceptible to complications. CT pattern of MSK developed late in this index case which is uncommon and is described in only 10% of affected subjects. Our case illustrates few reported serious complications of advanced CKD in the setting of late diagnosis of MSK which if diagnosed early may have been salvaged with preventive measures such as use of Potassium Citrate. The concept of prophylactic potassium citrates in MSK remains controversial and further studies are encouraged. MSK should be considered in the differential diagnoses of recurrent UTIs in elderly.

PUB510

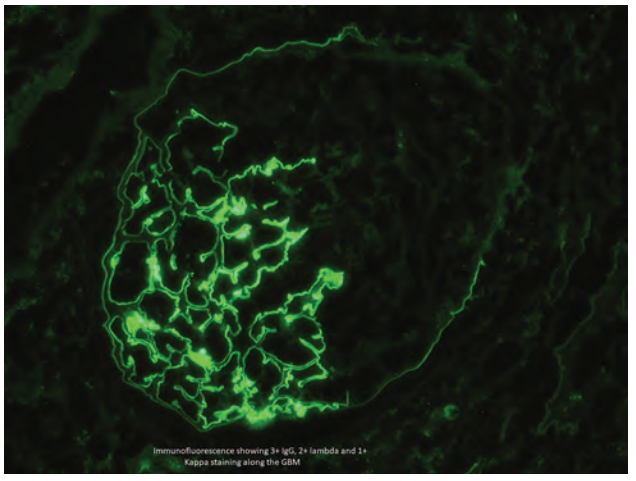
Anti-GBM Disease in the Elderly Patient: A Case Report

Emmanuel A. Adomako, Brittany Carter, Teena Zachariah, Deborah A. Fein. *Englewood Hospital and Medical Center, Englewood, NJ.*

Introduction: Anti-glomerular basement membrane (anti-GBM) disease is a known cause of rapidly progressive glomerulonephritis (RPGN) occurring in the third and seventh decade of life. As life expectancies continue to improve, there may be more cases of RPGN in the elderly. More robust data is needed to guide management in this population.

Case Description: An 81-year-old Caucasian female with history of hypertension and remote tobacco use presented with a two-week history of anorexia, malaise and cough. Home medications included daily atenolol 50 mg, hydrochlorothiazide 12.5mg, amlodipine 5mg and naproxen. Pertinent labs included creatinine 7.7mg/dl, 24-hour urine protein 850mg, urine negative for red or white blood cells, GBM antibody 1.9 AI, and anti-neutrophil cytoplasmic antibody (ANCA) positive with C-ANCA 1:40. She was started on hemodialysis for uremic symptoms and had a renal biopsy done. The biopsy was significant for predominantly acute focal necrotizing and diffuse crescentic glomerulonephritis, crescents in 50% of glomeruli, and minimal tubular changes, consistent with anti-GBM nephritis. She received a two-week course of plasmapheresis, pulse steroids and oral cyclophosphamide. Cyclophosphamide was discontinued after two and a half months due to agranulocytopenia and transient fever but she remains on prednisone taper. Anti-GBM and ANCA became negative after the initial two weeks of treatment with mild improvement of pre-dialysis creatinine but she remains dialysis dependent.

Discussion: Anti-GBM disease in the elderly patient offers a unique challenge due to limited data in this population. Dual-positivity of anti-GBM and ANCA are more likely to occur in the elderly population. Furthermore, elderly patients may be more susceptible to the adverse effects of treatment and this together with comorbidities may limit the duration and intensity of therapy. There is a need for further research to better serve the needs of elderly patients with anti-GBM disease.



PUB511

Metformin Associated Lactic Acidosis (MALA), In Elderly; Are The Prescribing Restrictions Adequate?

Maryyam Ali,[1] Jiwan K. Thapa.[2] [1]*U of MN Renal Division, Minneapolis, MN;* [2]*University of Minnesota, Minneapolis, MN.*

Introduction: Metformin associated Lactic acidosis (MALA), is rare but it has been associated with 40% mortality risk. It is usually related to elevated Metformin levels with overdose. Sustained release(SR) formulation theoretically has a lower risk of MALA, with lower plasma Metformin and lactate levels due to reduced systemic absorption. Our patient developed significant metabolic acidosis and elevated lactate with appropriate use of the drug per current FDA regulations.

Case Description: 78 year old male with a history of diabetes mellitus for >40yrs (on Metformin for 10yrs), heart failure with ejection fraction of 25% and chronic kidney disease with a creatinine of 1.1mg/dl and GFR 45-50ml/min, was admitted to the intensive care with generalized weakness and fall, hyperkalemia, high anion gap metabolic acidosis with elevated lactic acid. He had three admissions in the past three months with reversible serum creatinine (SCr) elevations secondary to CHF exacerbation, GI bleed and pre-renal state with low intake. Exam revealed frail elderly male with stable vitals. Labs showed increase in SCr to 1.7 mg/dl, bicarbonate 10 mmol/L, K 5.7 mmol/L, Anion gap 29mmol/L, sodium 142mmol/L Lactate level was high at 20mmol/L. No other sign of tissue hypo-perfusion and CT abdomen was negative for bowel ischemia. He had emergent hemodialysis for 4 hrs followed by high dose CVVHDF for 48 hrs for presumptive diagnosis of MALA, with improvement in bicarbonate and lactate level. Despite improvement in lab parameters, he developed progressive cardiogenic shock requiring iontropic support, and elected for comfort care. Subsequently, his Metformin level came back supra-therapeutic at 3.8mcg/ml.

Discussion: Recent updates on Metformin safety in CKD has expanded its use in low eGFR patients. Estimated GFR alone, however, may not capture the full risk especially in geriatric population with multiple co-morbidities. Sustained release Metformin compared to immediate release Metfomin, has similar glycemic control, but it is associated with lower systemic levels and thus lower lactate levels. Risk increases, in the presence of other factors like acute kidney injury, heart failure and old age, hence more care and vigilance is needed while prescribing Metformin to this population with multiple co-morbidities.

PUB512

No "Sugar-Coating": A Unique Case of Hyperinsulinemic Hypoglycemia with Renal Cell Carcinoma

Laila S. Lakhani,[1] Gonzalo Matzumura,[2] Huzair Ali.[3] [1]*UT Houston, Houston, TX;* [2]*University of Texas Health Science Center at Houston, Houston, TX;* [3]*University of Oklahoma, Macon, GA.*

Introduction: Hypoglycemia, as a manifestation of Renal Cell Carcinoma (RCC) is a rare event. Classically described as a paraneoplastic syndrome of non-islet cell tumor hypoglycemia, these patients have suppressed levels of glucose, insulin, proinsulin, C-peptide levels. Characteristically, they have elevated levels of insulin like growth factor (IGF)-2 and suppressed levels of IGF-1. We present a unique case of hypoglycemia from a paraneoplastic, non-islet cell insulin-producing RCC.

Case Description: A 92-year-old Hispanic woman with Chronic Kidney Disease IIIb, presented with recurrent episodes of altered mental status, found to have severe hypoglycemia, with a blood glucose of 37mg/dL on presentation. Her mentation improved with dextrose infusion and work-up for recurrent hypoglycemia was pursued. She denied history of diabetes and testing for inadvertent use of sulfonylureas or insulin was negative. Biochemical workup showed elevated levels of C-Peptide and insulin that was confirmed with repeat readings. In addition, IGF-1, IGF-2 and insulin Antibody were noted to be very low (Table 1). With the working diagnosis of hyperinsulinemic hypoglycemia, MRI abdomen was performed, showing normal pancreas anatomy, with an incidental finding of a 43x44x41mm heterogeneous enhancing right renal mass. Repeat CT abdomen with contrast confirmed the right renal mass with central necrosis and washout, consistent with radiologic features of renal cell carcinoma. Urology was consulted for surgical management, but given the patient's age and medical co-morbidities, nephrectomy was deferred. She was considered for ablation vs excision of the mass, however, her hypoglycemia responded to frequent oral intake, therefore these too were held off in the favor of conservative management.

Discussion: Hypoglycemia can be the initial presenting symptom in patients with renal cell carcinoma. This requires a thorough work-up to rule out other endocrine and medication related etiologies. While resection of the tumor generally resolves the hypoglycemia, the importance of identifying the underlying mechanism is crucial to provide adequate treatment of hypoglycemia in the acute setting while awaiting surgery or in non-surgical candidates like ours.

ANCA Vasculitis Masquerading as FSGS?

Anum Bilal,[1] Junaid Nasir,[1] Paul J. Der Mesropian,[2] Gulvahid G. Shaikh.[2] [1]*Albany Medical Center, Albany, NY;* [2]*Albany Stratton VA, Albany, NY.*

Introduction: We present the case of a 71 yr old man with renal-limited ANCA-associated vasculitis (AAV) with initial presentation of focal segmental glomerulosclerosis (FSGS) on renal biopsy.

Case Description: A 71 yr old non- diabetic white male was referred to renal clinic for evaluation of chronic kidney disease. On initial evaluation his serum Cr (SCr) was 2.2 mg/dl and he had chronic hematuria. Baseline SCr was 0.9-1 mg/dl. He denied NSAID use and had a 40 pack year smoking history. Spot urine albumin/Cr was 169 mg/g. Screens for HIV, Hepatitis B and C were negative. Serum and urine protein electrophoresis showed no para-proteins. C3, C4, ANA and dsDNA were normal. Renal biopsy was reported as Focal Segmental Glomerulosclerosis (FSGS), with some glomeruli showing increased mesangial matrix and 2 of 7 glomeruli being globally sclerosed. Focal mononuclear interstitial inflammation and mild tubulo-interstitial fibrosis were also noted. Patchy foot process effacement was seen on EM. 6 months later, SCr progressively rose to a peak of 5.7 mg/dl and urine alb/Cr increased to 973 mg/g. As the rapid loss of GFR did not correlate with the pathological findings of secondary FSGS, further serologic testing was performed revealing P-ANCA titer of 1:160 and MPO level of 30 AI. Cryoglobulins and anti-GBM were negative. He received IV steroids and underwent renal biopsy. Pathology confirmed pauci-immune glomerulonephritis with crescents in 2 glomeruli, endocapillary hypercellularity, more than 50% IFTA, and interstitial inflammation. He was treated with 4 weekly doses of Rituximab along with steroid taper. SCr eventually improved to 3.7 mg/dl.

Discussion: AAV often presents as a smoldering disease process. We believe that our patient had renal vasculitis masquerading as FSGS at the time of the first renal biopsy. It is possible that glomerular scarring and interstitial fibrosis observed then represented the healing process of active glomerular lesions. Persistent hematuria and the presence of a mononuclear interstitial infiltrate offered support for our theory. Interstitial nephritis has been previously reported to be an atypical histologic presentation of AAV. FSGS is an unlikely and under-reported presentation of AAV. Because AAV may have a relapsing/remitting course, it is possible that FSGS may be seen on pathology rather than typical findings of AAV.

PUB514

Polyclonal Crescentic Fibrillary GN Presenting with Macroscopic Hematuria

Yvelynne P. Kelly,[1] Veronica E. Klepeis,[2] Meghan E. Sise,[2] Sagar U. Nigwekar.[2] [1]*Nephrology, Massachusetts General Hospital, Boston, MA;* [2]*Massachusetts General Hospital, Boston, MA.*

Introduction: A 56 year old female presented with gross hematuria, symptomatic anemia and a serum creatinine of 6 mg/dl. She had a baseline serum creatinine of 2.0 mg/dl and was known to have microscopic hematuria and proteinuria but had never undergone a kidney biopsy. Her biopsy subsequently showed end-stage crescentic fibrillary glomerulonephritis. Given the chronicity of her disease, she was deemed unsuitable for immunosuppression and began work-up for renal replacement therapy. This case illustrates the importance of early diagnosis of glomerulonephritis in patients with chronic kidney disease and an active urinary sediment.

Case Description: A 56 year old obese Caucasian female with poorly controlled diabetes mellitus presented with gross hematuria and a serum creatinine of 6 mg/dl. She had a baseline serum creatinine of 2 mg/dl and had suffered from recurrent episodes of gross hematuria for many years. A urology work-up was negative. She had been given a presumptive diagnosis of IgA nephropathy. A serological work-up was completely negative. Urine protein:creatinine ratio was 8.76 g/g with a urine microalbumin:creatinine ratio of 4274 mg/g. A renal biopsy was performed showing end-stage crescentic GN with 15% cellular and fibrocellular crescents, 15% global glomerulosclerosis and 70% IFTA. IF was negative for IgA but positive for IgG, C3, kappa and lambda. Fibrillary glomerulonephritis was confirmed on electron microscopy. Given the equal kappa and lambda staining, investigations for monoclonal disease were not pursued. Similarly immunosuppression was not commenced given the chronicity of the patient's biopsy findings and clinical renal disease. She was prepared for progression to end-stage kidney disease and renal replacement therapy.

Discussion: This case illustrates the importance of early biopsy-based diagnosis for patients with progressive renal impairment and an active urinary sediment. It also highlights the differences in approach to patients with polyclonal fibrillary glomerulonephritis, compared to those with monoclonal glomerulonephritis for which a work-up for a clonal cell disorder should be pursued. The decision to commence immunosuppression for polyclonal fibrillary glomerulonephritis depends on disease duration as patients with advanced CKD have a poor renal prognosis and do not experience significant benefit from pursuing immunosuppressive therapy.

PUB515

Hydralazine Induced Antineutrophil Cytoplasmic Antibody-Associated Vasculitis with Acute Tubulointerstitial Nephritis: A Rare Constellation

Sandiya Bindroo,[1] Michael R. Lattanzio.[2] *[1]Internal Medicine, Crozer Chester Medical Center, Upland, PA; [2]Nephrology, Chester county Hospital, University of Pennsylvania, West Chester, PA.*

Introduction: Hydralazine is an adjunctive antihypertensive medication that is associated with antineutrophil cytoplasmic antibody (ANCA) - associated vasculitis. Kidney involvement usually comprises a pauci-immune, necrotizing glomerulonephritis with crescents.

Case Description: A 74-year-old Caucasian male on hydralazine, with a history of hypertension, presented with the acute onset of malaise and hematuria. On examination, lower extremity edema was noted. He remained hemodynamically stable. Lab work showed pancytopenia and elevation of serum creatinine (4mg/dl; normal range 0.6-1.1 mg/dl). Urinalysis showed proteinuria, dysmorphic red blood cells, and no red cell casts. Serology showed myeloperoxidase (MPO) positive high ANCA titers; positive anti-histone antibodies, positive cryoglobulins, and negative antinuclear antibodies. Renal biopsy revealed acute tubulo-interstitial nephritis (ATIN). Light microscopy examination revealed no segmental sclerosis, crescents, or areas of necrosis. Infectious work up, hepatitis B & C panel, was negative. Bone marrow biopsy was normal. Even though, he received a pulse dose of steroids and induction therapy with rituximab (375 mg/m2 IV q weekly doses) followed by oral prednisone 60mg daily, his hospital course got further complicated with hemoptysis. Subsequent lab work up revealed markedly elevated serum creatinine (5. 58 mg/dl), and persistent pancytopenia. CT scan of the chest revealed patchy areas of reticulation with ground glass opacities. Bronchoscopy exam revealed the presence of diffuse alveolar hemorrhage. He was started on renal replacement therapy for worsening kidney function. With two months of follow up, he remains on hemodialysis and on maintenance oral prednisone therapy.

Discussion: Hydralazine-induced ANCA vasculitis is a rare occurrence with pulmonary renal syndrome being the most severe presentation. Renal involvement is characterized by focal segmental crescentic and/or necrotizing glomerulonephritis. Mononuclear tubulointerstitial infiltrates have been noted in literature but these have usually been described in conjunction with glomerulitis which was not seen in this case. We report a case of hydralazine induced ANCA vasculitis with ATIN which is rare in the literature.

PUB516

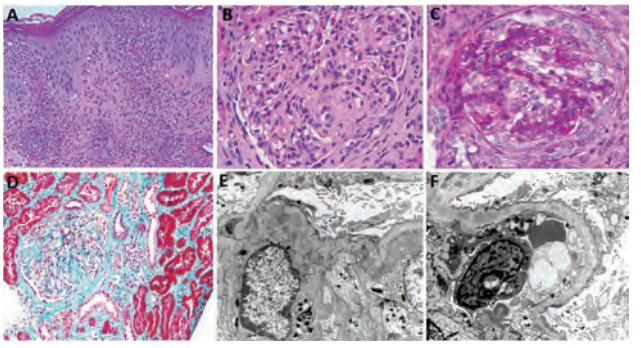
A Rare Case of Pyoderma Gangrenosum Masking Underlying Henoch-Schonlein Purpura

Jeremy Carlson,[1] Happy F. Sadiek,[1] Juan L. Chique,[1] Raafat F. Makary,[2] Leighton R. James.[1] *[1]UF Health, Jacksonville, FL; [2]Shands Hospital, UFL, Jacksonville, FL.*

Introduction: Henoch-Schonlein Purpura (HSP) is commonly diagnosed in childhood, however, it can occur in adults where the chances of renal involvement more than double. Here we introduce a unique case where an adult patient with Pyoderma Gangrenosum (PG) underwent further workup and was found to have uderlying HSP.

Case Description: A 21 year old, African American woman with history of hypothyroidism, idopathic heart failure, and recently diagnosed PG rash was admitted for heart failure exacerbation and nausea. Nephrology was consulted on admission for persistent hematuria, proteinuria, and AKI. Upon questioning, she had noticed pink to tea-colored urine and a lower extremity rash. Urinalysis showed protein (100mg/dl) and large blood. She underwent kidney biopsy for persistent, unexplained hematuria which showed focal proliferative and sclerosing glomerular changes with IgA deposits on immunoflourescence study, indicative of HSP. Skin biopsy of her rash showed leukocytoclastic vasculitis, seen in PG. She was treated with mycophenolate and steroids.

Discussion: When PG is diagnosed, 50% of patients have an underlying systemic disease. In this case, PG was diagnosed and clinical symptoms later on are what prompted a workup ultimately diagnosing HSP. Even though HSP is most commonly seen in children, when it occurs in adults renal dysfunction is more common, and consequently, this increases mortality. It is imperative that nephrologists and practicing hospitalists alike are able to keep a wide differential when they see nonspecific findings such as PG. Systemic vasculitides, such as HSP, should be kept in mind if patient's present with symptoms involving multiple organ systems in addition to the characteristic PG rash.



A. Skin biopsy with leukocytoclastic vasculitisB: HE stain showing increased mesangial matrix, cellularity in glomerulus

C: PAS stain suggestive of early crescent

D: Gomori Trichome stain showing global and segmental sclerosis

E&F: Electron microscopy consistent with proliferative immune mediated glomerulonephritis

PUB517

A Cool Case of Cryo

Paul M. Adams,[1] Taha Ayach.[2] University of Kentucky Nephrology *[1]Nephrology, University of Kentucky, Lexington, KY; [2]University of Kentucky, Lexington, KY.*

Introduction: Cryoglobulinemia is a rare but serious cause of vasculitis. Complement activation and inflammation can cause AKI with GN, rash, or alveolar hemorrhage. This case illustrates the recognition and treatment of systemic cryoglobulinemia vasculitis.

Case Description: A 66 year-old woman with history of DLBCL in remission presented with four weeks of lower extremity rash, abdominal pain, anemia, thrombocytopenia and AKI. Exam included palpable purpura over lower extremities, and abdominal tenderness. She was in no distress with unremarkable cardiopulmonary exam and normal vitals. Creatinine was 3.6 (baseline Cr 0.8), Hemoglobin 8.9, and platelets 129,000. UA was active: 6-10 WBCs, 1-3 RBCs, granular casts and mild proteinuria. Infectious workup with cultures, HIV, HVB, and HVC screens were negative. Peripheral smear did not support TTP or HUS. Evaluation with ANA, ANCA, MPO/PR3, anti-GBM were negative. Low C3 and C4 suggested immune complex formation. Steroids were started and a kidney biopsy was performed. After developing hypoxia, a CXR and CT chest were concerning for pulmonary hemorrhage. Bronchoscopy was planned for further evaluation, but was postponed due to hemoptysis requiring intubation. DAH prompted urgent plasmapheresis and Rituximab. Cryocrit returned positive at 1.5%, raising concern for cryoglobulinemic vasculitis. Kidney biopsy confirmed cryoglobulin MPGN, supporting systemic cryoglobulinemic vasculitis, likely a type II crogolbulinemia with unclear etiology. She improved with further plasmapheresis, rituximab and steroids, allowing complete recovery.

Discussion: This case illustrates systemic cryoglobulinemia vasculitis. Cryoglobulin GN manifests as MPGN with characteristic double contoured GBM "tram-tracking" due to membrane disruption and regeneration. "Cryo" immunoglobulins precipitate at low temperatures depositing in small vessels and leading to vasculitis. Causes include HCV, hematologic malignacy, endocarditis or other infalmmatory states. Cryoglobulins are classified as Type I monoclonal Ig, Type II polyclonal IgG monoclonal IgM (rheumatoid factor), or Type III polyclonal IgG polyclonal IgM. Type II or III related to chronic HCV or HBV are most common. Treatment of the underlying condition is paramount. Life or organ threatening cases are treated with steroids, plasmapheresis, and either cyclophosphamide or rituximab. Debate between cyclophosphamide and rituximab exists, but rituximab may be safer and as effective.

PUB518

An Unusual Case of Podocytopathy with Acute Renal Failure and Proximal Tubulopathy

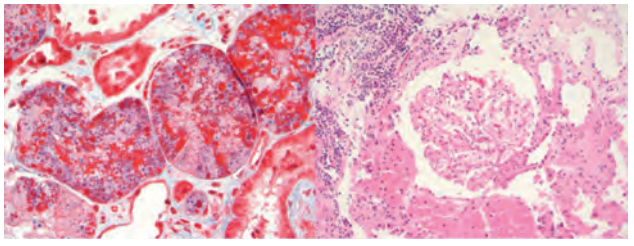
Jessamyn Carter, Narottam Regmi. *University of Oklahoma School of Community Medicine, Tulsa, OK.*

Introduction: Nephrotic syndrome (NS) in adults is most commonly secondary to diabetes, and when primary is predominantly focal segmental glomerulosclerosis. It is unusual for NS in adults to present with acute renal failure, but it has been reported in some cases of minimal change disease. The proposed cause is acute tubular necrosis (ATN) from proteinuria overwhelming proximal tubule reabsorption.

Case Description: 51 year old woman with history of stroke, hypertension, chronic kidney disease stage 3, intravenous drug use, and medical non-compliance presented for 1 day of flu-like illness. Flu testing was negative, and X-ray showed left lower lobe pneumonia. She also had acute kidney injury with creatinine 2.09 (baseline 1.2), oliguria, hematuria, and proteinuria (13.7g in 24 hours). She was diagnosed with ATN which did not respond to fluid, treatment of pneumonia, or later diuretic trial. Hematuria was mild and rapidly resolved, but proteinuria persisted. Renal biopsy showed proximal tubulopathy with accumulation of protein reabsorption droplets. This pattern of tubular injury is typically seen in light chain disease, but immunofluorescence showed no light chain disease. No light chain restriction was noted in our patient and serum protein electrophoresis and bone

marrow biopsy were unremarkable. Renal biopsy also showed 70% podocyte effacement without sclerosis. Hemoglobin A1c, ANA, ANCA, anti-GBM, hepatitis, HIV, and complement testing were normal. Underlying etiology of her NS remains unknown and she remains hemodialysis (HD) dependent.

Discussion: More than half of all NS in adults is secondary, and when presenting with renal failure it typically is transient. In our patient, an underlying cause is unknown and she remains anuric and HD dependent. Her tubulopathy is also unusual, as this degree of tubulopathy in NS is primarily reported in the pediatric population related to mitochondrial disorders and other rare genetic syndromes. Further attention to tubule injury in NS is needed to understand prognostic value and guide therapy.



Left: Proximal tubules with marked protein resorption droplets. Right: Benign light microscopy of glomerulus.

PUB519

Membranous Nephropathy Secondary to Systemic Sclerosis

Prakrati C. Acharya, Desiree Garcia Anton, Divya Monga. *University of Mississippi Medical Center, Ridgeland, MS.*

Introduction: Systemic sclerosis (SS) has rarely been described in literature as cause of membraneous nephropathy (MN). We hereby present a case of MN secondary to SS.

Case Description: 44 year old African American male with history of SS since2011 was referred to Nephrology clinic in 2016 for nephrotic syndrome and microscopic hematuria (spot urine protein creatinine ratio of 4, serum albumin of 2.9 g/dl, serum creatinine of 0.4 mg/dl and hyperlipidemia with anasarca). SS was manifested as interstitial lung disease, Raynaud's phenomenon, gastroesophageal reflux and hypertension. SS was initially treated with Penicillamine(from 2011 -2014) which was already stopped 2 years before presentation to our clinic. C3, C4, HIV, Hepatitis serology, dSDNA, SPEP, serum PLA2R were negative. Renal biopsy showed Membranous glomerulopathystage 3, with mesangial deposits, tubuloreticular inclusions within endothelial cells and 5-10% interstitial fibrosis. IgG subtype staining was nonspecific and capillary wall PLA2R staining was negative. Lisinopril was initiated butproteinuria continued to worsen, with maximum of 13 gram of urine protein per day in 24 hour urine collection, worsening skin thickening and interstitial lung disease. He was then started on mycophenolate mofetil 500 mg twice a day followed by marked improvement in nephrotic syndrome. As he was already off Penicillamine for 2 years before presentation and serology and other causes of secondary MN were ruled out, we postulate that his SSis the most likely cause of his nephrotic syndrome.

Discussion: Renal involvement is common in SSaffecting about 60-80% of patientswith scleroderma renal crisis being the most serious manifestation(5- 20% patients). 45-60% patients have mild proteinuria, elevated creatinine or hypertension and renal disease is generally not progressive. Most common reasons for impaired renal function are drug toxicity (D- Penicillamine, cyclosporine), prerenal causes (heart failure, pulmonary hypertension NSAIDs), and rarely glomerulonephritis (ANCA positive, secondary amyloidosis). The mean time to resolution of proteinuria after stopping d- penicillamine is 9-12 months and has been reported in some cases to be up to 2-3 years. MN secondary to SS has been reported as exceptionally rare with only few case reports in literature. We suggest including systemic sclerosis as a cause of secondary MN.

PUB520

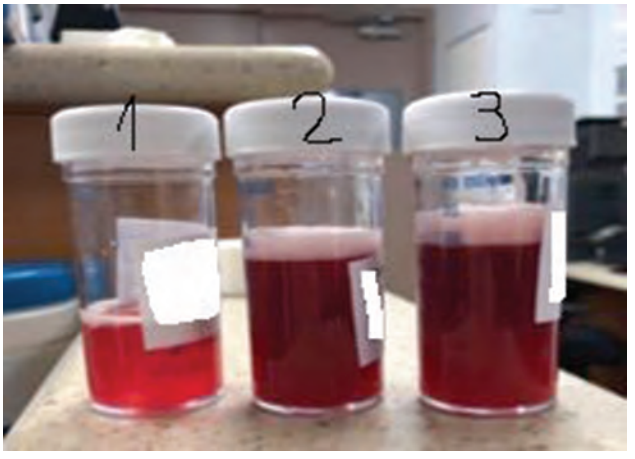
Diffuse Alveolar Hemorrhage in a Systemic Lupus Erythematosus Patient Treated with Rituximab

Joselyn Reyes Bahamonde, Nitzy N. Munoz casablanca, Nan Li. *Mount Sinai Beth Israel, New York, NY.*

Introduction: Diffuse alveolar hemorrhage (DAH) is a life threatening complication of systemic lupus erythematosus (SLE), it is an atypical manifestation of SLE associated with high rate mortality. Conventional therapy (cyclophosphamide, high-dose corticosteroids and plasma exchange) is recommended as therapy for DAH associated with SLE. Efficacy of alternative therapy such as Rituximab has also been described

Case Description: 36 year old woman with SLE membranous nephropathy, presented with acute onset of shortness of breath (SOB) and respiratory distress in the setting of increasing edema, elevated brain natriuretic peptide (BNP) to 10,000 and chest X-ray with bilateral opacities. Patient required non-invasive ventilation and started Furosemide for presumed fluid overload. Labs were significant for acute kidney injury (AKI) creatinine (Cr) 3.46 mg/dL, microhematuria, proteinuria, low C3 55 mg/dL, anti-ds-DNA 20 IU/mL. Despite aggressive diuresis, patient progressed to acute hypoxemic respiratory failure with acute respiratory distress syndrome (ARDS) requiring mechanical ventilation and renal replacement therapy (RRT). She underwent bronchoscopy which showed DAH. The overall clinical picture of AKI and DAH were consistent with acute lupus flare. Conventional therapy was delayed due to concern for active infection. Patient received two doses of Rituximab and did not require long term RRT, with creatinine of 1.4mg/dL a month later

Discussion: DAH is a catastrophic manifestation of SLE with a high mortality rate and treatment should be initiated as soon as the diagnosis is being established. Our patient received two doses of Rituximab with subsequent long term resolution of DAH and improvement of renal function. In summary, this case highlights the importance of early treatment to prevent fatal outcomes in DAH and also suggests that Rituximab might be a valid alternative therapy for DAH with SLE



Bronchoscopy specimen indicates DAH

PUB521

Case Report: Renal Failure Due to IgA Vasculitis with Massive Ascites Accompanied by Small Intestine Inflammation

Yoshitaka Shimizu,[1] Masafumi Ono,[2] Yumiko Suzuki,[3] Taro Misaki.[3] *[1]Seirei hamamatu general hospital, Hamamatu, Japan; [2]Seirei hamamatsu general hospital, Hamamatsu, Japan; [3]Seirei Hamamatsu General Hospital, Hamamatsu, Shizuoka, Japan.*

Introduction: IgA vasculitis with massive ascites accompanied by small intestine inflammation is very rare.

Case Description: A 26-year-old man with end-stage kidney disease and hypertension presented with headache that had persisted for one year. His visual acuity had decreased over a period of one year, and he visited an ophthalmologist. Physical and laboratory findings at that time revealed hypertension (200/114 mmHg) and end-stage renal failure (serum creatinine 8.06 mg/dL, urinary protein 4+, urinary occult blood 2+). He was admitted on an emergency basis and started on antihypertensive treatment. Anti-neutrophil cytoplasmic antibody, anti-glomerular basement membrane antibodies were negative. Serum complement (C3, C4) values and chest radiography findings were normal. A renal biopsy revealed that half of his glomeruli had global sclerosis. Crescents with endocapillary hypercellularity were found in most glomeruli and fibrilloid necrosis was evident in small arteries. Fluorescent antibody tests were impossible because of the sclerotic glomeruli. We diagnosed vasculitis of unknown cause and started him on treatment with methylprednisolone 500 mg/day for 3 days, followed by oral prednisolone 40 mg/day during seven days of hospitalization. Four days later, the patient complained of severe abdominal pain and abdominal CT revealed remarkable ascites retention and thickening of the small intestinal wall. Therefore, inflammation of the small intestine was diagnosed. Temporary ICU management was implemented and hemodialysis was started because his renal function had not improved. Steroid therapy improved the small intestinal inflammation, but he still needed maintenance dialysis. Renal biopsy specimens were reevaluated, and immunostained paraffin sections revealed IgA, C3-positive staining in the mesangial region, confirming a diagnosis of IgA vasculitis.

Discussion: Teaching Points: This patient had renal failure of unknown etiology complicated by small intestinal inflammation. To conclude a diagnosis was challenging, but IgA vasculitis was finally diagnosed by reassessment of a renal biopsy. Reviews of renal biopsies can be critically important to conclude a concrete diagnosis.

PUB522

An Unusual Case of Interstitial Nephritis in HIV/AIDS

Gurleen Kaur,[1] Birju R. Rao,[2] Koba A. Lomashvili.[1] *[1]Emory, Decatur, GA; [2]Emory University, Atlanta, GA.*

Introduction: Acute kidney injury (AKI) is a common occurrence in HIV-infected patients with most common etiologies including volume depletion, medication toxicity and acute tubular necrosis. We here describe an interesting case of granulomatous interstitial nephritis (GIN) in HIV/AIDS patient with disseminated mycobacterium avium complex (DMAC) infection.

Case Description: A 35-year-old female with history of HIV/AIDS (CD4 count of 14), DMAC infection (with recurrent positive blood cultures) and CMV retinitis presented for intravenous (IV) Foscarnet therapy. Her baseline creatinine was 1.3-1.4 mg/dL which increased to 3.0mg/dL on admission. Creatinine did not improve beyond 2.7mg/dl after 2 days of IV fluids. Urine studies showed trace leucocyte esterase. Spot urine revealed protein: creatinine ratio of 1.3g/g with microalbumin of 92mg, consistent with tubular

proteinuria. Hepatitis B surface antigen was positive with other serologies being negative. Renal ultrasound showed bilaterally increased renal echogenicity. Renal biopsy done on day 4 showed: interstitial, non-necrotizing granulomatous inflammation; moderate interstitial fibrosis/tubular atrophy, 1/20 glomeruli were sclerotic, non-sclerotic glomeruli were normal on light microscopy, and podocyte foot processes were effaced focally on electron microscopy. Given the patient had MAC bacteremia and MAC associated necrotizing mesenteric lymphadenopathy with chylous ascites, these granulomas most likely were induced by MAC infection. She completed 21 days of IV Foscarnet treatment. Her creatinine on discharge was 2.1mg/dL. We did not treat her with steroids, since benefit:risk ratio was not in favor of treatment. She was continued on MAC treatment with azithromycin 600 mg daily and dose adjusted ethambutol.

Discussion: GIN is an uncommon histological finding, representing ~0.5-1.37 % of native kidney biopsies. Most common etiology of this in developing nations is tuberculosis and fungal infections, however this may be easily overlooked as a cause of AKI in developed nations. GIN can be insidious and may go undetected for several years. Recognition and treatment of underlying cause can lead to improvement in some cases and renal biopsy is key to diagnose and to determine prognosis. Our case represents a complex case with various possible etiologies of AKI. In such a scenario a renal biopsy is imperative to help establish diagnosis and guide therapy.

PUB523

Renal Limited ANCA Vasculitis Can Be a Late Presentation in Patient with Rheumatoid Arthritis and Interstitial Lung Disease

Shehzad Ali,[1,2] Farhang Ebrahimi.[3] [1]*Richmond university med ctr, Staten Island, NY;* [2]*Medicine, NYMC-Metropolitan, NY,NY, NY;* [3]*Richmond university medical center, Staten Island, NY.*

Introduction: Renal limited mpo anca vasculitis has been rarely reported in patients with Rheumatoid Arthritis Here we present a case of a patient with not only Rheumatoid arthritis but also interstitial lung disease who developed renal limited mpo anca vasculitis glomerulonephritis Renal limited anca vasculitis carries significant morbidity, mortality if not diagnosed and treated promptly

Case Description: 60 year old white man a retired rescue firefighter at world trade center on 911 presented to ER with nausea, lack of appetite, heart burn, weight loss for a month His past history is significant for interstitial lung disease for many years and a diagnosis of Rheumatoid arthritis two years ago Patient was noted with low level anca by his rheumatologist for past year but was thought as bystander Renal sonogram was unremarkable and chest radiograph noted bilateral reticular markings from interstitial lung disease His lab studies reveal a blood urea nitrogen of 119mg/dl, serum creatinine 9.3mg/dl, urinanlysis with rbc casts, normal complement levels, negative hepatitis serology and antiglomerular basement membrane antibody MPO anca later came back high at 50.9u He was immediately started on pulse steroids a kidney biopsy revealed pauci immune crescentic glomerulonephritis. He was diagnosed with MPO Anca vasculitis glomerulonephritis and started on rituximab along with steroids. His symptoms improved, creatinine levels declined and patient went home on prednisine taper and maintenance rituximab infusion. His creatinine declined to 3.5mg/dl over next two months from a high of 9.3mg/dl

Discussion: Renal limited MPO-Anca vasculitis is uncommonly found with other immune mediated entities and creates diagnostic challenges. It can present in patients with rheumatoid arthritis who have disease for years with systemic symptoms Low level anca can also be present in patients with interstitial lung disease In this case patient had no systemic symptoms, had low anca titers noted for a year Anca titers and renal function should thus be closely monitored especially in patients with rheumatoid arthritis, interstitial lung disease without systemic symptoms as overlap can easily be overlooked and or mistaken with serious consequences Understanding of entities can help with early diagnosis, intervention and to avoid catastrophic outcomes as renal dysfunction and need for long term dialysis

PUB524

Cryoglobinemic Glomerulonephritis Post Streptococcal Pharyngitis

Sam Kant,[1] Avi Z. Rosenberg,[3] Derek M. Fine.[2] [1]*University of Maryland Medical Center, Baltimore, MD;* [2]*Johns Hopkins University School of Medicine, Baltimore, MD;* [3]*Johns Hopkins University, Baltimore, MD.*

Introduction: The most common inciting event of a post infectious glomerulonephritis (PIGN), from a historical standpoint and in developing countries, is streptococcal infection. Typically, PIGN presents as dominant C3 staining with frequent occurrence of subepithelial humps as well as subendothelial deposits. Diverse histological presentations of PIGN are being increasingly reported. We present a case of cryoglobinemic glomerulonephritis post streptococcal infection

Case Description: A 58 year old female, with a history of type 2 diabetes, presented with sore throat, fever and dysphagia for 2 days. She rapidly developed upper airway edema, and necessitated intubation. Subsequent nasopharyngeal cultures revealed presence of Streptococcus pyogenes and treated with Penicillin G. However, 2 weeks post admission, renal function was noted to be deranged with creatinine of 2.2 mg/dL (baseline 1.3 mg/dL), with presence of 3+ proteinuria (quantified to be 3g/g as per spot protein:creatinine ratio) and 33 RBCs/hpf on urinalysis. The creatinine increased by 1mg/dL each day (with peak at 6.2 mg/dL)-warranting initiation of methylprednisone, due to concerns of rapidly progressive glomerulonephritis. ANA, ANCA, anti-GBM, Hepatitis B/C and HIV were negative with elevated ASO titers (1057 IU/mL) and low C3 (33 mg/dL) and C4 levels (3 mg/dL). Subsequent renal biopsy revealed segmental endocapillary proliferation and occasional endocapillary leukocytes with segmental wire loop-type deposits on light microscopy. Immunoflurescence showed sparse granular peripheral mesangial staining for IgA, IgM, kappa and lambda light chains, C3 and C1q with casts stained 4+ for IgA, IgM, kappa and lambda light chains and protein resorption droplets stain 4+ for albumin. Electron microscopy showed subendothelial and mesangial electron dense deposit with no subepithelial deposits. Within 3 days of initiation of steroids, renal function showed evidence of rapid improvement.

Discussion: This case highlights that, albeit the history and clinical findings most likely point to a classic PIGN- the disease can have varied histologic presentations. Findings indicative of cryoglobinemic GN have been rarely reported and is a sequela to consider, especially in light of decreased C4 out of proportion to decrease in C3 levels and findings based on histology- making it imperative to pursue a renal biopsy if features akin to the aforementioned arise.

PUB525

A Bloody Cough and the Smoking Gun

Jiesu L. Sun, Akinwande A. Akinfolarin. *Baylor University Medical Center, Dallas, TX.*

Introduction: Goodpasture's Syndrome (GPS) is a rare autoimmune disease due to formation of antibodies targeting the glomerular basement membrane (GBM) in the lungs and kidneys. It is characterized by the presence of anti-GBM antibodies, life-threatening pulmonary hemorrhage and crescentic glomerulonephritis. Treatment of GPS should be initiated as soon as possible with a combination of steroids, plasmapheresis and cytotoxic agents.

Case Description: A 22-year-old breast-feeding female smoker presented to our facility with acute renal failure. She had been seen at an outside facility due to nausea, vomiting, shortness of breath and leg swelling. Preliminary evaluation revealed acute kidney injury. Laboratory data was positive for anti-GBM antibodies and a renal biopsy showed crescentic glomerulonephritis- however she absconded from medical care. She re-presented with worsening dyspnea at rest and oliguria. New laboratory data was notable for a serum creatinine of 10 mg/dL and elevated anti-GBM titers. She was initiated on daily plasma exchange, pulsed intravenous steroids, and rituximab with subsequent negative anti-GBM titers. However despite therapy, she developed hemoptysis and hypoxia necessitating ICU care. We thereafter started her on oral cyclophosphamide and re-instituted plasma exchange and pulsed steroid therapy which lead to the cessation of hemoptysis. Her kidney function did not improve and she remained dialysis dependent at discharge from our care. We discovered, she had returned to smoking cigarettes while hospitalized after we carefully re-interviewed her.

Discussion: Goodpasture's Syndrome has a low incidence with rates <1 per million. Lung involvement is more common in patients who are cigarette smokers and is theorized to be precipitated by denudation of the lung basement membrane. Inhaled smoke is thought to damage capillary endothelium allowing anti-GBM antibodies to reach alveolar basement membranes. The importance of smoking cessation is crucial to prevent life threatening alveolar bleeding and early institution of aggressive immune suppression will dramatically improve prognosis. There are no studies defining the appropriate therapy for GPS in women who are breast feeding due to its relative rarity- especially the appropriate dose of cyclophosphamide in this population. Given limited therapeutic options, it is imperative to develop a safe dosing regimen for cyclophosphamide in this population.

PUB526

Not an UTI! ANCA-Negative Pauci-Immune Crescentic Glomerulonephritis

Ivan Claudio-Gonzalez, Orlando Camacho, Luis Ortiz, Felix W. Perez. *Internal Medicine, Damas Hospital, Ponce, Puerto Rico.*

Introduction: Pauci-immune crescentic glomerulonephritis, so called due to lack of glomerular immunoglobulin deposition. Is one of the most common causes of rapidly progressive glomerulonephritis (RPGN). Approximately 90% of patients, pauci-immune crescentic glomerulonephritis is associated with ANCA, however 10% of patients with pauci-immune crescentic glomerulonephritis ANCAs are absent. Patients with ANCA-negative, pauci-immune RPGN are considered part of this spectrum, and may have similar clinical features, renal biopsy findings, and prognosis.

Case Description: A 21 year old Puerto-Rican female presents to emergency department complaining of fever. She was previously treated for a urinary tract infection with various antibiotics including sulfamethazole/timethroprim without resolution. Nephrology consultation was requested upon admission due to increased serum creatinine, associated with hematuria and proteinuria. Review of system was only positive for subjective fevers and general malaise. Exam and vital signs were unremarkable. Admission laboratories were remarkable for elevated WBC 12.30x10^3/uL, elevated ESR >140mm/hr, mild anemia with hemoglobin 11.1g/dL. Serum chemistries were remarkable for serum creatinin of 1.87mg/dL, low albumin 2.10g/dL. Analysis of urine revealed RBC 10-12/HPF, granular cast and urine PCR 6212mg/g and ACR 1723 mg/g. Serological workup including hepatitis panel, HIV, ANA, p-and c-ANCA, rheumatoid factor, complement levels were all normal. Given these finding kidney biopsy was performed, showing crescentic glomerulonephritis, involving 90% of viable glomeruli, with no immune deposits. Patient was treated with pulse steroids followed by rituximab 1gm once every 2 weeks for 2 doses and achived remision with improvement in serum creatinine to 1.1mg/dL, PCR 709mg/g and ACR 542 mg/g.

Discussion: We report a case of ANCA-negative vasculitis with cresentic glomerulonephritis, a relatively rare clinical entity that is only present in about 10% of pauci-immune vasculitis. Most patients present with non specific constitutional symptoms of fever and arthalgias. Treatment of this entity is derived from ANCA vasculitis, including non-specific cytotoxic agents. Crescentic glomerulonephritis must be diagnosed promptly so that appropriate treatment can be initiated given the high mortality risk. A better understanding of the pathophysiology is needed.

PUB527

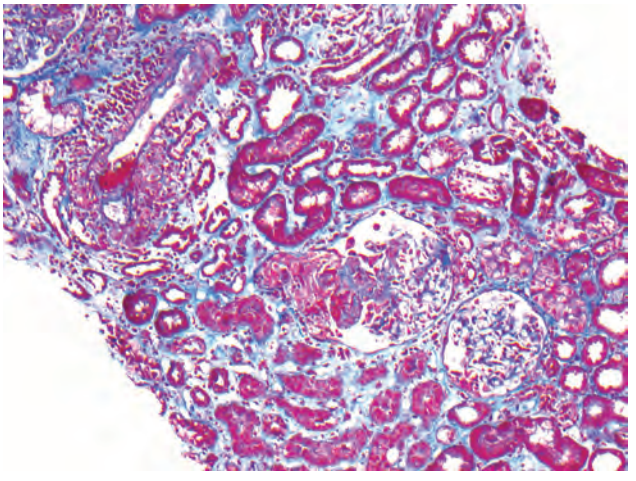
What's the Renal Reason for the Seizin'?

Romin Bonakdar,[1] Volker Nickeleit,[2] Gerald A. Hladik.[3] *[1]UNC Hospital, Durham, NC; [2]The University of North Carolina at Chapel Hill, Chapel Hill, NC; [3]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Introduction: ANCA disease is a well-appreciated cause of rapidly progressive glomerulonephritis (RPGN). It can also affect the nervous system, most commonly in the form of peripheral neuropathy, while central nervous system manifestations, including seizures, are exceedingly rare. We describe a case of new seizure in a previously healthy woman whose work-up led to a diagnosis of ANCA-associated RPGN prior to laboratory evidence of renal impairment.

Case Description: A 65 year old woman with hypothyroidism presented with generalized tonic-clonic seizure and was discharged on leviteracetam after an unremarkable brain MRI. One week later, she began to experience fevers prompting re-admission. Lumbar puncture was performed with unrevealing cerebrospinal fluid evaluation. Comprehensive vasculitis work-up including ANCA panel returned with a proteinase-3 titer of 123 u/mL (normally < 21 u/mL) in the setting of normal renal function (creatinine 0.76 mg/dL). Urinalysis revealed numerous dysmorphic red blood cells. Kidney biopsy showed a necrotizing glomerulonephritis with 40% crescents and red blood cell casts. She received intravenous high dose steroids and cyclophosphamide. Although the CNS manifestations of her ANCA vasculitis resolved, her creatinine at clinic follow-up increased to 2.77 mg/dL. She was then re-admitted for plasma exchange followed by a second dose of cyclophosphamide with improvement in creatinine to 1.8 mg/dL.

Discussion: Vasculitis should be included in the differential diagnosis of new onset seizures, especially when brain imaging is nonspecific. Importantly, lack of consideration of ANCA vasculitis as a potential cause of this patient's seizure, coupled with normal renal function at time of presentation, delayed the diagnosis and therapy of her renal disease. Recognition that CNS manifestations of ANCA vasculitis may clue to potential renal involvement prior to a rise in creatinine could have prompted earlier biopsy and treatment, potentially attenuating her renal injury.



PUB528

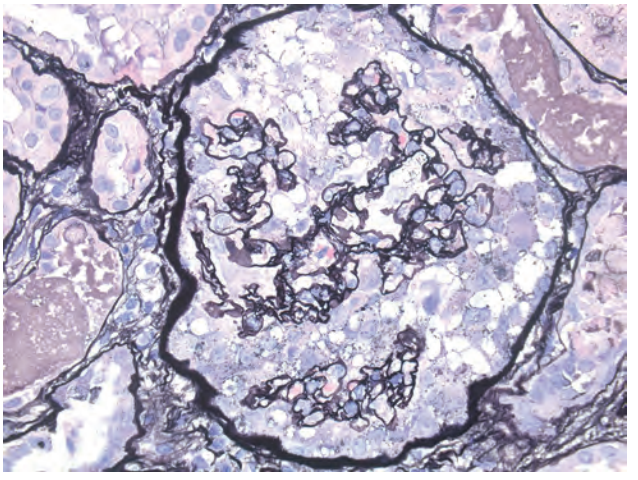
Case Report: Paraneoplastic FSGS Associated with Acute Lymphocytic Leukemia

Anushya Jeyabalan,[1] Abdallah Sassine Geara,[1] Jonathan J. Hogan,[1] Matthew Palmer.[2] *[1]Renal, Electrolyte and Hypertension Division, Hospital of the University of Pennsylvania, Philadelphia, PA; [2]Department of Pathology and Laboratory Medicine, Hospital of the University of Pennsylvania, Philadelphia, PA.*

Introduction: Paraneoplastic focal segmental glomerulosclerosis (FSGS) is rarely described in the literature. We report a patient who presented with nephrotic syndrome (NS) and FSGS on kidney biopsy during his initial presentation and recurrence of acute lymphocytic leukemia (ALL).

Case Description: An 11-year-old African American boy presented with NS (urine protein to creatinine ratio (UPCR) 9.7 g/g, serum albumin 2.1 g/dL) and normal renal function. He did not respond to empiric oral prednisone. Kidney biopsy revealed FSGS lesions and widespread podocyte foot process effacement. 6 months later, he developed leukopenia and was diagnosed with ALL. He was treated with Children's Oncology Group Protocol AALL0232 (cytarabine, vincristine, daunorubicin, dexamethasone, methotrexate, pegaspargase, cyclophosphamide, mercaptopurine, doxorubicin, thioguanine) and achieved complete remission of NS and ALL. At age 22, he developed NS again (UPCR 29.7 g/g) and acute kidney injury (serum creatinine(SCr) 14.7mg/dL) requiring hemodialysis (HD). Kidney biopsy showed collapsing FSGS lesions (Figure 1) and extensive podocyte foot process effacement. He also had leukopenia and was diagnosed with recurrent ALL (92% blast cells). He was treated with R-CVAD (rituximab, cyclophosphamide, vincristine, doxorubicin, dexamethasone) and intrathecal Methotrexate and Cytarabine. He was off HD within 9 days and at 7 months after kidney biopsy, SCr was 1.5 mg/dL and UPCR 7.6 g/g. He achieved complete remission of ALL after 3 weeks of chemotherapy and is on maintenance chemotherapy with 6-mercaptopurine, vincristine, methotrexate, and prednisone.

Discussion: We present a rare patient with NS and FSGS coincident with a diagnosis of ALL which occurred again on disease relapse. His kidney disease improved with chemotherapy in both instances.



Glomerulus demonstrating collapsing lesion, with collapsed capillary tuft and epithelial hypertrophy and hyperplasia (Jones silver stain, 400x)

PUB529

Decrypting the Dilemma of the Double Agent: Treating Pulmonary-Renal Syndrome Due to ANCA Vasculitis and Lupus

Antonio Gabriel D. Corona,[1] Akinwande A. Akinfolarin.[2] BigBallerBaylor *[1]Baylor University Medical Center, Dallas, TX; [2]Brigham And Womens Hospital, Mckinney, TX.*

Introduction: Anti-neutrophil cytoplasmic antibodies (ANCA) are a group of autoantibodies directed to cytoplasmic constituents of neutrophils and monocytes. Cytoplasmic ANCA is strongly associated with Granulomatosis with Polyangiitis (GPA) while perinuclear ANCA (p-ANCA) is strongly associated with Microscopic Polyangiitis and Renal-limited vasculitis. ANCA-associated vasculitides (AAV) present with pauci-immune rapidly progressive glomerulonephritis (RPGN). Very uncommonly, p-ANCA can be found co existing with other chronic inflammatory diseases, one of which is systemic lupus erythematosus (SLE). This presents a diagnostic and therapeutic dilemma.

Case Description: A 36 year-old Caucasian female presented to our institution with painless, gross hematuria. Laboratory data revealed a hematocrit of 25.2, D-dimer 17.1, platelets 186,000 and an elevated creatinine of 2.65. Her urinalysis showed numerous dysmorphic red blood cells and cellular casts. Her antinuclear antibody (ANA) was positive at a titer of 1:160 and elevated ANCA titers. She was started on pulse steroids and Mycophenolate Mofetil while awaiting for the results of a kidney biopsy. The biopsy report revealed diffuse, segmental proliferative and membranous lupus nephritis (type V) with moderate interstitial fibrosis (35%). She, however, suffered further deterioration in her kidney function which required the initiation of renal replacement therapy. In spite of immune suppression, she developed hemoptysis and then respiratory failure, chest tomographic imaging revealed patchy areas suspicious for pulmonary hemorrhage and bronchoscopy confirmed diffuse alveolar hemorrhage. Plasma exchange therapy was initiated concurrently with another course of pulsed steroids and cyclophosphamide. The patient responded well to therapy with subsequent recovery of kidney function.

Discussion: It is unclear whether patients that have lupus nephritis and positive ANCA antibodies have separate disease entities or whether it is a spectrum of an overlap syndrome. A high index of suspicion must exist for an overlap syndrome, especially if pulmonary symptoms occur in a "lupus syndrome", as the disease can be fulminant and life threatening without early diagnosis and aggressive plasma exchange and immune suppression therapy.

PUB530

Rituximab in a Young African American Female with Stage IV and V Lupus Nephritis: An Exceptional Response to an Unconventional Therapy

Ashton Ellison,[1] Renuka Chowdhury.[1,2] *[1]Methodist Dallas Medical Center, Dallas, TX; [2]Dallas Nephrology Associates, Dallas, TX.*

Introduction: Rituximab as a first-line treatment is an unusual, perhaps even wrong choice. Data supporting rituximab in patients resistant to both cyclophosphamide and mycophenolate (MMF) are limited. This case demonstrated its effectiveness in a patient who failed first-tier treatments.

Case Description: A 19-year-old female with a past medical history of SLE with lupus nephritis and G6PD deficiency is admitted to hospital due to worsening kidney function. She was diagnosed with lupus one year prior. Noted to have joint pain and poor kidney function with kidney biopsy confirming lupus nephritis, class IV, she developed worsening renal function while on MMF 500mg BID, hydroxychloroquine, and 30mg daily of steroids. Cyclophosphamide was initiated 1g/month for 5 months prior to current presentation. Kidney

biopsy performed 2 months prior to current admission showed class IV and class V lupus nephritis. She was admitted, started on methylprednisolone 1g/day, and rituximab, 600mg for two doses, one week apart. After completion of this treatment, she was discharged with anticoagulation (warfarin) given low albumin; 60mg of prednisone; pentamidine, while on steroids; and follow-up for contraceptive options. Creatinine improved after a further two doses of rituximab (see figure). She was continued on MMF from 12/20/18 until 3/29/18, when combination therapy with tacrolimus was initiated.

Discussion: This case demonstrates significant improvement in kidney function when treating lupus nephritis with rituximab, which is refractory to first-line treatments. Although initial studies of rituximab involved European populations, this case suggests generalizable, equal effects in African American populations. Additionally, while the use of combination therapy with MMF and tacrolimus is not a common practice, it was effective in this patient as a maintenance therapy.

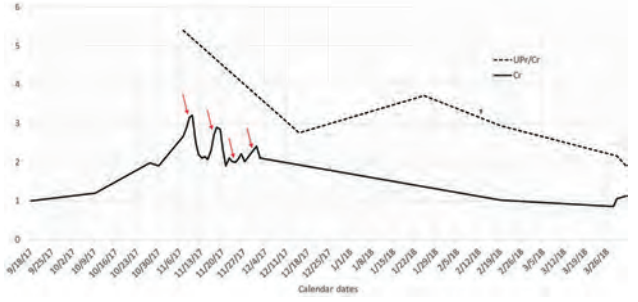


Figure: Kidney function before and after treatment with rituximab.Red arrow = rituximab administration; UPr/Cr = urine protein creatinine ratio; Cr = creatinine; † = 24-hour urine protein.

PUB531

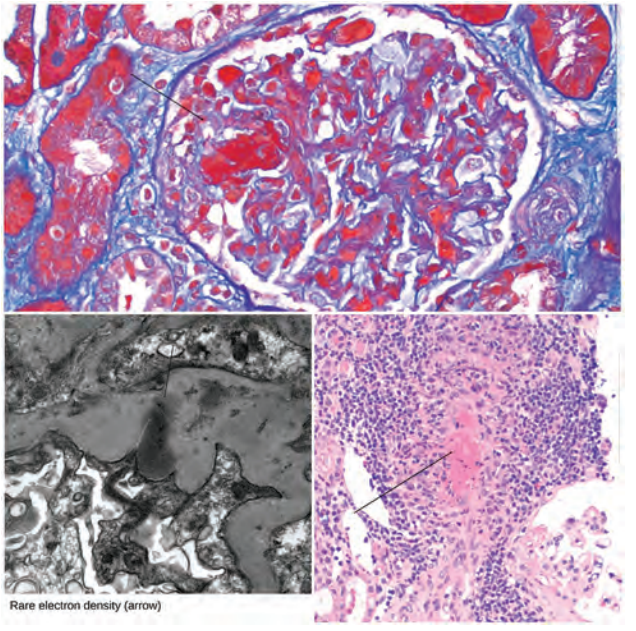
MPO-ANCA Positive Crescentic Glomerulonephritis in a Patient with History of Histoplasmosis

Sushma Edara, Madhu Kandarpa. *Kidney care specialists, Beavercreek, OH.*

Introduction: Immunosuppression increases risk of opportunistic infections. Here we present a patient with history of histoplasmosis requiring immunosuppresssive therapy for treating vasculitis

Case Description: 82-year-old female patient with remote history of histoplasmosis was evaluated for asymptomatic worsening proteinuria. She was diagnosed with polymyalgia rheumatica three years prior to this presentation when her temporal artery biopsy was negative. Patient was treated with prednisone which was discontinued after tapering over two years. Serologic testing revealed ANCA-MPO, rheumatoid factor was positive and remaining were negative. Kidney biopsy revealed crescentic necrotizing glomerulonephritis with features of vasculitis. Risks and benefits of immunosuppression were discussed with patient especially about the risk of reactivation of histoplasmosis Patient was initially treated with a Methylprednisolone and Cyclophosphamide. Her creatinine improved and proteinuria resolved with treatment. She was continued on low dose prednisone to prevent recurrence of vasculitis. There is no recurrence of histoplasmosis during treatment.

Discussion: The pathologic hallmark of ANCA-associated glomerulonephritis is a pauci-immune necrotizing crescentic glomerulonephritis. Acute lesions such as fibrinoid necrosis or glomerular crescent may completely disappear or reduce significantly after immunosuppressive therapy. Spontaneous remission is rare, and 80 to 90% of untreated patients progress to end-stage renal disease within 6 months. This patient responded to treatment with creatinine improving to near normal and no significant proteinuria. Immunosuppression poses an increased risk for disseminated and severe infection. This patient is being monitored for recurrence of histoplasmosis.



PUB532

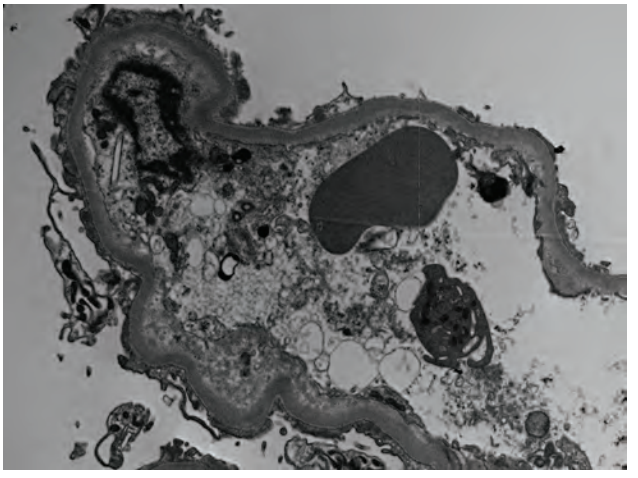
Nephrotic Syndrome in Hemophagocytic Lymphohistiocytosis

Agustin G. Velazquez perez. *LSU health shreveport, Shreveport, LA.*

Introduction: Hemophagocytic lymphohistiocytosis (HLH) occurs as a result of dysregulated activation of the immune system and is characterized by infiltration of organs by macrophages that phagocytose RBCs. HLH may be primary or secondary to malignancy, infection, autoimmune diseases. Renal involvement is uncommon, manifesting as ATN or nephrotic syndrome. We present a case of AKI and nephrotic syndrome in the setting of HLH secondary to HIV

Case Description: 33 yo M was transferred with 1 month history of fever, body aches, weight loss, generalized rash, lymphadenopathy and minimal edema. Initial laboratory workup was remarkable for pancytopenia, transaminitis and hyperferritinemia a creatinine 2.5mg/dl and 28gm of proteinuria. Urine analysis showed granular casts. Initial infectious workup including HIV testing was negative; no relief despite antibiotic therapy, lymph node biopsy showed reactive changes. Bone morrow biopsy, was diagnostic for HLH. Renal biopsy only 5 glomeruli were noted and was consistent with MCD or FSGS and acute tubular injury. He required hemodialysis due to worsening renal failure. On further evaluation, his CD4 count was 79/mm^3 and HIV testing for antibodies to p2 antigen was positive, leading to the suspicion that he was initially in the window period he was started on retroviral therapy, leading to enough renal recovery to get off dialysis.

Discussion: AKI with nephrotic syndrome in HLH is believed to be secondary to high pro-inflammatory cytokine levels leading to podocyte injury. ATN associated with collapsing glomerulopathy, minimal change disease or thrombotic microangiopathy are the histological features noted on biopsy and there is no macrophage infiltration of the kidney. If it occurs it is termed histiocytic glomerulopathy presenting as AKI alone. Collapsing glomerulopathy is noted in African Americans while MCD noted in Caucasians. With limited glomeruli on biopsy, collapsing glomerulopathy may have been missed. Management is supportive with treatment of the underlying etiology



PUB533

Lupus Nephritis in Patient with Co-existing SLE and HIV

Jeffy Kenny Thomas,[2] Jobira A. Woldemichael,[1] Furheen Baig,[3] Jason Cobb.[4] Emory University School of Medicine, Atlanta, GA,USA *[1]Emory university, Atlanta, GA; [2]Emory, Atlanta, GA; [3]Emory University, Atlanta, GA; [4]Emory University School of Medicine, Atlanta, GA.*

Introduction: Immune complex glomerulonephritis has been an increasingly reported phenomena in HIV patients with lupus-like feature but in the absence of histologic and clinical markers of systemic lupus erythromatous (SLE). Also, there are reports of patients with HIV developing autoimmune processes like SLE or a simultaneous diagnosis of HIV and SLE. This is a report of a rare clinical situation of a patient with long-term SLE being diagnosed with HIV and presenting with lupus nephritis.

Case Description: 40 years old black female with SLE for 30 years, and a newer diagnosis of HIV for 4 years. She presented for evaluation of increasing proteinuria (5.3 g/day), hematuria, and increased serum creatinine to 1.3 mg/dl. Patient had a normal CD4 count (1,143) and elevated HIV viral load (5.46 log value). The ds-DNA was elevated with low c3 and c4 levels. She was on an angiotensin coverting enzyme inhibitor, prednisone, plaquenil, and no HIV medications. Patient subsequently had a renal biopsy. The result showed immune complex glomerulonephritis compatible with membranous lupus nephritis (ISN/RPS Class V). The immunofluorescence staining was positive for IgG, IgA, IgM, c3, C1q (full house pattern). Also, she had focal global sclerosis in 31% and focal segmental glomerulosclerosis in 8% of the glomeruli. Interstitial fibrosis and tubular atrophy (IFTA), severe (90% and 80% respectively). The patient was started on mycophenolate mofetil. Unfortunately she had a fast progression of disease and started hemodialysis within 6 months.

Discussion: This is a rare case of a patient with long-term SLE that develops HIV. Some degree of HIV associated nephropathy cannot be excluded, the positive lupus serology and the presence of full house pattern of immunofluorescent staining supports the diagnosis of lupus nephritis. She wasn't on HIV treatment due to a high CD4 count but her HIV viral load was positive. Class V lupus nephritis has a good prognosis but her significant fibrosis and rapidly progressive disease course may have been related to her untreated HIV. Analysis of such individual case reports may lead to important insights into the pathogenic mechanism of both diseases along with solving the therapeutic dilemmas that will assist in the care of patients.

PUB534

Bilateral Facial Palsy as the First Manifestation in Granulomatosis with Polyangiitis (GPA)

Kashif A. Abad.[1,2] Y. Sun *[1]UNM, Albuquerque, NM; [2]NM VAHCS, Albuquerque, NM.*

Introduction: Granulomatosis with polyangiitis (GPA: formerly designated Wegener's granulomatosis) is a rare, autoimmune, multi system disease, first described by Friedrich Wegener in 1936. GPA is necrotizing granulomatous inflammation involving the upper and lower respiratory tract and necrotizing vasculitis affecting predominantly small to medium vessels. ANCA is present in >80 percent of patients with a peak age of presentation in the sixth decade of life. Renal disease, at presentation is seen in only 18% of patients; however develops with GPA progression. Bilateral facial paralysis as a primary manifestation of GPA is extremely rare.

Case Description: We present a 67 year old male with bilateral facial palsy, weight loss > 50 lb, dysphagia, anorexia, and depression. Initial extensive neurological evaluation was negative, except for the incidental finding of an abdominal aortic mural thrombosis. Creatinine (Cr) was 0.6 mg/dL. 3 months later he presented to our hospital with the same symptoms as well as increasing shortness of breath, malaise and foul smelling urine. He was diagnosed with acute renal failure and urinary sepsis. Pitting edema and an inability to close both eyes were noted. Cr ws 8.28 mg/dL. Urinalysis showed RBC's cast. ANCA (PR3+) and low C3, C4 were found (Anit GBM-). IV prednisone and cyclophosphamide were started. Head/Neck CT was unremarkable. A kidney biopsy was performed and confirmed the diagnosis of GPA and segmental necrotizing glomerulonephritis. There was mild improvement in renal function and marked improvement in facial palsy, but 2 months after, renal disease worsened and dialysis was initiated.

Discussion: The clinical manifestation of GPA is heterogeneous. The typical triad consists of the upper respiratory tract, lungs, and kidneys involvement. However, bilateral facial palsy as the first manifestation of GPA, like in this patient, is very rare and only a few cases have been reported in the literature. ANCA and PR3 revolutionized the diagnosis of GPA, since they allow early diagnosis. The specificity of positive ANCA testing in GPA is greater than 95%. In such cases, physicians play a crucial role in recognizing the early symptoms of the disease and starting the appropriate therapy to reduce mortality and morbidity.

PUB535

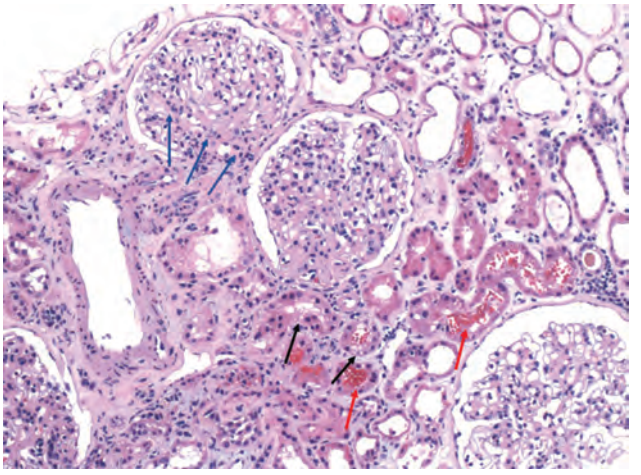
Methicillin-Sensitive Staphylococcus Aureus Bacteremia Associated with Normo-Complementemic, IgA-Predominant, Rapidly Progressive Glomerulonephritis - A Case Report

Abbas Raza,[1] Muhammad O. Hanif,[1] Sandeep Aggarwal,[2] Li Li,[2] Karthik M. Ranganna.[1] *[1]Drexel University, Philadelphia, PA; [2]Drexel University College of Medicine, Philadelphia, PA.*

Introduction: Infection associated with Rapidly Progressive Glomerulonephritis (RPGN) tends to be crescentic with hypocomplementemia or pauci-immune. IgA predominant, non-crescentic, post-infectious GN is rarely associated with clinical RPGN. We present a case of normo-complementemic, IgA predominant, non-crescentic, and steroid responsive, RPGN in a patient with Methicillin-sensitive Staphylococcus Aureus (MSSA) bacteremia.

Case Description: A 52-year-old male with past medical history of a chronic left foot wound infection, diabetes type II presented with fevers and found to have MSSA bacteremia. Creatinine on admission was 4.3 mg/dL whereas few months prior, creatinine was 0.6 mg/dL. The patient was started on antibiotics and fluids. In the next few days, creatinine remains above 4 mg/dL. Autoimmune serologies, viral hepatitis panel, and complements were within normal limits. Urine microscopy showed >50 red blood cells (RBC)/field, urine protein to creatinine ratio was 1.4 G/g. A renal biopsy performed for ongoing AKI showed : 1) Light microscopy - mesangial proliferation without endocapillary/extracapillary proliferation, bowman's space hemorrhage with several tubular RBC casts, mild acute, and chronic tubular injury (Figure 1). 2) Electron microscopy - mesangial electron dense deposits. 3) Immunofluorescence- IgA/C3 codominant 3+ staining. The patient was treated with intravenous and oral steroids with significant improvement of renal function.

Discussion: Definitive diagnosis of the cause of RPGN is required to determine the management course. Our case emphasizes the role of renal biopsy as the cornerstone in the diagnosis of RPGN as usual lab investigations may not reveal the diagnosis.



Kidney biopsy (light microscopy): Blue arrows indicating mesangial proliferation, black arrows indicating tubular injury and red arrows indicating tubular red blood cell casts.

PUB536

A Case of Light Chain Nephropathy

Faizan Syed. UNMC *University of Nebraska Medical Center, Omaha, NE.*

Introduction: The development of proteinuria and deterioration in renal function in a patient with diabetes mellitus and hypertension usually suggests diabetic nephropathy. However, other causes of renal failure should also be considered.Fibrillary glomerulonephritis (FGN) is among the newly recognized primary glomerular diseases. This rare cause of end-stage kidney disease has characteristic electron microscopic findings based upon the deposition of randomly distributed (10-22 nm) microfibrills in the mesangium and less frequently in the capillary basement membrane.Here we report a case of a 67 y/M with DM who was found to have IgG Kappa MGUS with FGN with dramatic improvement in his kidney function after the initiaion of chemotherapy.

Case Description: 67 years old male with type 2 diabetes mellitus since the age of 43 as well as photocoagulated retinopathy, hypertension, gout. He developed nephrotic syndrome. Serum creatinine level was 2.6 eGFR 28, urine protein excretion 6 gram and albumin 24 grams. Physical examination showed 2+ leg edema. His secondary workup for Nephrotic syndrome revealed elevated light chains IgG Kappa M-protein 0.32,Kappa Free light chains 338, Lambda Free light chains 34 and kappa Lambda ratio of 9.95. This prompted B/M biopsy revealing plasma cell dyscrasia(4%). Kidney biopsy confirmed diabetic glomerulosclerosi with superimposed fibrillary glomerulonephritis. The patient was treated with dual RAS blockers initially and then later after discussion with oncology he was started on bortezomib, cyclophosphamide and dexamethasone(CyBorD). After continuing 4 cycle treatment his Cr improved to 1.6 and PCR was decreased to 2.1

Discussion: FGN is a rare glomerular disease seen in 0.5–1% of native kidney biopsy. Clinical features at the time of kidney biopsy commonly include hypertension, proteinuria, hematuria, and varying degree of renal insufficiency. Serum creatinine could also be in normal range. Nephrotic syndrome, as in our patient, can be seen in one-third of the Diagnosis of FGN typically portends a poor prognosis, with approximately half of the patients progressing to end-stage kidney disease within a few years especially if asscoaite with DM. Unfortunately there is no established therapy specific for FGN, However, treating the underlying malignancy is assocaited with good outcomes. In our case we were able to achieve good response after starting the patient on CyBorD therapy for his plasma dyscrasia.

PUB537

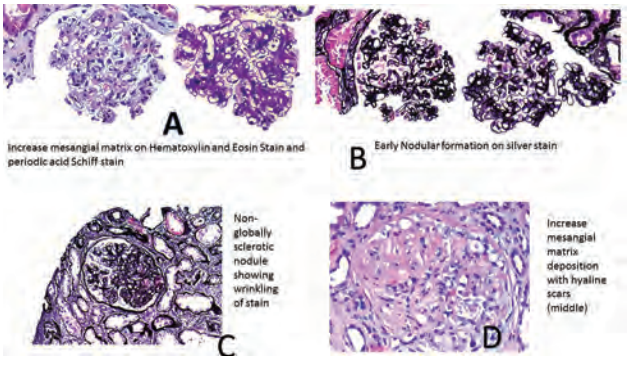
Nephrotic Range Proteinuria with Nodular Pattern on Biopsy in a Patient with No History of Diabetes

Hussain Aboud. *University of Florida, Gainesville, FL.*

Introduction: Kimmelstiel Wilson nodule had been described extensively in the literature as pathognomonic for patient with diabetes, however it had been also reported in patient who had amyloidosis, multiple myeloma and also reported in idiopathic nodular glomerulosclerosis when diabetes had been ruled out and other causes had been excluded.

Case Description: Herein; our patient is a 70-year-old white man with history of cerebrovascular accident, hypertension, chronic obstructive pulmonary was referred to us for evaluation of elevated creatinine that was 2 mg/dl which was 1.5 mg/dl six months prior, he does have proteinuria on his urinalysis 4 years prior, on his last 24 hour collection, he had nephrotic range proteinuria at 7.4 gm per day, he is a smoker with 54 years pack history and drink occasionally, he presented to us with blood pressure that was 135/63 on lisinopril and diltiazem with pulse of 66 and his BMI was 27. His complements level were normal limit, his hemoglobin A1C off any medication 5.5 -5.8 over the last 2 years, his hepatitis, HIV profile all came back to be negative. Kidney ultrasound showed signs of chronic kidney diseaes with no obstruction.

Discussion: Patient was diagnosed with idiopathic nodular nephrosclerosis on biopsy as shown on figures attached, his serum protein electrophoresis was within normal range, Congo red stain was negative and there had no immune complex deposition seen on his Immunofluorescence. Idiopathic nodular nephrosclerosis is a diagnosis of exclusion, it is seen more commonly in elderly; white males who are hypertensive and has strong correlation to smoking. Studies had showed that people who continued to smoke with idiopathic nodular glomerulosclerosis had higher risk of nephrotic syndrome, lower serum albumin and rapid progression to end stage renal disease. Neovascularization thought to play part in the pathogenesis of idiopathic nodular glomerulosclerosis. We also suggest establishing a pathology bank for future diagnosis and treatment for patients with idiopathic nodular glomerulsclerosis and reporting every case seen.



PUB538

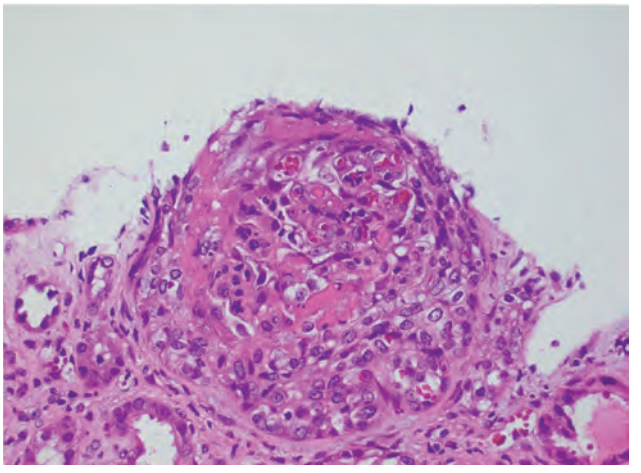
In Bad Company: Crescents and ANCA Are Bad News for Kidney Recovery in Lupus Nephritis

Alwin Lopez-Toro,[1] Roberto L. Collazo-Maldonado,[1,2] Lisa M. Sebastian.[1,2] *[1]Methodist Dallas Medical Center, Dallas, TX; [2]Dallas Nephrology Associates, Dallas, TX.*

Introduction: Lupus Nephritis (LN) classification highlights the importance of histopathological findings and kidney outcomes. Investigators have found a potential association between positive ANCA serology leading to poor outcome in Lupus GN. This is a case of lupus GN with an impressive biopsy and unexpected serology findings.

Case Description: 40 y/o Caucasian woman with a history of obesity and SLE presented to ER with generalized swelling. On exam, she was very hypertensive (210/120mmgh), with low grade fever (99.1F), sinus tachycardia and anasarca. Initial labs showed a Hgb 6.9 g/dL, Cr 5.4 mg/dL (baseline 1.0 mg/dL), BUN 45 mg/dL, and U/A with overt proteinuria (>300mg) and microscopic hematuria with RBC casts. She reported taking 2-3 ibuprofen daily for several weeks due to joint pain, but denied any other medications or toxic habits. Serology for ANA, anti-dsDNA, **ANCA (MPO&PR3)**, and ASO were **positive. Complements** were **normal.** Biopsy showed **45 of 48 glomerulus with hypercellular crescents** (some with fibrinoid necrosis [image]), full house pattern on IF, except for **negative C1q**. EM showed subendothelial and mesangial deposits. Findings were compatible with **Class IV diffuse lupus nephritis.** She started on dialysis in addition to high dose cyclophosphamide and steroids. She is currently on her third month of treatment with no signs of renal recovery.

Discussion: The amount of crescents in LN is crucial in establishing kidney prognosis. Studies have shown a correlation between the amount of crescents in LN with poor outcome and higher risk for relapse. Fibrinoid necrosis has also been associated with poor recovery. A positive ANCA may occur in about 20% of LN, specially in class IV. Although it suggests to be a bad association, there is not yet enough data available to support a correlation with poor prognosis. The chances of kidney recovery in this patient appear to be low as she remains on dialysis after 3 months of adequate treatment.



PUB539

AKI as the Initial Presentation of Burkitt Lymphoma

Usman A. Khan, Usman Z. Bhutta, Sardar H. Ijaz, Aemen S. Khakwani. *OUHSC, Oklahoma City, OK.*

Introduction: Burkitt's lymphoma is a highly aggressive B cell non-Hodgkin lymphoma characterized by the translocation and dysregulation of the *MYC* gene on chromosome 8. Renal involvement in non-Hodgkin's lymphoma is usually seen after the original disease has been diagnosed and has been reported as 30-50 percent at autopsy.The differential for acute kidney injury (AKI) in patients with underlying lymphoma includes tumor lysis syndrome (TLS), tumor infiltration, urate nephropathy etc.Diffuse bilateral kidney infiltration causing acute renal failure as an initial manifestation of NHL is very rare. We present a case of a patient (pt) who presented to an outpatient clinic for workup of AKI and was diagnosed to have lymphoma based on a renal biopsy.

Case Description: A 46 year old male with a PMH of SLE for 5 years presented to an outpatient clinic due to concern for AKI with creatinine (Cr) elevation from 0.8 mg/dL to 3.57 mg/dL over 8 weeks.A detailed history and physical exam did not reveal any etiology for his AKI. Further work up revealed mildly low complement levels and bilaterally enlarged kidneys with symmetric edematous appearance of the renal parenchyma. Renal biopsy was done to ascertain the etiology of AKI which showed high grade B cell lymphoma positive for BCL-6 and CD-10 (weak), while negative for BCL-2 and Ki-67 index greater than 90%.This warranted a PET scan which showed extensive hypermetabolic lymphadenopathy in the cervical, mediastinal, abdominal and pelvic region.The pt was started on chemotherapy, developed acute TLS with worsening of renal function, was started on CRRT later transitioned to IHD after 4 days.His urine output improved by the second week of chemotherapy, AKI resolved and he was able to come off of dialysis.A repeat kidney ultrasound showed decrease in his kidney sizes.

Discussion: Renal infiltration has been reported in 30% to 50% of the cases in autopsy of non-Hodgkin's lymphomas, but is clinically silent, with 0.9% to 23% of them developing renal insufficiency. Impairment of renal function due to tumor infiltration as the initial manifestation of lymphoma is very rare, with only a few cases reported in the literature. Prompt diagnosis and early institution of treatment is imperative, as it can partially or completely reverse AKI.Our patient was fortunate enough to have a complete response to chemotherapy with recovery of renal function to baseline.

PUB540

Anti-Neutrophil Cytoplasmic Antibody Associated Vasculitis and Crescentic Glomerulonephritis in Diffuse Systemic Sclerosis: Renal Failure Not Due to Scleroderma Renal Crisis

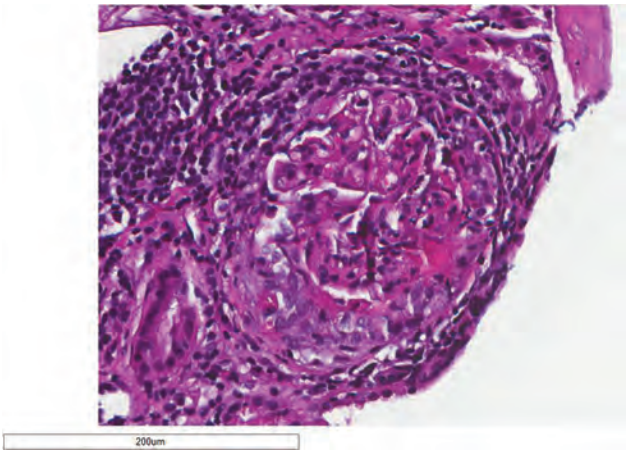
Azza Abdel Hak, Ummerubab Syeda, Rakesh Gulati. *Thomas Jefferson University Hospital, Philadelphia, PA.*

Introduction: Scleroderma renal crisis (SRC) is characterized by rapidly progressive renal failure with severe hypertension. Rarely, a small number of patients with systemic sclerosis develop anti-neutrophil cytoplasmic antibody (ANCA) associated glomerulonephritis and renal failure. These patients are usually normotensive. Differentiating between the two entities is important and can be challenging.

Case Description: A 57 year old female with history of diffuse systemic sclerosis, was admitted for evaluation of progressive renal failure, proteinuria and microscopic hematuria. Her blood pressure was 104/63 mm Hg on RAAS blockade. Creatinine level was 2 mg/dl, up from a baseline of 1 mg/dl, and her hemoglobin was 9.2 g/dl. Urine analysis was significant for +1 protein, +3 Blood and 93 red blood cells per high power field. Complement levels were normal. Anti-double stranded DNA and anti-RNA polymerase III antibodies were negative. Anti-Myeloperoxidase (MPO) antibodies were positive. Renal biopsy was consistent with necrotizing, crescentic glomerulonephritis (Figure 1). The patient was started on Rituximab and eventually discharged with plans for outpatient follow-up.

Discussion: Renal involvement in scleroderma is associated with high morbidity and mortality. Scleroderma renal crisis (SRC) is the most serious manifestation and usually presents with abrupt onset of moderate to severe hypertension and rapidly progressive renal dysfunction. The mainstay of treatment of SRC is prompt control of blood pressure in which

ACE inhibitors are the most effective. Rarely, as in our case, patients with scleroderma present with acute renal failure associated with ANCA related crescentic glomerulonephritis. This subset of patients are usually normotensive. Differentiating this from SRC is important as treatment usually involves immunosuppression with cyclophosphamide or rituximab and cautious use of steroids if necessary.



PUB541

Lupus Nephritis with Negative Antinuclear-Antigen-Antibodies

Jaime R. Jimenez Lopez, Samardia Missick, Ivan E. Porter. *Mayo Clinic Jacksonville, Jacksonville, FL.*

Introduction: Immune-complex-mediated membranoproliferative glomerulonephritis (MPGN) with "full house nephropathy" on kidney biopsy is well described on lupus nephritis. Antinuclear antigen (ANA) antibodies are one of the laboratory hallmarks, found in 99%, of patients with systemic lupus erythematosus (SLE). This case challenges the close to obligatory ANA positivity for diagnosing lupus nephritis, and represents a different presentation of an old condition.

Case Description: A 53 year-old Caucasian woman with history of chronic anemia presented with nephrotic range proteinuria, of 6307 mg in a 24 hour urine collection, and an estimated glomerular filtration rate (eGFR) of 87 mL/min. Physical exam was unremarkable, with no evidence of arthritis, skin or any organ system involvement, except for trace dependent edema. Urinalysis showed microscopic hematuria, with 20-40 RBCs per high power of field. Initial serological battery showed decreased C3 at 78 mg/dL (normal range: 90-180 mg/dL), normal C4, negative ANA, rheumatoid factor, HIV serology, hepatitis serologies, factor H, C3 nephritic factor and cryoglobulins. Additionally, workup for paraproteinemias resulted negative as well, and serum albumin was 2.9 g/dL. A kidney biopsy was obtained, showing MPGN type 3 pattern, with diffuse endocapillary GN plus segmental membranous features, and moderate interstitial fibrosis and tubular atrophy. Immunofluorescence was positive at 3+ for IgG and C1q, 2+ for C3, kappa and lambda, and 1+ for IgM, at mesangium, capillary loops and tubulointerstitium. Electron microscopy demonstrated glomerular basement duplication and severe foot process effacement, with no tubuloreticular inclusions. Lisinopril, sodium restriction and mycophenolate mofetil were used, with the latter stopped, due to lack of improvement, after 3 months of treatment. At 3 year follow-up, her eGFR continued to worsen to 27 mL/min, and proteinuria remained unchanged. ANA were consistently negative.

Discussion: ANA-negative cases of lupus nephritis, with no extra-renal involvement, pose a challenging condition to diagnose and treat. Possible explanations to this presentation includes alternative processes, or a different SLE related pathophysiologic mechanism of renal involvement. This case exemplifies the challenge lupus nephritis represents, and contributes to further discussion about new diagnostic and therapeutic options for this condition.

PUB542

A Unique Case of Bilateral Giant Cell Arteritis with Renal ANCA-Associated Vasculitis

Pace Romney,[3] Josephine Abraham,[2] Monica P. Revelo Penafiel,[2] Siddhartha Kakani,[1] Laith Al-Rabadi.[1] *[1]University of Utah hospital, Salt Lake, UT; [2]University of Utah, Salt Lake City, UT; [3]University of Utah Medical Center, Salt Lake City, UT.*

Introduction: Giant cell arteritis (GCA) is an autoimmune vasculitis characterized by infiltration of medium and large vessels by monocyte-derived giant cells leading to local and systemic inflammation. It is a panarteritis preferentially involving the extracranial branches of the carotid artery. Herein, we describe an extremely rare entity of biopsy-proven GCA and renal failure with a kidney biopsy consistent with pauci-immune necrotizing glomerulonephritis (GN).

Case Description: An 81-year-old man presented with weakness, jaw claudication, right temporal artery ache and tenderness, altered mentation, and elevated inflammatory markers. Bilateral temporal artery biopsy revealed active arteritis with transmural inflammation predominantly of mononuclear cells, and disruption of the internal elastic lamina consistent with vasculitis. There were no giant cells or granulomas. He had no vision loss, stroke, or extremity claudication. Imaging of the great vessels and large arteries was negative for vasculitis. He had proteinuria 0.5 g/g, hematuria without casts, and renal insufficiency (creatinine 1.3 from baseline of 0.9). He had a high titer of perinuclear antinuclear cytoplasmic antibodies (ANCA) and antibodies to myeloperoxidase (MPO). Renal biopsy revealed pauci-immune necrotizing GN. He was diagnosed with microscopic polyangiitis. The patient was started on prednisone and also given 2 doses of rituximab 2 weeks apart.

Discussion: Renal involvement with GCA is rare and, to our knowledge, only few cases have been reported of associated pauci-immune necrotizing GN. In contrast to small vessel vasculitides which can be linked to ANCA, large vessel vasculitides have no known associated antibodies. The patient in this case being MPO-ANCA positive with renal vasculitis and GCA represents an extremely rare clinical overlap between small, medium, and large vessel vasculitis. Histologic analysis is the standard for diagnosis; Absence of fibrinoid necrosis and involvement of vasa vasorum favors the diagnosis of GCA over ANCA-associated vasculitis (AAV). All patients diagnosed with GCA should have evaluation for possible associated renal disease. Doing so has important therapeutic implications as the presence of renal vasculitis requires the addition of another immunosuppressant such as rituximab.

PUB543

A Case of Proliferative Glomerulonephritis with Monoclonal IgG Deposits (PGNMID) Presenting with a Rare Pathological Feature

Kotoko Shinya, Akihiro Minakawa, Takashi Iwakiri, Ryuzoh Nishizono, Masao Kikuchi, Yuji Sato, Shouichi Fujimoto. *University of Miyazaki, Miyazaki, Japan.*

Introduction: PGNMID is a recent entity of glomerulonephritis caused by monoclonal IgG gammopathy. Diagnosis of PGNMID requires the presence of a single subclass of IgG heavy and light chains deposition by immunofluorescent study, granular deposits by electron microscopy (EM), and the absence of cryoglobulinemia. We report a patient with PGNMID who presented with a rare pathological feature.

Case Description: A 38-year-old woman was admitted to our department with a 7-month history of moderate proteinuria. A urinary test showed proteinuria of 1.2 g/day and no microscopic hematuria. A blood test showed the following: 0.63 mg/dL of creatinine, 5.98 g/dL of total protein, 3.54 g/dL of albumin, 68 mg/dL of C_3, and 25 mg/dL of C_4. Cryoglobulinemia was not detected. Renal biopsy showed the microscopic feature of membranous nephropathy (MN) with IgG deposition. We performed IgG subclass immunostaining and an EM study because a young adult woman presenting with idiopathic MN is uncommon. Additional immunofluorescence showed monoclonal IgG1-kappa monoclonality. EM showed granular deposits in subendothelial, subepithelial and intra-glomerular basement membranes. A bone marrow examination and serum and urine electrophoresis did not show evidence of underlying hematological disease. We diagnosed the patient with PGNMID and maintained with an angiotensin converting enzyme inhibitor. Her renal function and proteinuria did not worsen until the time of this report.

Discussion: A common pathological feature of PGNMID is MPGN like lesion with deposition of IgG3-kappa, while MN with IgG1-kappa is rare. PGNMID is rarely accompanied by underlying hematological disease, and thus its diagnosis may be difficult without suspicion. To avoid missing this disease, an aggressive immunofluorescence study to detect monoclonality should be performed, even in the case of non-proliferative GN. Mass spectrometric analysis of this case is in progress at the time of writing this report, and we will present the possibility of using this method as an alternative for detecting monoclonal IgG deposition.

PUB544

Hydralazine Induced ANCA Vasculitis - The Dark Side of Medication

Amal Qureshi,[1] Zahra Deen.[2] *[1]Ziauddin Medical College, Karachi, Pakistan; [2]Department of Nephrology, CHI St. Luke's Health - Baylor Medical Center, Houston, TX.*

Introduction: Kidney related side effects of Hydralazine.

Case Description: 82-year-old African American female with PMH of DLD, HTN, CKD III (baseline Cr 1.73 mg/dl) presented to the E.R with abdominal pain, diarrhea and decreased urine output for 2 weeks. On examination, she was lethargic but oriented, appeared anorexic and lungs clear to auscultation. Patient was hemodynamically stable. Her medications included statins, beta blocker and recently started hydralazine. Initial labs perfomed, as mentioned in the table. UA showed microscopic hematuria and proteinuria - prompting further workup as no improvement was seen with 24 hours of IVF. Secondary work up was performed as mentioned in table. These results were confusing for RPGN secondary to lupus nephritis vs ANCA vasculitis with our differential being hydralazine induced lupus with false positive ANCA. After further discussion kidney biopsy was pursued, which to our surprise showed crescentic glomerulonephritis, pauci-immune with moderate to severe interstitial fibrosis and marked arterial sclerosis. Complements were repeated and continued to remain low. Hydralazine was discontinued and the patient was started on Prednisone, Rituximab and initiated on dialysis.

Discussion: Hydralazine is FDA-approved for essential hypertension and recommended by the AHA for the treatment of CHF in African-Americans. The auto-immunogenic capability of hydralazine has been shown through its ability to induce lupus and vasculitis. Hydralazine-induced lupus differs from idiopathic lupus both clinically and serologically. Clinically it rarely involves the kidneys (only 5 %) or nervous system. Serologically while all patients are positive for ANA and can be positive for antihistone antibody, they do not have positive dsDNA or hypocomplementemia. The consideration for hydralazine-induced ANCA vasculitis should be higher for patients who are African-American, if they have positive MPO ANCA antibody at a high titer and positive ANA.

Antibodies to elastase and lactoferrin are also common in hydralazine-induced ANCA vasculitis and hypocomplementemia can be seen.

Crescentic Glomerulonephritis in Henoch-Schönlein Purpura with ANCA: A Therapeutic Dilemma

Rickinder Grewal, Bruce Goldman, Anirban Bose. *University of Rochester Medical Center, Rochester, NY.*

Introduction: The significance of immune complex staining in ANCA-associated glomerulonephritis (AAGN) is unclear and there are no established guidelines for treatment. We report a case of crescentic glomerulonephritis with strong IgA deposition and ANCA positivity.

Case Description: A 49-year-old male with a history of hypertension and rheumatoid arthritis presented to the hospital with a purpuric rash, nephrotic syndrome, and AKI with a very active urine sediment. Serology showed ANA 1:80, c-ANCA 1:640, and PR3 antibody of 180 U. Renal biopsy demonstrated diffuse active necrotizing crescentic glomerulonephritis with dominant IgA deposition (Figure 1). Skin biopsy showed leukocytoclastic vasculitis with focal IgA staining suggestive of Henoch-Schönlein Purpura. He was pulsed with high-dose steroids with plans for outpatient Rituximab (RTX) and cyclophosphamide (CYC) but was soon readmitted with pulmonary symptoms and worsening renal function. He was again treated with high-dose steroids and started on plasmapheresis and hemodialysis. He was then started on IV CYC 500 mg every 2 weeks and weekly IV RTX 375 mg/m^2 for a total of 4 doses every 6 months. However, the patient refused CYC after 2 doses due to concerns for toxicity. Although his PR3 antibody levels normalized on RTX, he has not shown signs of renal recovery and remains on peritoneal dialysis.

Discussion: Concurrent crescentic IgA nephropathy (IgAN) and AAGN is very rare. Our case illustrates the difficulty in treating such patients and the dilemma encountered in determining the predominant pathology. While CYC has been used to effectively treat both IgAN and AAGN individually, there is no data to support the use of RTX in crescentic IgAN. In such cases of concurrent crescentic IgAN and AAGN, primary therapy with CYC should be considered.

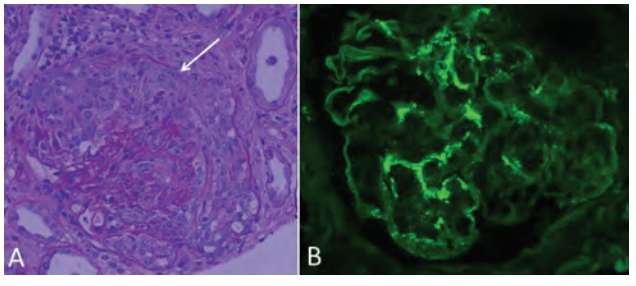

Figure 1: Renal biopsy with a fibrocellular crescent (arrow) on PAS stain (A) and dominant IgA deposition on immunofluorescence (B).

Cryoglobulinemic Vasculitis: Unusual Presentation of Multiple Myeloma

Cidcley N. Cabral,[1] Mirna D. Meira,[2] Ana Paula Gueiros,[1] Ericson C. Gouveia,[1] Augustus C. Freitas,[1] Luiz antonio M. Da fonte filho,[2] Moacir C. Netto,[3] Rafaela M. Gouveia,[3] Thayná R. Moraes,[3] Heliana M. Mello.[2] *[1]IMIP, RECIFE, Brazil; [2]IMIP, Recife, Brazil; [3]Imip, Recife, Brazil.*

Introduction: Type I cryoglobulins (CGs) are immunoglobulins that precipitate at low temperatures, causing inflammation and tissue damage. They are compounds of a monoclonal immunoglobulin, mainly IgG, and are associated with hematological malignancies. Around 10% of patients with multiple myeloma (MM) present detectable CGs, althoough few develop symptoms. We report the case of a patient with severe cryoglobulinemic vasculitis secondary to MM.

Case Description: This was a female patient, aged 42, with previous hypertension. During the previous four months, she experienced a strong, burning pain in the lower limbs, that developed into purpuric, necrotic lesions at the extremities. She presented a rapid deterioration of renal function, requiring dyalisis. She experienced a mild microscopic hematuria and, due to the risk of crescentic glomerulonephritis, was submitted to pulse therapy with methylprednisolone 1g/day for 3 days. Laboratory tests revealed: ANA, anti-SM, p-ANCA, c-ANCA, anti-HCV, HBsAg, VDRL, anti-HIV, antiphospholipid antibodies, all negative. Only the C3 was discreetly reduced. Hemoglobin 6.0 g/dL; platelets 149,000, with no schizocytes, DHL=696 U/L (125-220) with an ADAMTS-13 activity of 45%. She underwent a kidney biopsy, evolving with bleeding, which resulted in nephrectomy. The biopsy revealed areas of fibrinoid necrosis and intracapillary thrombi with focal granular deposits and in vessels of IgG, C3 and Kappa. CGs research was positive and serum protein electrophoresis revealed a monoclonal peak. The patient presented with pulmonary hemorrhage and a chest CT scan revealed bilateral ground-glass infiltrate. She received pulse treatment with cyclophosphamide and was subjected to plasmapheresis. A bone marrow biopsy and immunohistochemistry were compatible with MM. After a fresh episode of pulmonary hemorrhage, the patient died without receiving treatment for MM.

Discussion: Rarely reported, type I CGs associated with MM appear to worsen the prognosis, especially if diagnosis is delayed. This study emphasizes the need to investigate neoplasms, mainly hematologic, in the presence of cryoglobulinemic systemic vasculitis.

PUB547

A Case of Severe Diffuse Membranoproliferative Glomerulonephritis in Lupus Nephritis with Thrombotic Microangiopathy

Ujjala Kumar,[1] Kioumars Bolourian kashi,[2] Danuta Trzebinska.[2] *[1]UCSD, San Diego, CA; [2]UCSD Medical Center, San Diego, CA.*

Introduction: Renal involvement is common in patients with Systemic Lupus Erythematous (SLE). An abnormal urinalysis (proteinuria and/or hematuria) is present in up to 75% of patients with SLE. Elevated creatinine develops in ~ 30% and ~ 10% of patients with Lupus Nephritis (LN) develop End Stage Renal Disease (ESRD). Furthermore, Blacks and Hispanics have worse outcomes including death and ESRD.

Case Description: We present a case of a 41-year-old Hispanic male presenting with lower extremity edema, joint pain, high blood pressure and a skin rash. His medical history is noteworthy for SLE diagnosed seven years ago and class IV/V lupus nephritis diagnosed three years ago treated with an incomplete course of IV Cyclophosphamide due to severe infectious complications and was switched to Mycophenolic acid (MMF). He was on MMF 500mg twice a day prior to admission. Patient was in acute renal failure with serum creatinine of 4.0 mg/dL (baseline creatinine around 1.8 mg/dL). Complement levels C3 and C4 were extremely low at 19 mg/dL and < 2 mg/dL respectively. Urinalysis showed active urinary sediments. Urine protein to Cr ratio was 4.0. Repeat kidney biopsy revealed class IV diffuse membranoproliferative glomerulonephritis with focal crescents and thrombotic microangiopathy, moderate interstitial fibrosis and tubular atrophy ~ 30%. Patient was pulsed with Solumedrol for three days and dose for MMF was titrated up to 1.5 gms twice daily. Despite aggressive treatment his renal functions deteriorated leading to initiation of hemodialysis. A course of therapeutic plasmapheresis (TPE) was also initiated. Patient underwent a total of 6 every other day treatments consisting of one plasma volume exchange. He was also continued on intermittent hemodialysis for a total of 4 treatments, at which point his renal function recovered enough to get off the dialysis. Patient was discharged home on MMF, prednisone and plaquenil.

Discussion: In conclusion, our patient with severe proliferative LN with TMA had a favorable outcome from treatment regimen consisting of plasmapheresis and standard immunosuppression. Previous studies have demonstrated variable effectiveness of TPE in patients with lupus nephritis. Additional prospective studies are desired to consolidate the role of plasmapheresis in treatment of severe LN with renal TMA.

PUB548

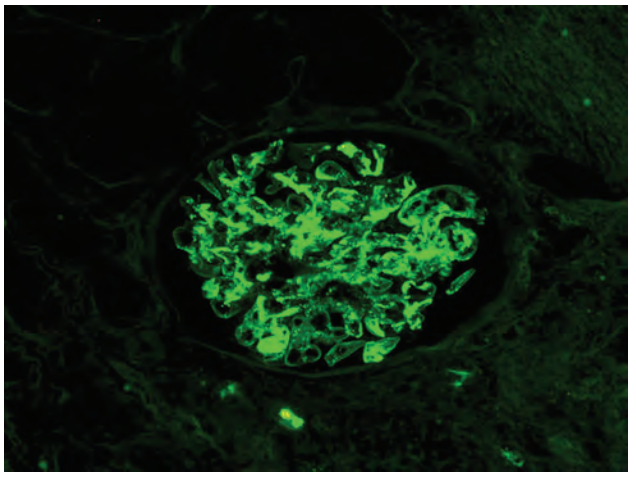
A Case of an Elderly Patient with IgA Vasculitis

Romela Petrosyan, Blake D. Shusterman. *Greenville Health System, Greenville, SC.*

Introduction: IgA vasculitis (Henoch-Schonlein) is primarily seen in children between the ages of 3 and 15 years of age with annual incidence of 15 cases/100,000 compared to 1.3 cases/100,000 per year in adults. HSP is only responsible for 0.6 to 2% of adult nephropathies.

Case Description: A 77-year-old Caucasian male was admitted with septic shock and acute renal failure secondary to duodenal diverticulitis and urinary tract infection. The patient had accompanying confusion, nausea, vomiting, diarrhea, epigastric abdominal tenderness, and decreased urinary output. Physical exam demonstrated palpable purpura on bilateral upper and lower extremities. He was hemodynamically stable and afebrile. Laboratory studies revealed a BUN of 106, Creatinine 6.14 (baseline 1), C3 60.0, C4 14 and normal platelets. Other serologies were negative. Urinalysis was significant for >182RBCs/hpf and protein/creatinine ratio of 0.45mg/dL. Skin biopsy revealed florid acute vasculitis involving small vessels with intramural and perivascular fibrin deposition. Renal biopsy revealed mesangial IgA dominant immune-complex deposits with focal endocapillary proliferation and exudation. The patient received pulse methylprednisolone and was transitioned to 60mg of prednisone with a prolonged taper. He initially improved with reduction of hematuria, proteinuria, and creatinine, but recurrence occurred during the steroid taper.

Discussion: IgA vasculitis prognostication in adults is not well characterized. Steroids shorten the duration of symptoms but do not affect the course of the disease. Glomerular IgA predominantly consists of galactose-deficient IgA1, which is specific to both IgA vasculitis with nephritis and IgA nephropathy, thus distinguishing them from other glomerular diseases. Though IgA vasculitis and IgA nephropathy are distinct clinical entities, they may share a common renal pathogenesis.



IgA immune-complex deposition on immunofluorescence

PUB549

HSP - Not Always Purpura

Sai K. Koyoda. *Monmouth Medical Center, Ocean, NJ.*

Introduction: Henoch-Schonlein Purpura (HSP), an IgA vasculitis seen in pediatric age group and rarely in adults, manifests as palpable purpura, diffuse abdominal pain, hematuria, arthritis, and in some cases even as bullous rash as seen in our case. It is important to differentiate HSP nephritis which is treated with immunosuppressants from its close proximity diagnosis Staphylococcus associated glomerulonephritis, which needs only antibiotics.

Case Description: This is a case of a 54-year-old female with uncontrolled diabetes mellitus. She was admitted for left foot cellulitis of the left great toe. Both the blood and wound cultured fast-growing staphylococcus aureus and was started on intravenous(IV) antibiotics. On the second day of admission, she developed bullous lesions over her bilateral foot. Succeeding, she complained of abdominal pain accompanied by diarrhea, followed by hematuria and generalized purpuric vasculitic rash. Subsequently, she developed oliguric acute renal failure. Skin and kidney biopsy performed were consistent with the diagnosis of staphylococcal IgA nephropathy/Henoch-Schonlein Purpura. She was started on 500mg methylprednisolone and maintained followed by daily prednisone and continued with IV ertapenem for 42 days. Her hospital course was complicated by paroxysmal atrial fibrillation, electrolyte abnormalities, volume overload leading to a requirement for chronic dialysis.

Discussion: HSP rarely manifests as bullous lesions in contrast to classic purpuric rash. In vasculitis, the blood vessels are already narrowed owing to on-going inflammation, and steroids, in turn, being procoagulant may not be the best drugs of choice. Few studies of similar cases being treated with cyclophosphamide(CYC) has shown better clinical outcome compared to steroids. CYC may be a better drug of choice in these vasculitic conditions, though more studies and further data are needed to change the guidelines.

PUB550

IgA Nephropathy Associated with Chronic Ulcerative Colitis: Clinical Case Report

Cynthia G. Cervantes, Veronica Valdivia cerda, Marisol Lopez, Jonathan Chavez, Guillermo Garcia-Garcia. *Hospital Civil De Guadalajara, University of Guadalajara, Zapopan, Mexico.*

Introduction: IgA nephropathy (IgAN) as an extraintestinal manifestation of inflammatory bowel disease (IBD) has a low incidence, during 12 years it has been reported in 24% of 83 patients of kidney biopsy specimens from patients with IBD and acute or chronic kidney failure or proteinuria.

Case Description: A 22-year-old male with CUCI not yet in remission. Maintains treatment with Prednisone 30mg and azathioprine 100mg daily. Ten years ago initiated mezalasin, prednisone and after 6 months suspended for lack of improvement. He also has diagnosis of lithiasis a year ago, and gross hematuria that occurred when running. Hematuria and proteinuria have been reported for 1 year, accompanied by elevation of creatinine and urea. On physical examination the vital signs were normal and he has Cushing appearance, on laboratory exams he has mild leukocytosis, Creatinine 1.3mg/dL, cholesterol 216mg/dL, Uric acid 5.19mg/dL, DHL 506 Ui, urine examn with proteinuria 100mg/dL, hematuria 7 ppf, in collected urine 800mg per 24 hours, ANAs and ANCAs and VIH, VHB, VHC were negative. A renal biopsy was performed that reports IgA nephropathy Oxford MEST-C: M1, S0, E1, T0, C0. Therefore, immunosuppression with Prednisone was increased and Enalapril was initiated, with reduction in creatinine to Cr 1.04 and proteinuria maintain en 860mg per 24 hours

Discussion: The association between IgA nephropathy and IBD is infrequent. A genetic connection has been reported between both diseases, the majority of the loci involved in the pathophysiology of IgAN are directly associated with the risk of IBD or the maintenance of the intestinal epithelial barrier with its response to mucosal pathogens. In addition, genetic linkage has been suggested due to the presence of HLA-DR1 in IgAN and HLA-DR1 / DQw5 in IBD. The reduction of chronic antigenic stimulation of IgA production and blood levels of nephrotoxic cytokines after the elimination of the source of chronic inflammation is the main objective of the treatment, so achieving remission of the disease would allow the improvement of the kidney damage, even when there are extensive sclerotic changes in the kidneys. The aggressive treatment of IBD can improve the manifestations of IgAN, it is important to bear in mind the correlation of glomerulonephritis as an extraintestinal manifestation of IBD.

PUB551

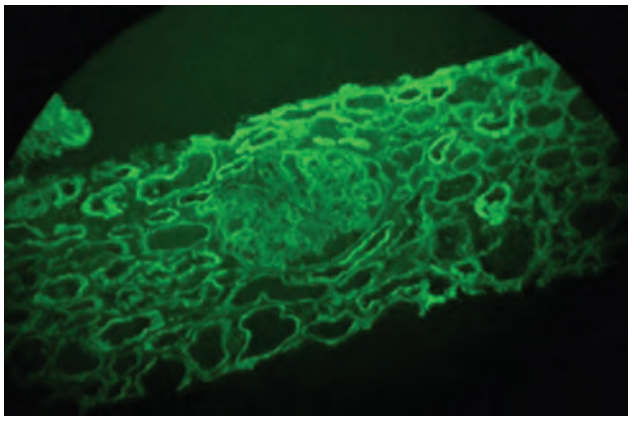
A Case of Severe Renal Impairment with Nephritic/Nephrotic Picture and MPGN Pattern of Injury in a Patient with Monoclonal Gammopathy

Abubakr Abdelaziz, Amanda D. Renaghan, Sana F. Khan, Itunu O. Owoyemi. University of Virginia, Department of Nephrology *University of Virginia, Charlottesville, VA.*

Introduction: In 2012, the term MGRS was introduced to describe patients who had MGUS with Renal dysfunction being the only systemic manifestation. The most recent diagnostic criteria for Multiple Myeloma require the presence >10% clonal Plasma cells in the Bone Marrow plus of one or more CRAB or Myeloma Defining Events. Here we present a patient with Multiple Myeloma whose only presentation was severe Renal impairement (requiring dialysis) with MPGN pattern of Injury on Kidney biopsy who responded well to Chemotherapy and came off Dialysis in about 4 weeks.

Case Description: This is a 64 yr old male with no significant medical Hx. He presented with Lower extremity edema and Hypertension. Wokup showed Nephrotic syndrome (24 hr Urine Protein: 15 g, S. Albumin 2.3, and Edema). Serologic tests were negative (HepC, HepB, HIV, ANA, ANCA, Anti GBM). C3 and C4 were both low. RRT was initiated soon after admission (Cr up to 7, baseline~1). Despite the absence of other CRAB features, SFLC, SPEP and UPEP were obtained. His Kappa/Lambda free light chain ration was 0.11 Kidney Biopsy: LM showed an MPGN pattern of injury, IF with linear Lambda staining and IgG3, EM with moderate effacement of foot the foot processes. Bone Marrow showed 40% clonal plasma cells.

Discussion: Despite the absence of the other classic CRAB criteria, Renal involvement in this patient was severe, with MPGN, Nephrotic/Nephritic picture and AKI requiring RRT. His response to Chemotherapy (CyBorD) was excellent, and he came off dialysis in about 4 weeks (Creatinine now~1.5). Screening for MGRS and Multiple Myeloma in patients with Renal disease is important, Chemotherapy should be initiated as appropriate, and many patients respond well to this approach.



LM, EM and Bone Marrow slides will also be included in the final presentation (not included here due to the size of the images).

PUB552

An Unusual Case of Glomerulonephritis (GN) with Prominent Glomerular Complement Deposition

Jessica M. Nelson,[1] Sergey V. Brodsky,[1] Brad H. Rovin.[2] *[1]Ohio State Wexner Medical Center, Columbus, OH; [2]Ohio State University Wexner Medical Center, Columbus, OH.*

Introduction: The presence of glomerular immune complexes (ICs) is critical to determining the correct diagnosis and treatment of GN with prominent complement C3 staining. Although ICs are usually easily shown by immunofluorescence (IF), sometimes this is more complicated.

Case Description: A young white woman developed acute congestive heart failure that was attributed to viral myocarditis. Within 9 months she recovered. She went wilderness hiking and two weeks later developed fever, arthralgias, proteinuria (2.2 g/d), and elevated serum creatinine (SCr) (1.64 mg/dL). Infectious evaluation was negative but she was treated with antibiotics and fever resolved. The kidney disease was felt to be infection-related GN, however it did not clear and 9 months after the febrile illness she had a kidney biopsy. The biopsy demonstrated moderate glomerulosclerosis and interstitial fibrosis on light microscopy, negative IF except for bright glomerular C3, and large subepithelial humps on electron microscopy. C3GN was considered, but no functional or genetic abnormalities of the alternative complement pathway were found. Proteinuria decreased to 0.2 g/d and SCr was stable so the patient was followed closely. Over the next 15 months proteinuria increased to 1.1 g/d. A kidney biopsy was identical to the first biopsy with persistent C3 on IF, subepithelial deposits, and only mild progression of interstitial fibrosis. Paraffin-embedded tissue was protease-digested and repeat IF showed kappa-restricted granular IgG deposits in the mesangium and GBM. Paraffin-embedded tissue was retrieved from her first biopsy, protease-digested, and it showed kappa-restricted IgG deposits. These findings led to a diagnosis of membranous-like glomerulopathy with masked IgG kappa deposits. No circulating or urinary paraproteins were found and bone-marrow biopsy is pending.

Discussion: The diagnosis of this patient's kidney disease rested on the discovery of immune deposits that were unmasked only after IF on protease-digested paraffin-embedded sections. In glomerular diseases with prominent complement deposition the presence or absence of immune complexes will affect treatment decisions. In the absence of staining on routine IF, protease digestion of paraffin tissue should be considered to exclude masked immune deposits.

PUB553

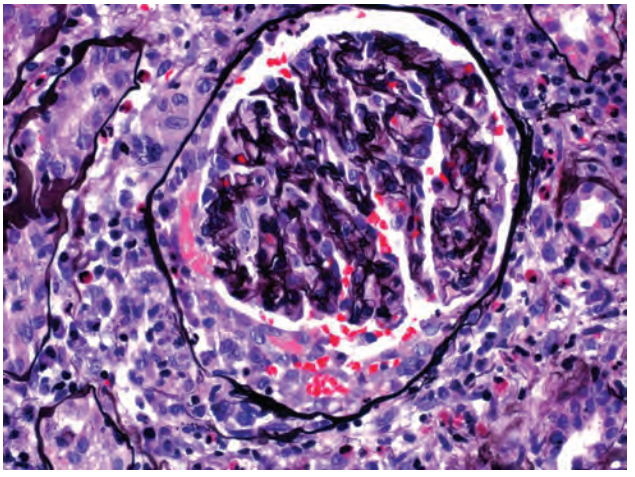
Doxycycline Induced ANCA Vasculitis Causing Crescentic Glomerulonephritis

Gina A. Routh,[1] Mark M. Belz,[2] Jennifer Thompson,[3] Anubha Mutneja.[2] *[1]Iowa Methodist Medical Center, Des Moines, IA; [2]Iowa Kidney Physicians, PC, Des Moines, IA; [3]MUSC, Ankeny, IA.*

Introduction: ANCA mediated vasculitis is characterized by the absence of immune complex deposition. Certain drugs may be implicated in development of ANCA mediated vasculitis and are associated with constitutional symptoms, arthralgias and cutaneous vasculitis. Rarely, crescentic glomerulonephritis and alveolar hemorrhage may also be present. We describe a rare case of doxycycline induced ANCA vasculitis causing pauci-immune crescentic glomerulonephritis.

Case Description: A 68 year-old female presented with fever and cough and was prescribed levofloxacin followed by moxifloxacin for an upper respiratory tract infection. She failed to respond to these antibiotics and was switched to oral doxycycline 100 mg twice daily. After initiation of doxycycline, she developed a lacy, reticular rash on bilateral lower extremities. Doxycycline was discontinued but she continued to have fevers, arthralgias and fatigue. Labs revealed acute kidney injury with a creatinine of 2.0 mg/dl. Urinalysis showed hematuria along with proteinuria 100+. Serological work-up showed positive c-ANCA (1:1024) along with low C4 (9 mg/dL). Her serum creatinine peaked at 4.39 mg/dL and renal biopsy was performed. Renal biopsy confirmed necrotizing and crescentic glomerulonephritis, pauci-immune type, along with necrotizing arteritis. Patient was initiated on pulse-dose steroids along with Rituximab 375 mg/m2 four weekly doses. Two weeks after the initiation of treatment, patient's renal function showed improvement with a serum creatinine of 2.87 mg/dL with complete resolution of constitutional symptoms.

Discussion: We describe an uncommon presentation of doxycycline causing ANCA vasculitis and leading to pauci-immune glomerulonephritis. In patients developing drug rash and constitutional symptoms with antibiotics like doxycycline, renal function should be assessed. Prompt diagnosis and timely initiation of immunosuppressive agents are essential to renal recovery.



Necrotizing Crescent

PUB554

Occurrence of Post-Infectious Crescentic Glomerulonephritis in a Patient with Small Lymphocytic Lymphoma

Tunde O. Omitogun, Marjan Afrouzian, Tina Kochar, Hania Kassem. *UTMB Galveston, Galveston, TX.*

Introduction: Chronic lymphocytic leukemia/ Small Lymphocytic Lymphoma (CLL/SLL) is the most common non-Hodgkin lymphoma associated with glomerular disease but there are only 8 cases of crescentic glomerulonephritis (cGN) associated with CLL/SLL. We are reporting a patient with history of CLL/SLL presenting with acute kidney injury (AKI) and in whom the renal biopsy revealed a crescentic Post Infectious GN (PIGN) with concurrent interstitial infiltration of malignant lymphoid cells. To our knowledge, no such case has been reported in the literature.

Case Description: A 59 y/o diabetic male with history of CLL/SLL, hypertension, seizures, recurrent DVT/PE and CKD was admitted for work up and management of AKI. His only complaint was chronic lower extremity (LE) swelling. His physical exam was remarkable for a BP of 157/106, jugular venous distention, severe pitting edema in the LE's, and a right thigh abscess. Initial labs showed a WBC of 9.9 with 53.7% lymphocytes, Creatinine of 4.10mg/dl, and 24hr urine protein of 8g. Serology for Hepatitis B, C, HIV and ANCA was negative. Complements were normal. He received antibiotics and the abscess was drained. Renal function improved and patient was discharged to follow up with his hematologist. The renal biopsy revealed crescents in 7/20 glomeruli, endocapillary proliferation and rare double contours superimposed on diabetic glomerulosclerosis. A dense interstitial infiltration of neoplastic lymphocytes staining positively for CD20, CD23, CD43 and CD5 was also present. By immunofluorescence microscopy, C3 was deposited along the capillaries. By electron microscopy, a large subepithelial hump was identified. Therefore, the patient was diagnosed with crescentic PIGN with associated interstitial infiltration of SLL.

Discussion: All SLL-associated cGN cases were reported as pauci-immune GN, with one case showing infiltration of neoplastic lymphoid cells within the interstitium. The combination of endocapillary proliferation, glomerular crescents, C3 deposition and a single subepithelial hump characterizes our case as PIGN. Compared to Pauci-immune GN, PIGN is an occurrence not previously reported in this setting, dictating a completely different patient management.

PUB555

Hemoptysis, Renal Failure, and Positive C-ANCA: Is It Truly Wegener's?

Sanjay Kumar,[2] Anmol Baranwal,[1] Christine joy Junia.[3] *[1]MacNeal Hospital, Berwyn, IL; [2]Macneal Hospital, Berwyn, IL; [3]Loyola-MacNeal, Berwyn, IL.*

Introduction: Goodpasture syndrome (GPS) is characterized by diffuse alveolar hemorrhage, rapidly progressive glomerulonephritis and positive anti-glomerular basement (Anti-GBM) antibody. Treatment initiation is invariably based on a positive Anti-GBM antibody. We present a case of anti-GBM negative, C-ANCA positive GPS.

Case Description: A 66 year-old male with history of hypertension presented with intermittent hemoptysis for three months and one week of hematuria, fever and chills. On admission he was normotensive and with otherwise normal physical exam. Laboratory abnormalities included: BUN 119mg/dL, creatinine 14.43mg/dL, potassium 3.3mmol/L, hemoglobin 8.4g/dL, ESR 66 and C-reactive protein 3.5mg/dL. CT chest, abdomen and pelvis showed scattered areas of opacities throughout the lungs bilaterally. Urine

microscopy showed RBC casts and 50-100 RBCs/HPF. Work-up revealed an elevated ANA, and negative anti-RNP, scl-70, anti-SM, anti-SSA, anti-LA, and anti-dsDNA. C3 and C4 levels were normal. Patient had a rapid clinical deterioration with increased hypoxemia and worsening hemoptysis. Methylprednisolone was started for suspected Wegener's granulomatosis. Additional tests revealed a positive c-ANCA with a titer of1:320 and negative anti-GBM antibody. Patient had cardiac arrest and expired. Lung autopsy revealed red epithelization and hemorrhage. Histologically, there was minimal necrosis of the alveoli which is expected of Wegener's granulomatosis. The kidneys showed intra-tubular hemorrhage but no crescents or active glomerulonephritis were seen, instead intra-alveolar hemorrhage with organization in the alveolar space was found suggestive of early GPS.

Discussion: GPS is characterized by presence of autoantibodies against α3 chain of type 4 collagen found in alveolar and glomerular basement membrane. Antibody detection rate by ELISA has a false negative rate < 5%. It is important to note that 15%-30% of patients with GPS have positive antinuclear cytoplasmic antibody (ANCA), 3/4th of those cases being C-ANCA. Proper management includes plasmapheresis and immunosuppressive therapy. It is important to differentiate ANCA associated vasculitis from GPS. Serologic testing is the fastest method of diagnosing GPS but carries limitations. Renal biopsy, although gold standard, is difficult to perform in critically ill patients making decision making for timely management challenging for physicians.

PUB556

A Paradox: MPGN After the Treatment of Hepatitis C

Leena Pathikonda, Renuka Chowdhury. *Methodist Dallas Medical Center, Dallas, TX.*

Introduction: Membranoproliferative glomerulonephritis is caused by two main mechanisms: immune complex deposition leading to activation of complement and persistent activation of alternate complement pathway. This dysregulation causes a thickened glomerular basement membrane and increased mesangial and capillary cellularity. MPGN is challenging to treat especially when the underlying cause is unknown.

Case Description: A 66-year-old Asian man with history of hepatitis C cirrhosis presented to the emergency room with increased abdominal distention and lower extremity edema for the past month. On physical exam he had large ascites and 2+ bilateral lower extremity pitting edema. His creatinine was 1.25, but urinalysis revealed >600 protein. Renal ultrasound showed normal kidneys, but there was 13 grams of proteinuria on 24-hour urine collection. Patient's hepatitis C was diagnosed two years ago, and he was treated with Ribavirin and Epclusa with cure. HCV RNA PCR during this admission was undetectable. Serologic work up included HIV, RPR, ANCA panel, RF, complements, free light chains, cryoglobulins, and anti-PLA2R antibody. Kidney biopsy showed MPGN in the setting of sustained viral response from hepatitis C, with no evidence of chronicity or ATN. IF was consistent with immune complex mediated MPGN and EM was consistent with subendothelial deposits. It was positive for IgG, IgA, IgM, C3c, C1q, kappa and lambda. Serologic work-up was normal, serum C3 and C4 were both low and cryoglobulins were negative. He was treated with IV induction steroids and then transitioned to oral prednisone. Repeat 24 hour urine protein was 6.5 grams which improved from 13 grams on admission. Since patient had partial response to steroids, Rituximab was started. Anasarca improved with improving proteinuria and diuresis.

Discussion: MPGN has a variety of causes including infections, autoimmune disease, and monoclonal gammopathies. The IF microscopy showed a "full house" picture with properties of both complement mediated, and immune complex mediated MPGN. This is typically seen in autoimmune disorders, although autoimmune work up was negative. Though HCV has been associated with MPGN, currently there is sparse literature about MPGN in patients after successful treatment of HCV. Thus, this patient with treated HCV most likely developed primary MPGN.

PUB557

Renal-Limited Vasculitis with Unique ANCA Serology: A Great Candidate for Rituximab Therapy

Alwin Lopez-Toro,[1] Lisa M. Sebastian.[1,2] *[1]Methodist Dallas Medical Center, Dallas, TX; [2]Dallas Nephrology Associates, Dallas, TX.*

Introduction: Pauci-Immune glomerulonephritis is the most common cause of RPGN in adults and elderly patients. ANCA serology is usually positive and has shown to play a role in the clinical presentation, kidney manifestations, and renal recovery. Rituximab continues to gain popularity as the first option in treatment. This is the case of ANCA negative pauci-immune glomerulonephritis with good response to Rituximab in combination with methylprednisolone and plasmapheresis.

Case Description: A 65 y/o African American Male with history of hypertension, tobacco use, and prostate CA in remission presented to the ER complaining of progressive general malaise and 15lb weight gain over 2 weeks. He reported sudden uncontrolled BP control in the last 3 months. Physical exam positive for scrotal and +2 pitting edema of lower extremities. Initial labs showed Hgb 14.8 g/dL, Cr 1.4 mg/dL (baseline 0.8mg/dL), BUN 37 mg/dL, Alb 2.3 g/dL and U/A with proteinuria (>600mg) and microscopic hematuria. A 24hr urine collection revealed 45 gm of protein. Serology workup was negative including ANCA, paraproteinemia, and infectious process. Patient denied taking any medicines besides anti-HTN's. Kidney biopsy revealed pauci-immune focal segmental necrotizing glomerulonephritis with one cellular crescent along with 25% tubular atrophy and interstitial fibrosis. He was started on methylprednisolone with weekly Rituximab for 4 weeks. After 2 weeks, his creatinine was still rising. At this time plasmapheresis was initiated and continued for 7 days. After the 3rd dose of rituximab, his Cr went down to 0.8 mg/dL with resolution of edema.

Discussion: Pauci-immune GN usually presents with either positive c-ANCA or p-ANCA. Rarely, it can present with negative serology which can delay diagnosis and initiation of therapy. ANCA negative RPGN presentation is atypical. It usually lacks extra-renal involvement and presents with nephrotic range proteinuria. Kidney biopsy is key to early institution of appropriate therapy that can impact on kidney recovery and long term prognosis. Nephrologists should be highly suspicious of this possibility and be prompt to order kidney biopsy.

PUB558

Treatment of Hashimoto Associated Mesangioproliferative Glomerulonephritis

Fadee Abu Al Rub. *Nephrology, University of South Florida, Tampa, FL.*

Introduction: Mesangioproliferative glomerulonephritis (MesPGN) consists of a group of disorders histologically characterized by an increase in mesangial cells and expansion of the mesangial matrix secondary to deposits of specific immunoglobulins, complements, or immunocomplexes. This insult leads to nephrotic range proteinuria, hematuria, and hypertension (HTN). We present a case in which the deposits consist of immunocomplexes in the setting of autoimmune thyroiditis (AIT).

Case Description: The patient is a 23-year-old female with history of autoimmune thyroiditis and HTN who was referred to Nephrology for evaluation of hematuria and proteinuria. Symptomatically, the patient denied arthralgia and rash. Her family history was positive for lupus and Hashimoto disease. Physical exam was unremarkable. Initial workup revealed: Cr 1.7, microscopic hematuria and proteinuria, urine protein/Cr ratio 3010 mg/g. Serology showed an ANA of 1/40 with negative anti Smith ab and anti ds-DNA. Rheumatology consult ruled out lupus. A kidney biopsy was obtained and revealed immune complex mediated focal mesangioproliferative glomerulonephritis. Immunofluorescence was significant for deposition of IgG, IgM, and C3. The patient was initiated on an ACE inhibitor, mycophenolate mofetile (MMF) 1000 mg BID and prednisone. Microscopic hematuria resolved shortly after starting therapy and proteinuria improved to less than 1000 mg/g. Two years into treatment, prednisone was titrated off. MMF was titrated down 3 years after diagnosis. Patient continues to follow-up in clinic and has been in remission for 4 years status post discontinuation of immunosuppression.

Discussion: AIT has been associated with membranous nephropathy, IgA Nephropathy, and focal segmental glomerulonephritis, but there have been no prior reports of association with MesPGN. Given disease rarity, there are no randomized trials regarding treatment. In patients presenting with mild proteinuria and HTN, ACE inhibitors can prevent progression to nephrotic range proteinuria. For patients with nephrotic range proteinuria, steroids can prevent progression to FSGS. Immunosuppressants have gained popularity as a treatment modality. MMF, in particular, works by improvement of mesangial cell and matrix hypercellularity. The comparative efficacy of MMF in conjunction with steroids to other therapies has yet to be established.

PUB559

Scleroderma Renal Crisis – A Genetic Complementopathy?

Joshua S. Waitzman,[1] Niranjan Gunasekaran,[1] Yashpal S. Kanwar,[2] Cybele Ghossein.[1] *[1]Division of Nephrology and Hypertension, Department of Medicine, Northwestern University, Feinberg School of Medicine, Chicago, IL; [2]Department of Pathology, Northwestern University, Feinberg School of Medicine, Chicago, IL.*

Introduction: Complement dysfunction is a major contributor to the pathophysiology of atypical hemolytic uremic syndrome (aHUS). Scleroderma renal crisis (SRC) shares many clinical and pathologic features with aHUS. We present a case of SRC in a patient with a homozygous mutation associated with aHUS.

Case Description: A 44-year-old woman with a 17-year history of scleroderma presented to rheumatology clinic with new onset hypertension and a rising creatinine. She was admitted to the hospital and started on captopril for blood pressure control; her blood pressure was lowered to her baseline within 48 hours. A 24-hour urine protein demonstrated 1.7 g proteinuria. Given the late presentation of her kidney injury relative to her diagnosis of scleroderma, she underwent a renal biopsy. Blood vessels showed moderate-to-severe wall thickening with semi-occlusive/occlusive changes and some of the vessels revealed "onion skinning," consistent with SRC (Fig 1). Her creatinine stabilized at 2 mg/dl and she was discharged. She was readmitted one week later with recurrent hypertension and an elevated creatinine. The patient underwent genotyping for mutations of the complement pathway and was found to have a homozygous polymorphism within an intron of the membrane cofactor protein/CD46, which has been associated with aHUS. She was initiated on eculizumab. She subsequently developed an infection and had an antibiotic drug reaction that caused her renal disease to progress and she was initiated on dialysis.

Discussion: SRC and aHUS are two entities that are clinically and pathologically similar. SRC pathogenesis may be related to alternative complement pathway dysfunction.

PUB560

The Great Mimicker – A Diagnosis That Should Not Go Undetected

Lumen A. Mendez Castaner,[1] Emilian A. Cristea,[2] Lorena Cuebas-Rosado,[3] Oliver Lenz,[2] David B. Thomas.[4] *[1]Jackson Memorial Hospital, Miami, FL; [2]University of Miami, Lauderhill, FL; [3]Miami VA Hospital, Miami, FL; [4]University of Miami, Miller School of Medicine, Miami, FL.*

Introduction: Fibrillary glomerulonephritis (FGN) is a rare disease found in 1% of native kidney biopsies. Most commonly seen in Caucasians, with a predominance of female to male ratio 2:1. Is characterized by glomerular accumulation of non-branching, haphazardly arranged fibrils measuring 10-30 nm in thickness in the mesangium. Undistinguishable from amyloid fibrils except for lack of reactivity to congo red staining. Light microscopy variable patterns that include membranoproliferative, diffuse proliferative, mesangial proliferation and expansion. IF most often reveal polyclonal deposit of IgGs, particularly IgG4 and IgG1. Very little is known about pathogenesis of FGN, however the presence of IgG and complement suggests a glomerular deposition of immune complexes with the ability to undergo fibrillogenesis. Renal outcomes for this disease are poor with progression to ESRD in 4 years in 50% of the patients. No standard therapies are available

Case Description: 71 year old Caucasian male with history of Bladder cancer and Hypertension who developed nephrotic range proteinuria 3.5g/d, serum cr level 1.72 mg/dL, eGFR (MDRD) 39 mL/min/1.73^2. Five months prior with baseline serum creatinine 1.18 mg/dL and eGFR 64.68mL/min/1.73m^2. C3: 123, C4: 32, HIV, Hep B/C, ANA and PLA2R negative. Kappa/lambda 0.78. SPEP and UPEP negative for monoclonal protein. Physical exam significant for +2 lower extremity edema. Kidney biopsy yielded 20 glomeruli. Light microscopy showed diffuse and global mesangial expansion without proliferation. IF was positive for IgG +3, C3 +2, kappa +3 and lambda +3. EM showed sub-epithelial and sub-endothelial densities composed by randomly arranged, non-branching fibrils measuring 20nm consistent with FGN. Patient was treated with two doses of rituximab (1G IV x 2). Six months later, serum creatinine 1.68mg/dL and eGFR 40 mL/min/1.73m^2, with a decrease UPCR to 1.2

Discussion: FGN is an uncommon disease, reason why no controlled clinical trials have been conducted. Small case series propose rituximab as a promising treatment for FGN with the pathology rationale of predominant polyclonal IgG deposits seen in mesangium and glomerular basement. Favorable results were observed in patients with preserved renal function at baseline, similar to our patient suggesting that early diagnosis is necessary to prevent or decrease progression to ESRD.

PUB561

IgA Nephrology After Liver Transplant

Christin M. Giordano McAuliffe,[1] Edward Gould.[2] *[1]Medicine, Vanderbilt University Medical Center, Nashville, TN; [2]Center for Kidney Disease, Vanderbilt University, Nashville, TN.*

Introduction: IgA nephropathy is the most common biopsied glomerulonephritis worldwide and typically has a slowly progressive course. IgA nephropathy has been associated with end-stage liver disease with biopsies of patients prior to liver transplant or ex-plant in liver-kidney transplant patients demonstrating IgA nephropathy in up to 50% of cases. However, it has been rarely reported as new diagnosis post-liver transplantation. Here, we present a case of IgA nephropathy which developed several years after liver transplantation.

Case Description: Patient is a 62 year-old male with a history of hepatitis C and alcohol-related cirrhosis who underwent liver transplantation in 2009. Prior to transplant, he had no renal dysfunction, hematuria or proteinuria. He presented to nephrology clinic in 2016 with worsening chronic kidney disease (CKD) and proteinuria. His hepatitis C had been successfully treated post-transplantation. Laboratory examination at time of initial consultation showed tacrolimus levels at goal, creatinine of 2.4 mg/dL and urine protein-creatinine ratio of 3.3. Because of his proteinuria, with no clear explanation, he underwent renal biopsy which showed co-dominant IgA and IgG mesangial and segmental capillary loop staining by immunofluorescence as well as subendothelial deposits by electron microscopy and focal nodular hyalinosis. These findings are consistent with IgA focal proliferative glomerulonephritis and calcineurin inhibitor toxicity. He was placed on an angiotensin converting enzyme inhibitor and his creatinine has stabilized with a reduction in his proteinuria.

Discussion: CKD, usually secondary to calcineurin inhibitor toxicity, is a known complication of liver transplantation. There is also a known association of IgA nephropathy with end-stage liver disease. However, the development of IgA nephropathy following liver transplantation has been rarely reported. This case demonstrates the importance of considering other etiologies of chronic kidney disease in post-transplant patients, particularly if hematuria or proteinuria are present.

PUB562

A Case of Malignant Hypertension with Thrombotic Microangiopathy Mimicking Small-Vessel Vasculitic Diseases

Masaki Itagane, Ko Sudo, Hitoshi Miyasato. *Okinawa Chubu Hospital, Uruma, Japan.*

Introduction: Malignant hypertension may present with a number of clinical sequela, however, pulmonary hemorrhage and palpable purpura are rarely associated with the disease presentation. We present a case of malignant hypertension presenting with thrombotic microangiopathy (TMA).

Case Description: A 37-year-old woman presented with a 2-month history of anasarca and a 2-week history of progressive dyspnea with hemoptysis. Her past medical history was significant for untreated hypertension. On arrival, the patient's blood pressure was 230/150 mmHg. She had bilateral inspiratory crackles on lung auscultation and bilateral pretibial slow pitting edema and palpable purpura on her extremities. She had a microcytic anemia (Hb 10.5 g/dl) and mild thrombocytopenia (129,000 platelets/μl) without evidence of schistocytosis. The LDH value was 819 U/l and serum creatinine level was 4.3 mg/dl. The urinalysis demonstrated hematuria and proteinuria with granular casts. The spot urine protein to creatinine ratio was 0.8 g/gCr. Her chest radiograph showed bilateral diffuse ground grass opacities. The patient subsequently received a sequential bronchoalveolar lavage, which demonstrated alveolar hemorrhage. Small-vessel vasculitic diseases were suspected, yet the patient's serum ANA, MPO-ANCA, PR3-ANCA, anti-dsDNA, and anti-GBM antibodies were all negative. A skin biopsy showed the presence of microthrombosis within the dermis. The histology of the renal biopsy was compatible with TMA, revealing glomerular intracapillary fibrinoid necrosis with fibrinoid thrombosis and accumulation of fragmented erythrocytes, mucoid intimal thickening and concentric myointimal proliferation. After initiating treatment with antihypertensive drugs, the patient's serum Hb, platelets and LDH normalized. Her renal function also recovered without dialysis. Follow-up evaluation identified no secondary causes of resistant hypertension.

Discussion: A high index of suspicion of malignant hypertension with TMA is warranted in patients with a history of uncontrolled hypertension and symptoms of pulmonary renal syndrome and purpura, which are typically manifestations of small-vessel vasculitic diseases. Early and aggressive blood pressure control may reduce long-term morbidity and mortality in these patients.

PUB563

Life Threatening Bleeding from Arcuate Kidney Artery Aneurysm as a Rare Complication of Granulomatosis with Polyangiitis

Piotr Skonieczny,[1,2] Zbigniew Heleniak,[1] Tomasz Liberek,[1] Barbara Bullo-Piontecka,[1] Bartosz Bascik,[3] Alicja Debska-Slizien.[1] *[1]Department of Nephrology, Transplantology and Internal Medicine, Medical University of Gdansk, Gdansk, Poland; [2]Department of Physiology, Medical University of Gdansk, Gdansk, Poland; [3]Department of Radiology, Medical University of Gdansk, Gdansk, Poland.*

Introduction: Granulomatosis with polyangiitis (GPA) is a systemic necrotizing inflammation of small and medium-size vessels. It most commonly affects the upper respiratory tract and the kidneys. Bleeding from aneurysms formed during the disease is a rare complication.

Case Description: 50y old patient was transferred to the Department of Nephrology with the suspicion of GPA. The patient was hospitalized for one month with fever, night sweats and progressive pedal edema. The blood test revealed high CRP, the CT scan suggested staphylococcus pneumonia, although patient condition did not improve with antibiotic therapy. Development of kidney failure (creatinine rise from 0.7mg/dl to 3.7mg/dl) and progression of pulmonary infiltrates with cavity formation raised the suspicion of GPA. On admission creatinine was 4.1mg/dl, CRP 211mg/l, cANCA 1:2560, anti-PR3 titer 188RU/ml and among clinical symptoms dominated significant shortness of breath what corresponded with massive pulmonary infiltrates in CT scan. The diagnosis of life-threatening GPA was establish and patient received i.v. methylprednisolone, plasma exchange therapy and pulses of cyclophosphamide. Simultaneously hemodialysis was initiated. On the 15th day of hospitalization patient suffered from a very strong pain in the right flank with significant hemoglobin lowering. Angio-CT scan was performed and showed massive hematoma adjacent to the right kidney with active bleeding from the raptured aneurysm of the arcuate artery. Numerous small non-bleeding aneurysms in both kidneys were also visualized. Urgent embolization of the bleeding vessel was performed which stopped the hemorrhage. After third pulse of cyclophosphamide the condition of the patient improved, regression of the pulmonary infiltrates was observed, although the patient

remained dialysis dependent. The follow up immunosuppressive therapy was planned on an outpatient basis.

Discussion: Clinical manifestations of GPA can be highly varied and are dependent upon which organ is affected by vasculitis. Major hemorrhage from an aneurysm of a medium or large-size artery is a rare manifestation of ANCA-associated vasculitis. Urgent diagnostic CT and intravascular radiology intervention or surgery can ameliorate the patient condition.

PUB564

Lupus Optic Neuritis in ESRD Patient

Gajapathiraju Chamarthi,[3] Justin Lee Loy,[2] Abhilash Koratala.[1] *[1]Nephrology, University of Florida, Gainesville, FL; [2]University of Florida Gainesville, Gainesville, FL; [3]University of Flroida, Gainesville, FL.*

Introduction: Optic neuropathy is an uncommon finding in dialysis patients and has been associated with uremia, ischemia (arteritic and nonarteritic), drugs (isoniazid, ethambutol), infections (tuberculosis) and intracranial hypertension. Inflammatory optic neuritis associated with lupus nephritis is however extremely rare. Herein, we present one such case.

Case Description: A 50-year-old Indian-American female with a history of end stage renal disease (ESRD) secondary to Lupus nephritis, on renal replacement therapy for 2 years presented to the ER with intermittent left eye loss of vision described as "foggy vision, as if looking through a curtain at the edges" for six days without flashing lights. Fundus examination showed optic disc edema with mild obscuration vessels (arrow) and peripapillary flame hemorrhages and retinal pigment epithelial mottling of the macula [Figure], consistent with inflammatory optic neuritis from Lupus. Her dialysis sessions were uneventful and the most recent monthly Kt/V was 1.4.

Discussion: Clinical and serological lupus activity is thought to be substantially reduced after the onset of ESRD and most of the extra-renal manifestations are hematological. The main determinants of lupus activity are age of the patient and time on dialysis therapy, reaching 39% after 5 years on dialysis.Our patient was admitted to the hospital and treated with intravenous methylprednisolone 250 mg pulsed every 6 hours for 3 days and then was transitioned to oral steroids on outpatient basis. Visual symptoms showed gradual improvement. Apart from eye infections related to catheter-related blood stream infections, optic neuritis from Lupus is another important ophthalmologic condition that Nephrologists need to be familiar with to facilitate prompt treatment.

PUB565

An Unusual Cause of Hematuria on a Patient with Granulomatous Polyangiitis

Ngozi Okoba. *Yale School of Medicine, New Haven, CT.*

Introduction: Granulomatous polyangiitis (GPA) is an inflammatory condition characterized by often relapsing hematuria, proteinuria and renal damage. Here, we present a case of an 87 year old man with history of GPA who presented with persistent hematuria, raising concern for a flare of his GPA, and subsequently a bladder wall malignancy when a mass was found in his bladder. However, evaluation, notable for an elevated urine pH and mild leukocyturia, ultimately led to the diagnosis of Corynebarcterium urealyticum cystitis, an uncommon condition seen in immunosuppressed patients.

Case Description: An 87 year old man with an 18 year history of GPA with renal involvement and prostate cancer presented to his rheumatologist with 1 month of intermittent hematuria and weakness. He was found to have elevated serologic titers and was presumptively treated for GPA relapse with high dose steroids and rituximab. Symptoms persisted, however, and he returned with gross hematuria. On admission, he was hemodynamically stable and afebrile. Cr was 2, up from a baseline of 1.5, and the CRP and ESR were normal. Urinalysis showed 3+ blood, 3+ protein, 3+ leukesterase, 20-25 wbc and a pH of 9. Urine sediments was impressive for RBCs and WBCs but no dysmorphic cells were seen. Urine culture was initially negative. Hematuria improved with CBI; cystoscopy demonstrated a calcified bladder mass, and a transurethral resection of bladder tumor was recommended. The culture eventually grew Corynebacterium urealyticum and Nephrology recommended antibiotic therapy. Cystoscopy was nevertheless performed with resection of the mass; pathology showed no evidence of malignancy but predominantly denuded urothelium with reactive changes, atypical stromal cells, necrosis, and active chronic inflammation with calcium deposits.

Discussion: C. Urealyticum is a fastidious, urea-splitting gram-positive organism typically seen in immunosuppressed patients, often introduced by frequent bladder catheterization, as it was in this gentleman. Our patient's presentation, with an encrusted cystitis and pyelitis, is typical. The elevated urine pH and the presence of the bladder mass in a chronically catheterized immunosuppressed patient were clues to the diagnosis and an invasive intervention might have been avoided.

PUB566

Congo Red Positive Fibrillary Glomerulonephritis

Akram Audi, Jeffrey W. Rosenberg, Sai Subhodhini Reddy, Bruce Goldman, David Levy. *University of Rochester Medical Center, Rochester, NY.*

Introduction: Patients with nephrotic range proteinuria and longstanding diabetes mellitus (DM) are often presumed to have diabetic nephropathy (DN). Therefore kidney biopsy is often not performed. However as the prevalence of DM in the general population is rising, the number of cases of nephrotic range proteinuria that are falsely attributed to DN also may be increasing.

Case Description: A 62 year-old female with a history of DM, CKD stage 3, and HTN presented with elevated creatinine and proteinuria. She was noted to have newly diagnosed nephrotic range proteinuria (8 grams/day) which was not consistent with her disease course and therefore kidney biopsy was performed. The light microscopy showed capillary wall and mesangial matrix expansion as well as interstitial fibrosis with a chronic lymphocytic inflammatory infiltrate. Immunofluorescence was significant for smudgy deposition of C3 (1+), IgG (1+), kappa light chain (1+) and lambda light chain (2+). Electron Microscopy (EM) showed fibril deposition with fibril diameters being greater than those typical of amyloid. Furthermore, Congo red staining was weakly positive but did not show green birefringence. Fibril identification by liquid chromatography/mass spectrophotometry (performed at Mayo Laboratories, Rochester MN) was negative for monoclonal light chain but showed positivity for iDNAJB9, a sensitive and specific marker of fibrillary glomerulonephritis (FGN).

Discussion: FGN is defined by the presence of organized fibrils on EM that are usually thicker than those of amyloidosis, usually positive for polyclonal IgG and C3, and importantly are unstained with Congo red. Our patient was found to have this rare diagnosis. This case highlights the importance of renal biopsy in patients with DM and nephrotic range proteinuria, who present with an atypical disease course. Additionally, when renal biopsy shows organized deposits, mass spectroscopy should be considered to ensure an accurate diagnosis.

Diffuse Alveolar Hemorrhage, a Rare Complication of Henoch-Schönlein Purpura

Elbert Chow,[1] Corey J. Cavanaugh,[2] Ethan P. Marin.[2] *[1]Norwalk Hospital, Norwalk, CT; [2]Nephrology, Yale University, NewHaven, CT.*

Introduction: Henoch-Schonlein purpura (HSP) is a small vessel vasculitis typically seen in children. Less commonly the disease can occur adults, with renal disease more severe than that seen in children. Diffuse alveolar hemorrhage (DAH) is a rare complication of HSP which if not promptly recognized, carries a high mortality.

Case Description: A 50 y/o male with history of hypertension treated with hydralazine, alcoholic cirrhosis, prior documented leukocytoclastic vasculitis (LCV) presented with lower extremity cellulitis and was treated with vancomycin. On second day of admission he was noted to have significant hypoxia and hemoptysis prompting intubation. There was interval development of purpuric rash in the trunk, bilateral arms and legs. A CT scan demonstrated diffuse lung consolidation and bronchoscopy findings consistent with DAH. Laboratories were remarkable for creatinine: 2.81mg/dL, BUN: 45mg/dL with associated hematuria and minimal proteinuria. Serologies revealed elevated MPO-ANCA (544 AU/ml), double stranded antibodies (119 IU), anti-histone (3.8) but normal anti-GBM and anti-proteinase 3 titers. Intravenous methylprednisolone and plasmapheresis were started for presumed ANCA associated vasculitis (AAV). Renal biopsy revealed diffuse mesangioproliferative glomerulonephritis and acute tubular necrosis without crescents on light microscopy. Immunofluorescence (IF) showed 2+ IgA, 2+ IgM and 2+ C3, all in a mesangial pattern. Electron microscopy demonstrated segmental effacement of foot

processes without tubuloreticular inclusions. Biopsy of his purpuric rash demonstrated LCV but was negative for IgA on IF. Due to development of leukopenia, rituximab was started over cytoxan. Despite treatment, he was unable to recover any renal function requiring dialysis. He was intubated for a prolonged intubation course and was ultimately transitioned to comfort care.

Discussion: HSP with DAH is a fatal complication, with reported prevalence between 1.6%-5% and a mortality rate of 27.5%. Our patient was suspected to have AAV given his positive ANCA and MPO serologies, however kidney biopsy argued against a pauci-immune glomerulonephritis. Instead, a diagnosis of HSP with DAH was felt most likely, and treated with corticosteroids, plasmapheresis and rituximab. The poor outcome in this case, highlights challenges in treatment of this particularly devastating disease.

PUB568

A Case of a Pregnant Woman Carrying Dichorionic Diamniotic Twins and Having Nephrotic Syndrome Eventually Diagnosed as IgA Nephropathy and Preeclampsia After Delivery

Nagisa Koda,[2] Kei Matsumoto,[3] Shuichiro Yamanaka,[2] Masahiro Okabe,[1] Kentaro Koike,[2] Yukio Maruyama,[2] Nobuo Tsuboi,[2] Tetsuya Kawamura,[2] Takashi Yokoo.[2] *[1]Jikei University School of Medicine, Tokyo, Japan; [2]The Jikei University School of Medicine, Tokyo, Japan; [3]The Jikei University school of medicine, Tokyo, Japan.*

Introduction: A 35-year-old Chinese pregnant with dichorionic diamniotic (DCDA) twins developed nephrotic syndrome (NS). However, her blood pressure (BP) continued to be normal throughout her gestation and puerperium. After delivery, her NS got worse. A renal biopsy (RBx) revealed IgA nephropathy (IgAN) and preeclampsia. She was treated with steroid therapy and her NS improved. This is a rare case presenting a combination of IgAN and preeclampsia pathologically but not meeting preeclampisa criteria in the clinical course.

Case Description: A 35-year-old Chinese female with no history of renal disease was pregnant with DCDA twins. At 31 weeks of pregnancy, she presented with nephrotic range proteinuria (8.9 g/day) and hypoalbuminemia (1.7 g/dL) for the first time. However, her BP was normal, at approximately 110/80 mmHg. She did not match the criteria of preeclampsia. At 34 weeks of pregnancy, she delivered twins by cesarean section. At 16 days after delivery, she presented with syncope and her NS got worse; her proteinuria was 21.1 g/day. She underwent an RBx, and we started treatment with m-PSL pulse followed by conventional prednisolone therapy. Her pathological findings were extracapillary cell proliferation and 3+ staining for IgA over the mesangial area on immunofluorescence, and electron microscopy revealed electron dense deposits in the paramesangial area along with endotheliosis and epithelial cell changes. Therefore, her pathological diagnosis was a combination of IgAN and preeclampsia. After beginning steroid therapy, her NS gradually improved.

Discussion: This case showed development of severe proteinuria without hypertension, which is rare. IgAN cases diagnosed as a result of NS comprise less than 10% of all IgAN cases. In addition, NS due to renal diseases reportedly occurs in 0.028% of pregnant women. Therefore, if pregnancies present severe gestational proteinuria without hypertension, a pathological preeclampsia diagnosis should be considered.

IgAN and Pregnancy

Maternal age(yr)/gestation age (wk)	Past History	Hypertension During pregnancy	Cr at presentation	Peak proteinuria During/After pregnancy(g/day)	Serum Albumine During/After pregnancy (g/dL)	Diagnosis	Pathology
27/19	IgAN	(-)	0.9	8.3/not discribed	2.7/3.9	Aggrivation of IgAN	Mesangial cell proliferation, Cellular crescent, IgA deposition
26/18	IgAN	(+)	0.88	1.2/9	2.9/4.5	A combination of IgAN and preeclampsia	Mesangial cell proliferation, Fibrous cellular crescent, IgA deposition
28/29	IgAN	(+)	0.61	5.6/7.2	2.5/not discribed	A combination of IgAN and preeclampsia	Cellular crescentendotheliosis, thrombus, IgA deposition
35/33 (This case)	None	(-)	0.82	1.3/21.1	1.6/1.0	A combination of IgAN and preeclampsia	extracapillary cell proliferation, endotheliosis and epithelial cell changes, IgA deposition

Podocyte Infolding Glomerulopathy: A Rare Cause of Proteinuria in SLE

Neelofar R. Khan,[1] Kenar D. Jhaveri,[1] Sonali Narain,[3] Vanesa Bijol,[2] Rimda Wanchoo.[1] *[1]Nephrology, Zucker School of Medicine at Hofstra Northwell, GREAT NECK, NY; [2]Pathology, Zucker School of Medicine at Hofstra/ Northwell, Great Neck, NY; [3]Rheumatology, Zucker School of Medicine at Hofstra Northwell, Manhasset, NY.*

Introduction: Podocyte infolding glomerulopathy (PIG) is a pathologic entity characterized by diffuse podocyte infolding into the glomerular basement membrane (GBM) associated with ultrastructurally demonstrable microspherular aggregates. The clinical features, significance, and pathogenesis of this condition are still not well delineated because only a few cases have been documented to date, all from Japan and India. We report a case of PIG associated with SLE in an AA woman who presented with nephrotic syndrome.

Case Description: A 25 year old AA female was seen in nephrology clinic as a transition of care from pediatrics. She had a diagnosis of SLE for over 10 years. She had a kidney biopsy 5 years ago that showed Class III+V lupus nephritis that required treatment with tacrolimus monotherapy. Since, her renal function was normal and her proteinuria minimal at <1gm/24 hours tacrolimus was discontinued. Over the next one year, her proteinuria progressed to 3gm. A kidney biopsy revealed PIG along with Class 1 lupus nephritis. EM analysis of the biopsy specimen revealed unusual subepithelial aggregates of microspherules admixed with few microtubules alongside extensive infolding of podocyte foot processes into the underlying GBMs. Characteristic clustering of these microparticles near the invaginated tips of podocyte foot processes in the GBM was observed on EM. With elevated dsDNA levels, and normal secondary workup of all viral etiologies, it was presumed to be secondary to SLE and treatment was initiated with rituximab (2 doses) 1gm over 2 weeks apart. She was maximized on conservative therapy with enalapril. Her proteinuria peaked at 5gm and the most recent is 2gm. Her dsDNA levels have been down-trending as well.

Discussion: PIG is a rare entity initially described as a nucleopore glomerulopathy in the 1980s. Most of the recent cases described have been in the Japanese and the Indian population. Majority of the patients had a contaminant diagnosis of SLE or other autoimmune diseases. The diagnosis is made with findings on EM as IF shows minimal reactivity to immunoglobulins. Response to immunosuppression can be variable. In our case, there was a partial response to rituximab therapy. Nephrologists and rheumatologist need to be aware of this rare form of glomerular disease in patients with SLE and other connective tissue disorders.

PUB570

Immunological Remission in PLA2R-Antibody–Associated Membranous Nephropathy in a Kidney Transplant Patient After Excision of Breast Cancer

Aldo E. Torres Ortiz,[1] Youssef Al hmada,[2] Iasmina Craici,[1] Wisit Cheungpasitporn.[1] *[1]Nephrology, University of Mississippi Medical Center, Jackson, MS; [2]University of Mississippi Medical Center, Jackson, MS.*

Introduction: M-type phospholipase A_2 receptor(PLA_2R) is the major antigen in primary membranous nephropathy(MN). It is suggested that coexistent PLA2R-positive MN and cancers are coincidental since previous reported cases did not achieve remission of proteinuria after tumor resection. We present a case of coexistent PLA2R-positive MN and breast cancer after kidney transplant(KTx), who subsequently had immunological remission in PLA2R-Ab and reduction of proteinuria after excision of breast cancer.

Case Description: A 76-year-old Caucasian female, who was a recipient of a deceased donor zero-ABDR mismatch kidney, developed worsening proteinuria over the first year post KTx. Long-standing HTN was the presumed cause of her ESRD. She received induction with rabbit anti-thymocyte globulin and was maintained on cyclosporine, prednisone and mycophenolic acid. At 2-month follow-up, she developed 2+ (100 mg/dL) proteinuria. Thus, lisinopril was initiated and was titrated up to 20 mg daily. Her serum Cr had been 1.0 mg/dL which was her baseline. However, her proteinuria had been gradually worsening, measured at 4 g/24h at 8-month post-KTx. Renal allograft biopsy revealed MN with +glomerular PLA2R deposition. The PLA2R Ab in the serum was also positive. IgG subtyping showed intense IgG4 staining along the glomerular capillary walls. Lab testing showed negative for monoclonal protein, ANA, HBV, HCV, and HIV. She underwent age-appropriate screening for malignancy, and was found to have newly diagnosed ductal Carcinoma in Situ of left breast. She underwent lumpectomy and did not require chemotherapy. The patient did not receive higher immunosuppression or any additional treatment for her MN. On 9-month follow-up studies, proteinuria in a 24-hour urine collection decreased to 1.1 g/24h with stable serum Cr. Serum PLA2R-Ab was repeated and came back negative.

Discussion: The coexistence of MN, solid tumors, and PLA2R positivity has been previously reported, and is suggested that the coexistence could be coincidental. In addition, recent studies showed that appearance of PLA2R-Ab post-KTx may suggest a more resistant MN. To our knowledge, this is the first case of KTX patient, who achieved immunological remission in PLA2R-Ab and reduction of proteinuria after excision of breast cancer.

PUB571

Crescentic Lupus Nephritis Treated with MMF, a Promising Outcome: 2 Patient Series

Kavitha Ramaswamy,[1] Ummerubab Syeda,[2] Omar H. Maarouf.[2] *[1]Nephrology, Thomas Jefferson University, Philadelphia, PA; [2]Thomas Jefferson University Hospital, Philadelphia, PA.*

Introduction: Crescentic lupus nephritis is a severe disease that requires an aggressive approach to treatment. Recent randomized clinical trials showed that mycophenolate mofetil compared favorably with cyclophosphamide (traditional approach) for remission induction. However, the role of mycophenolate mofetil in treating **crescentic lupus nephritis** remains unclear, because such patients were excluded from these trials. Many nephrologists still prefer to treat this patient population with cyclophosphamide despite its known toxicities. Here, we present a case series of two patients with severe crescentic lupus nephritis (class 4 G) treated with MMF –as an induction therapy-with an excellent response within 6 months of treatment.

Case Description: Patient 1: 34 year old African American female with class 4 lupus nephritis complicated by crescents as evidenced by her renal biopsy. Upon induction with MMF and steroids, she has had marked improvement in serological markers of activity including dsDNA titers (173 to 15) and improvement in serum albumin (1.7 to 3.6) within 3 months of treatment. Patient 2: 30 year old African American female with crescentic lupus nephritis class 4, was also initiated on MMF and steroids. Her kidney function has markedly improved with creatinine dropping from 3.5 mg/dL to 1.33 mg/dL. Her proteinuria has markedly decreased from 9.5g to 1.2g within 3 months of induction.

Discussion: Lupus nephritis represents a significant complication of SLE with substantial morbidity and mortality. Although treatment has improved, treating crescentic lupus nephritis portends a challenge to nephrologists that they fall back to old therapies like cyclophosphamide despite its significant morbidity, including an increased risk of serious infections and amenorrhea. In clinical practice, MMF is now the preferred induction regimen for patients with lupus nephritis (not crescentic) who wish to preserve fertility, which is a large patient population given that the disease commonly presents in women of child-bearing age. Unfortunately, most randomized controlled studies of lupus nephritis do not offer insight on treating cases complicated by crescents given their reduced occurrence. Our abstract sheds the light on the use of MMF as induction therapy for crescentic lupus nephritis which offers these patients a drug with less toxicity.

PUB572

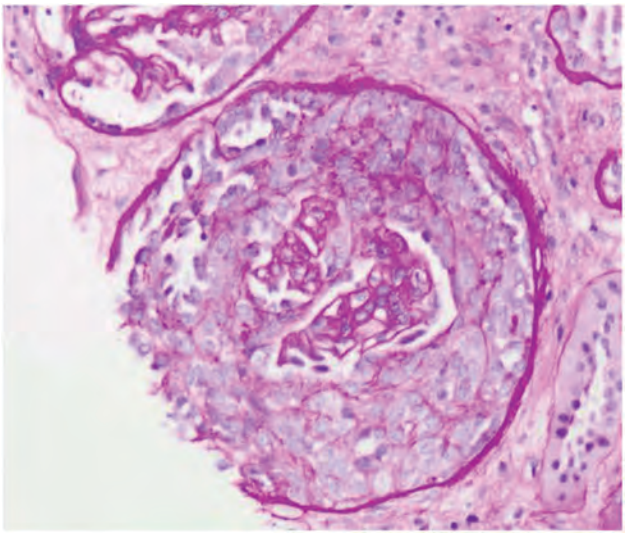
Crescentic Primary Membranous Glomerulonephritis

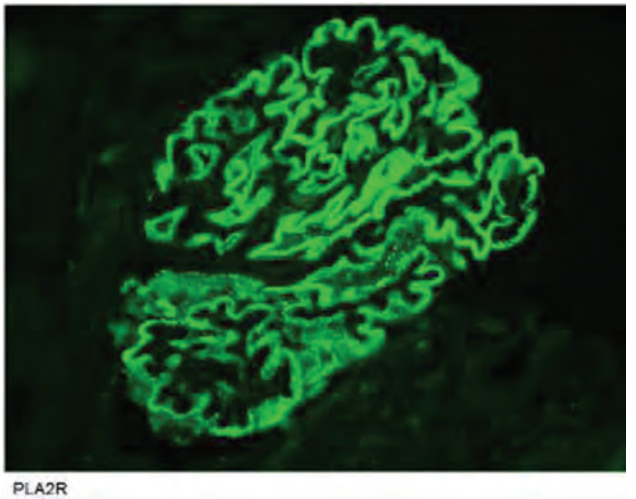
Jessica M. Nelson,[3] Jonathan A. Ducastel,[2] Robin Shah,[1] Isabelle Ayoub.[1]
[1]Nephrology, The Ohio State University, Columbus, OH; [2]OSU Nephrology, Columbus, OH; [3]Ohio State Wexner Medical Center, Columbus, OH.

Introduction: Membranous nephropathy (MN) is one of the common causes of nephrotic syndrome in adults and is most often primary (pMN). Kidney function is usually normal at presentation. Mild mesangial hypercellularity may be seen in pMN but significant proliferation and crescent formation raise suspicion of a secondary process. This case illustrates an unusual presentation of pMN.

Case Description: A 20 year old black woman presented with swelling. Diagnostic work up was significant for AKI with Scr 3.9 mg/dl, active urine sediment and nephrotic syndrome (24h urine Protein/Creatinine 15.7g/g and serum albumin 1.8g/dl). Kidney biopsy showed crescentic GN with IgG1, IgG4, and PLA2R staining on IF, and electron dense subepithelial deposits along the glomerular capillary loops (figures 1 and 2). Serum anti-PLA2R was 338 units/ml. Work up for secondary or additional etiology was negative. She received 2g IV methylprednisolone. Ten days later her Scr improved to 1.2mg/dl. She is currently on cyclophosphamide and prednisone, anticoagulation and lisinopril.

Discussion: pMN with rapidly progressive and crescentic glomerulonephritis is unusual. The predominant IgG1 and IgG4 staining and the positive serum anti-PLA2R and tissue PLA2R with negative work-up for secondary/additional etiology support the diagnosis.





PUB573

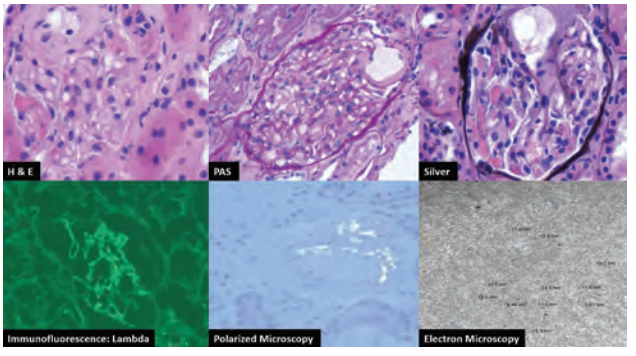
Elderly White Man with Proteinuria Does Not Always Have Membranous Nephropathy or Minimal Change Disease

Justin Lee Loy, Gajapathiraju Chamarthi, Abhilash Koratala. *University of Flroida, Gainesville, FL.*

Introduction: Heavy proteinuria with or without overt nephrotic syndrome may occur in association with a wide variety of primary and systemic diseases. Kidney biopsy is not always indicated, especially when secondary cause is suspected but the serologic work up should be 'complte' prior to making a decision. We describe a case where incomplete serological work up with respect to serum immunofixation (IFE) delayed the diagnosis and appropriate treatment.

Case Description: A 70-year-old White man without any known systemic disease was seen for second opinion regarding worsening proteinuria and edema. His symptoms started 1 year ago at which time, he had 700 mg/g proteinuria. SPEP, UPEP and Serum Free light chain assay (FLC) were negative for monoclonal protein. Screening for common vasculitides and viral hepatitis was negative. However, serum/urine IFE was not obtained. His proteinuria worsened to 5g/g in 1 year and developed hypoalbuminemia with relatively preserved creatinine. The patient was told by his prior nephrologist that it's most likely membranous nephropathy vs. minimal change disease and the plan was to empirically treat with prednisone. Therefore, patient was resistant to undergoing renal biopsy and requested us to obtain serum PLA2R autoantibody testing. Eventually, he agreed and the biopsy revealed λ light chain (AL) amyloidosis. Bone marrow biopsy revealed abnormal plasma cells with monotypic λ light chains and he was referred for bone marrow transplant.

Discussion: Most patients with AL amyloidosis have little or no intact monoclonal immunoglobulin, but are characterized by the presence of monoclonal free light chain. IFE of serum and urine is required because the monoclonal peaks in amyloid tend to be small and frequently do not produce a spike detectable with electrophoresis alone. It's noteworthy that in one series, the diagnostic sensitivity of the FLC κ/λ ratio was 76%, that of IFE of both serum and urine was 96%, and their combination correctly identified the amyloidogenic light chains in 100% of patients.



PUB574

Tacrolimus and Intravenous Cyclophosphamide as Effective Therapy for Membranous Nephropathy in a Patient with Mixed Connective Tissue Disease

Shunichiro Hanai, Fumihiko Furuya, Kenichiro Kitamura. *Third Department of Internal Medicine, University of Yamanashi, Chuo-shi, Japan.*

Introduction: Renal involvement occurs in about 25% of patients with mixed connective tissue disease (MCTD), and it usually takes the form of membranous nephropathy (MN).

Case Description: A 61-year-old woman was admitted to our hospital complaining of lower extremities edema. She was diagnosed with MCTD because of Raynaud's phenomenon and positive anti-RNP antibody at the age of 39 years old. Since no organ involvement was observed, she did not receive any glucocorticoid or immunosuppressant. She developed nephrotic syndrome at the age of 60, and renal biopsy revealed the association of MN. PAM staining of renal histopathology showed spiking of the glomerular basement membrane and Masson trichrome staining showed diffuse sub-endothelial deposit. Anti-phospholipase A2 receptor antibody was negative. Oral prednisolone (PSL) 30mg and mizoribine (MZB) 100mg daily were initiated, but failed to achieve remission. Switching MZB to tacrolimus (TAC) 3mg daily decreased urine protein/creatinine ratio (UPCR) to 2.0-4.0 g/gCr, but persistent proteinuria remained. Because she developed cellulitis of her left lower extremity due to severe edema and became unable to walk, intravenous cyclophosphamide (IVCY) was added expecting immediate improvement. UPCR was reduced to 0.5-1.0 g/gCr and walking difficulty was significantly ameliorated following IVCY. TAC + IVCY combination therapy was continued and PSL was tapered.

Discussion: Efficacy of TAC + mycophenolate mofetil combination therapy for lupus nephritis (LN) has been well documented. Since Asian LN patients have much higher response rate to CY than black or white patients, IVCY could be a beneficial treatment for the LN. TAC is also safe and effective for class V LN. Although no standard therapy has been established at this point, TAC + IVCY could be a beneficial therapeutic option for MN associated with MCTD according to treatment strategy for LN.

PUB575

IgA Nephropathy Associated with Evans' Syndrome

Heliana M. Mello,[1] Ana Paula Gueiros,[1] Denise M. Costa,[1] Camila B. Oliveira,[1] Carolina A. Vasconcelos,[1] Mirna D. Meira,[1] Cidcley N. Cabral,[1] Rafaela M. Gouveia,[1] Luiz antonio M. Da fonte filho,[1] Marlene A. Reis.[2] *[1]Instituto de Medicina Integral Professor Fernando Figueira - IMIP, Recife, Brazil; [2]Federal University of Triangulo Mineiro - UFTM, Uberaba, Brazil.*

Introduction: IgA nephropathy (IgAN) is associated with autoimmune diseases. Evans' syndrome (ES) is characterized by immunological hemolytic anemia (HA) and thrombocytopenia (TCP), and may be idiopatic or secondary. Systemic lupus erythematosus (SLE) is associated with IgAN and ES. We report the case of a patient with primary ES and IgAN, treated for SLE

Case Description: Female patient aged 23. At 13, after a viral infection, she was diagnosed with SLE due to edema, macroscopic hematuria and hypertension. At the time, she presented: creatinine 2.0 mg/dL, hemoglobin 7.0 g/dL, positive direct Coombs test, platelets 95,000. The urine analysis: 3+ protein and numerous red blood cells; proteinuria (PTN) 500mg/24h; negative ANA, anti-DNA, VDRL. C3 46 (NR 90-180 mg/dL). A kidney biopsy (KB) in her medical records described lupus glomerulonephritis. After treatment with methylprednisolone (methyl) and cyclophosphamide (CP), the glomerular filtration rate (GFR) was normalized. Maintenance treatment was azathioprine. She continued with subnephrotic PTN, microscopic hematuria, intermittent HA and TCP, negative ANA and no other clinical manifestations of SLE. A myelogram was performed, which was normal. At 16, mycophenolate mofetil was initiated. After 3 years with no remission of PTN, she did a KB that showed mesangial expansion and hypercellularity, segmental sclerosis and adherence to the Bowman's capsule, with no endocapillary proliferation; immunofluorescence: intense granular deposits of IgA in the mesangium and capillary loops, characterizing IgAN. At 23, she suffered a rapid GFR decline, with HA and TCP. A new KB confirmed a diagnosis of crescentic IgAN. The treatment was methyl and CP for 5 months. With no clinical response, a KB was performed with electron microscopy (EM): chronic IgAN, with no lesions suggestive of SLE. There was a need for dialysis.

Discussion: This is the first report of IgAN associated with idiopatic ES. We emphasize the importance of EM for an adequate diagnosis of glomerulonephritis, especially when the clinical signs are not definitive

PUB576

Use of Rituximab as a Steroid Sparing Agent to Achieve and Maintain Complete Remission in an Initial Episode of Minimal Change Disease

Win Win Moe, Ruby Zhao, Nobuyuki (Bill) Miyawaki, James Drakakis. *NYU Winthrop Hospital, Mineola, NY.*

Introduction: Adults with minimal change disease (MCD) will experience complete remission over 80% of the time with corticosteroids. Data for using steroid sparing regimens to treat the initial episode is limited mostly to case reports, with most experience involving Cyclophosphamide (CYC) or Cyclosporine (CsA). We report a case of adult MCD where steroids were not given, and nephrotic syndrome persisted despite nearly 1 year of CsA. It was only after administering Rituximab that complete remission was achieved and maintained.

Case Description: A 26 year old female with history of type I diabetes mellitus developed sudden weight gain and edema. Workup revealed albumin of 1.3 g/dL and 13 g/g of proteinuria. Kidney biopsy (54 glomeruli) showed diffuse podocyte effacement with normal light microscopy and immunoflorescence, consistent with MCD. Due to glycemic concerns, steroids were avoided and CsA initiated. Peak albumin on this therapy was 2.6 g/dL, with nadir proteinuria 4 g/g. When proteinuria again rose to 11 g/g after 8 total months, Rituximab was given as 2 doses of 1000 mg, 2 weeks apart. Proteinuria 6 weeks later was 21 mg/g, and remained <100 mg/g over subsequent months. After 6 months she received a single maintenance dose of Ritiximab 500 mg, while CsA was being weaned down. She now remains in complete remission with the latest proteinuria <100 mg/g and albumin 4.5 g/dL.

Discussion: There are scenarios whereby relative contraindications to high dose steroids exist, despite being considered the mainstay of therapy for MCD. There is little literature to guide alternative treatment strategies. Relapses occur frequently with patients becoming steroid resistant, steroid dependant (SD), or frequently relapsing (FR). In these settings, evidence for using alkalating agents or calcineurin inhibitors exists. The use of Rituximab to effectively prevent relapses of SD or FR MCD has been reported as well. Insights into how exactly Rituximab works in the treatment of MCD may help elucidate details of pathogenesis. Some hypotheses include protective actions on podocytes or targeting of B-cell subsets that secrete humoral factors injurious to podocytes. These ideas may lead to a novel approach to therapy, with this case an example of achievement of remission despite the first line agent never having been administered.

PUB577

A Case of ANA, dsDNA Negative Anti-Ro/SSA, Anti Smith Positive Lupus Nephritis

Vinay Srinivasa. Townsville department of Nephrology *Nephrology, Townsville Hospital, Townsville, QLD, Australia.*

Introduction: Systemic lupus erythematosus (SLE) is a multisystemic autoimmune disorder that is characterised by antibodies to nuclear and cytoplasmic antigens. Renal involvement in SLE is known as lupus nephritis and is associated with anti-nuclear antibody (ANA) positivity. ANA is negative in 5% of cases of SLE.

Case Description: We present a case of a 56 year old burmese refugee who presented to hospital with hypertensive crisis. Her blood pressure on admission was 220/120 mmHg with urinary protein studies revealing a protein excretion rate of 11grams/day. Furthermore urine cytology revealed dysmorphic red blood cells consistent with glomerular bleeding. Serum creatinine was 156 micromol/L with previous blood tests showing normal creatinine levels 6 months prior to hospital admission. Serum ANA, dsDNA were negative but anti ro/ssa and anti smith antibodies were positive. Renal biopsy was performed with histology revealing membranoproliferative glomerulonephritis suggestive of class III/IV nephritis.

Discussion: SLE is a multisystemic autoimmune disease that is characterised by nuclear and cytoplasmic antibodies to antigens. Antibodies to DNA play a role in the pathogenesis and activity of lupus nephritis. There are few cases of lupus nephritis described in the literature with no detectable antibodies. The role of anti ro/ssa and anti smith antibodies in lupus nephritis is not established. In this report we highlight the possible role of anti ro and anti smith antibodies in the pathogenesis of lupus nephritis. The mechanism of this is still misunderstood with further studies required.

PUB578

PCSK9 Inhibitors: A Novel Therapy for FSGS?

Jeanne Kamal,[1] Richard Gargiulo,[2] Olga Zhdanova.[3] *[1]Nephrology, New York University, New York, NY; [2]New York University, New York, NY; [3]New York University Medical Center, New York, NY.*

Introduction: Alirocumab, an anti-proprotein convertase subtilisin/kexin type 9 (PCSK9) monoclonal antibody is used for the treatment of primary dyslipidemia. PCSK9 is implicated in the pathogenesis of hyperlipidemia associated with nephrotic syndrome. In experimental models of focal segmental glomerulosclerosis, (FSGS) lipid infiltration in glomerular cells was found to induce podocyte injury and proteinuria.

Case Description: We present the case of a 60 year old African American man with obesity (BMI 42) and history of hypertension, hyperlipidemia, chronic kidney disease (CKD) with nephrotic range proteinuria. He previously had an episode of acute kidney injury due to statin-induced rhabdomyolysis that required temporary hemodialysis. He subsequently recovered and stabilized his renal function at CKD stage 3. His creatinine was 1.7 (eGFR: 45), had 5 g/g proteinuria, without hematuria and normal serum albumin (3.8 g/dL). Viral serologies were negative for HIV, Hepatitis B and C. He had biopsy-proven secondary FSGS thought to be related to obesity and possibly APOL1 due to his African American ethnicity. He was tried on a weight loss regimen and started on maximum RAAS blockade without improvement in his proteinuria. Given his poorly controlled hyperlipidemia (Chol: 345, LDL: 238, HDL: 73, TG: 171) while on ezetimibe, colesevelam, and niacin, he was started on PCSK9 inhibitor-Alirocumab. His proteinuria improved to 1 g/g soon after Alirocumab was initiated and has remained stable.

Discussion: PCSK9 levels correlate with the severity of hyperlipidemia and the degree of proteinuria. Once in remission, patients with nephrotic syndrome have decreased PCSK9 levels. Inhibition of the PCSK9 pathway should be investigated further as a novel therapeutic option in patients with proteinuria.

PUB579

Between a Rash and a Hot Knee: Distinguishing IgA Vasculitis from IgA Dominant Post-Infectious Glomerulonephritis

Justin Lee Loy,[1] Gajapathiraju Chamarthi,[1] Rajesh Mohandas.[1,2] *[1]Division of Nephrology, Hypertension and Renal Transplantation, University of Florida, Gainesville, FL; [2]Renal Section, North Florida / South Georgia Veterans Administration, Gainesville, FL.*

Introduction: Methicillin-resistant Staphylococcus aureus (MRSA) bacteremia has been associated with post infectious glomerulonephritis (PIGN) and dominant IgA deposits. On the other hand, infections can precipitate a de novo IgA vasculitis. Distinguishing between the two is critical, since management options are different.

Case Description: A 61-year-old male was admitted with MRSA bacteremia and septic arthritis of the knee. Urinalysis and renal function were normal. Three weeks later he developed a non-pruritic erythematous rash on his extremities (Fig 1A), nephrotic range proteinuria and creatinine increased to 1.5 mg/dl. Serologies were negative with normal complement levels. Renal biopsy revealed focal areas of neutrophil infiltration (Fig 1C). Immunofluorescence (IF) showed heavy granular mesangial and glomerular capillary loop staining for IgA (Fig 1B), and focal C3 deposition. Electron microscopy revealed focal subepithelial and subendothelial mesangial deposits and a single large sub-epithelial deposit (Fig 1D).

Discussion: Distinguishing MRSA associated GN from IgA vasculitis can be challenging. The pertinent distinguishing features and our patient's clinical features are summarized in Table-1. Given the clinical picture favoring MRSA related GN, persistent bacteremia and lack of convincing evidence favoring immunosuppressive therapy in IgA vasculitis, we elected for conservative treatment. Follow up showed stable creatinine at 1.4 mg/dl, despite persistent bacteremia, arguing for a cautious approach to treatment in such patients.

Table 1: Comparison of clinical characteristics of Staphylococcus infection-associated glomerulonephritis and idiopathic IgA nephropathy

Clinical Characteristics	Staphylococcus Infection Associated GN	IgA Vasculitis
Demographics		
Age	50-89 years*	20-30 years
Sex	80-90% males	~70% males
Race	Japanese, Caucasian*, Hispanics	Highest Asians, Low in blacks
Association with infection	Usually active infection*	History of infection in 30-40%
	Deep seated infections* about 70% MRSA*	Upper respiratory or mucosal infection Viral or Bacterial infection
	Latent period 5-10 weeks*	Latent period 1-2 days
Clinical Features	Low complements (30-40%)	Normal complements*
	Nephrotic range proteinuria*	Nephritic sediment
	Cryoglobulins may be present	Cryoglobulins are absent
	Renal dysfunction is common*	Renal failure is rare
Pathology	Endocapillary proliferation*	Mesangial proliferation
	Neutrophil infiltration*	Crescentic glomerulonephritis
	Stronger staining for C3 than IgA	Dominant IgA staining*
	IgA polyclonal	Ig A monoclonal (Ig A1)
	Sub-epithelial humps on EM*	EM: Mesangial deposits occasionally extending to peripheral capillary loops

* Clinical characteristics associated with our patient EM: Electron microscopy

A Case Series of Rituximab for Resistant Focal Segmental Glomerulosclerosis in Adults

Ellia Zhong,[1] Siavash Ghadiri,[1] Judith G. Marin,[2] Sean Barbour.[1] *[1]University of British Columbia, Richmond, BC, Canada; [2]Providence Health, North Vancouver, BC, Canada.*

Introduction: Adults with primary focal segmental glomerulosclerosis (FSGS) are frequently resistant to multiple immunosuppressive (IS) agents. Rituximab (RTX) is considered a last resort treatment, however there are few successful cases reported in adults. As such, we reviewed all patients with FSGS in the province of British Columbia (Canada) who were treated with RTX from January 2014 – April 2018. We included patients >19 years old with FSGS in the native kidney. RTX dosing was decided by the treating physician. Chart reviews were performed to extract clinical and laboratory data.

Case Description: Of the 121 patients who applied for RTX funding, 10 had FSGS of whom 3 met our inclusion criteria and 7 did not because they were children or had kidney transplants. Patient 1, a 41 year old female, was on prednisone, MMF and tacrolimus (TAC) and had previously failed galactose. Her creatinine (sCr) was 71 μmol/L, albumin (alb) 23g/L and proteinuria (prot) 4.95g/d. She was treated with RTX 375mg/m^2 weekly for 4 doses followed by single 375mg/m^2 doses with CD20 reconstitution. After RTX she was tapered off all other IS, with sCr 69μmol/L, alb 34g/L and prot 0.33g/d. Patient 2, a 21 year old male, was on prednisone and MMF, and had previously failed TAC, cyclosporine, cyclophosphamide, infliximab and galactose. His sCr was 168μmol/L, alb 30g/L and prot 8.69g/d. He was treated with RTX 375mg/m^2 weekly for 4 doses followed by single 375mg/m^2 doses with CD20 reconstitution. After RTX he was tapered off all other IS, with sCr 187μmol/L, alb 39g/L and prot 1.68g/d. Patient 3, a 26 year old female, was steroid sensitive but unable to taper prednisone without a disease flare despite concurrent use of cyclophosphamide, cyclosporine and TAC. At the time of being treated with RTX 1g every 2 weeks for 2 doses she was on TAC 3mg BID and prednisone 20mg/d, with sCr 63μmol/L, alb 35g/L and prot 0.38g/d. After RTX treatment, her prednisone has been tapered to 2.5mg every 2 days (the lowest dose without a flare in the previous 8 years) and TAC 2mg BID, with sCr 61μmol/L, alb 36g/L and prot 0.37g/d.

Discussion: By systematically evaluating all adults in a large Canadian province treated with RTX for FSGS, we have shown that RTX can be effective in FSGS resistant to multiple other IS agents. These findings support the need for a prospective trial in adults with resistant FSGS.

PUB581

Monoclonal Immunoglobulin-Associated Renal Disease Diagnosed by Liquid Chromatography-Tandem Mass Spectrometry: A Report of Three Cases

Yasuhisa Matsushita,[1,2] Hideki Inoue,[1] Keiko Okamura,[1] Mami Sugimoto,[1] Yoshimi Nakashima,[1] Takehiro Ko,[2] Yutaka Kakizoe,[1] Takashige Kuwabara,[1] Masataka Adachi,[1] Yushi Nakayama,[1] Masashi Mukoyama.[1] *[1]Nephrology, Kumamoto University Hospital, Kumamoto, Japan; [2]Tamana Central Hospital, Tamana, Japan.*

Introduction: Monoclonal immunoglobulin (MIg)-associated renal disease (MIg-ARD) results from direct deposition of nephrotoxic MIg or its light- or heavy-chain fragments in various renal compartments. Immunofluorescence (IF) and electron microscopy (EM) are essential to identify MIg and define its tissue distribution. We here report three cases of MIg-ARD diagnosed by liquid chromatography-tandem mass spectrometry (LC-MS/MS).

Case Description: Case 1: A 73-year-old woman was referred due to proteinuria and hematuria. She had been diagnosed with non-ischemic cardiomyopathy 6 years before. Plasma electrophoresis showed the presence of IgGκ monoclonal protein. Light-chain amyloidosis was suspected upon renal biopsy, but MIg heavy-chain deposition was revealed by IF and LC-MS/MS. We finally diagnosed her with renal heavy- and light-chain amyloidosis. Case 2: A 75-year-old woman with Sjögren syndrome was referred because of proteinuria and hematuria. Cryoglobulinemia, hypocomplementemia, and IgMκ monoclonal protein were detected. Renal biopsy showed membranoproliferative glomerulonephritis (MPGN). Although there was positivity for IgM and C3 with negative staining for κ and λ light chains on IF, MIg light-chain deposition was revealed by EM and LC-MS/MS. We diagnosed her with cryoglobulinemic glomerulonephritis with light-chain deposition. Case 3: A 70-year-old woman was referred because of proteinuria. Although serum immunoglobulin levels were especially low, none of MIg proteins were shown by plasma and urine electrophoresis. However, on the basis of high κ/λ free light-chain levels in serum and hyperplastic bone marrow, multiple myeloma was diagnosed. Renal biopsy showed MPGN. Although there was weak positivity for IgM with negative results for κ and λ light chains on IF, light-chain deposition disease was finally revealed by EM and LC-MS/MS.

Discussion: LC-MS/MS is effective to identify MIg deposits in renal tissue compartments, especially when the findings of IF and EM are inconsistent with the background of monoclonal gammopathies.

PUB582

Goodpasture's Syndrome Superimposed on Autosomal Dominant Polycystic Kidney Disease

Matthew Day, Khaled Abdel-Kader, Beatrice P. Concepcion. *Vanderbilt University Medical Center, Nashville, TN.*

Introduction: Autosomal dominant polycystic kidney disease (ADPKD) is a multisystem disorder characterized by multiple, bilateral renal cysts associated with cysts in other organs. The average rate of GFR decline is 4.4-5.9 mL/min/year. Here, we report a case of unexplained AKI with nephrotic syndrome in a patient with known ADPKD.

Case Description: 56/F with a history of ADPKD presented with 2 wks of worsening abdominal pain, lethargy, and oliguria described as darker than usual. Vitals were T-36.7, BP 163/84, HR 85, RR 20, O2sat 96% on RA. PE was significant for diffuse abdominal tenderness. Lungs were clear, and she had no edema nor any rashes. Admission SCr was 15 mg/dL with a prior normal baseline in 2010. Labs were significant for nephrotic-range proteinuria (PCR of 12.2) and microscopic hematuria. CXR revealed patchy perihilar and bibasilar opacities. No improvement in renal function was noted with IV fluids. Serological workup revealed normal complements, negative ANA, ANCA, SPEP/UPEP, HIV, and hepatitis panel. Worsening anemia thought to be secondary to hemoptysis complicated her hospital course. Chest CT revealed evidence of diffuse alveolar hemorrhage prompting a bronchoscopy that demonstrated blood throughout the tracheobronchial tree. Anti-GBM antibody levels were subsequently found to be elevated (209 AU/mL). Renal biopsy was not pursued due to technical difficulty and high risk of bleeding complications. She was started on high dose methylprednisolone (1 mg/kg/day) followed by plasma exchange and cyclophosphamide 25 mg PO BID. Her pulmonary symptoms improved with the above-stated therapy. However, she ultimately progressed to end stage renal disease requiring maintenance hemodialysis.

Discussion: In most patients with ADPKD, renal function is maintained despite relentless growth of cysts until the 4th to 6th decades of life. When renal function begins to decline, this occurs at an average rate of 4.4-5.9 mL/min/year. Unexplained AKI should prompt an evaluation for coexisting etiologies, which includes examination of the urinary sediment, a serologic work-up and possibly a renal biopsy, if technically feasible. In this case, the patient's clinical picture and positive anti-GBM titer led to the diagnosis of Goodpasture's syndrome superimposed on ADPKD. Her pulmonary symptoms improved with high dose steroids, plasma exchange, and cyclophosphamide therapy.

PUB583

Posterior Reversible Encephalopathy Syndrome Complicating Therapy of Membranous Nephropathy

Kothai divya Guruswamy sangameswaran, Krishna M. Baradhi. OU Tulsa *OU -Tulsa School of Community Medicine, Tulsa, OK.*

Introduction: Posterior reversible encephalopathy syndrome (PRES) is a rare, poorly-understood, reversible syndrome characterized by headache, altered mental status, seizures, visual disturbances and radiologically by vasogenic brain edema, predominantly

in the parietal and occipital lobes. PRES is frequently associated with severe hypertension, hemolytic uremic syndrome, lupus, ANCA vasculitis and several drugs including calcineurin inhibitors (CNI). We report a case of PRES, in a young male with membranous nephropathy associated with tacrolimus use and highlight the importance of early recognition as treatment involves withdrawal of the offending agent.

Case Description: A 27-year-old male presented with generalized tonic-clonic seizures, altered mental status and hypertensive emergency with blood pressure of 270/130 mm Hg. Medical history was known for biopsy proven membranous nephropathy on immunosuppression with tacrolimus and prednisone in the past one year. Exam revealed pallor and profound anasarca. Labs revealed acute kidney injury (AKI), hypoalbuminemia and tacrolimus level of 10.3 ng/ml (target range 5-8 ng/ml). Brain MRI showed symmetrical posterior subcortical vasogenic edema consistent with PRES. Management included discontinuation of immunosuppression with goal-directed optimization of blood pressure and volume status. He recovered well, with partial resolution of his AKI and without recurrence of seizures. Repeat renal biopsy showed advanced membranous nephropathy with mild tubular atrophy and interstitial fibrosis. Patient was conservatively managed without use of alternative immunosuppression due to higher risk of PRES associated with their use.

Discussion: PRES, also known as reversible posterior leukoencephalopathy syndrome was first described by Hinchey et al in 1996 and refers to a clinical conundrum of reversible subcortical vasogenic edema and severe hypertension. Tacrolimus is a macrolide derived immunosuppressant that competitively inhibits calcineurin and associated with severe vasoconstriction, hypertension, AKI and neurotoxicity. The estimated incidence of neurotoxicity is 7-32% in transplant recipients on CNI. It needs to be emphasized that PRES is a non-dose dependent adverse effect. Prompt recognition and discontinuation of the offending agent, with goal directed supportive care is paramount for complete neurological recovery.

PUB584

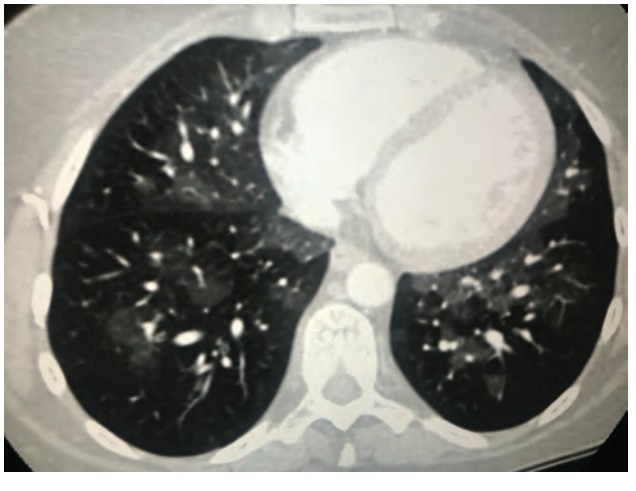
A Case of IgA and Bronchiolitis Obliterans in a Young Dialysis Patient

Susan M. McAnallen,[1] Ronan Cunningham,[2] Robert Mullan.[3] *[1]Renal Unit, Antrim Area Hospital, Antrim, United Kingdom; [2]Northern Trust, ANTRIM, United Kingdom; [3]Northern Health and Social Care Trust, Antrim, United Kingdom.*

Introduction: IgA Nephropathy is the commonest cause of glomerulonephritis worldwide, with typical presentation ranging from microscopic haematuria to rapidly progressive glomerulonephritis. It is estimated that 20% of people with IgA nephropathy(IgA GN)will progress to ESRD over10-15 years. The exact pathophysiology remains unknown %given the spectrum of disease, other associations including pulmonary disease have been described.

Case Description: A 36 year old female with ESRD%biopsy proven IgA GN had been haemodialysis(HD) dependent since 2010. One year after starting HD, she developed dyspnoea&reduced exercise tolerance. Investigations, including pulmonary function tests revealed a marked reduction in transfer factor (FEV1 0.7L, 24% predicted). CT Thorax demonstrated bilateral ground glass opacification consistent with small airways disease(Image I). Pulmonary screen was negative&the patient underwent two bronchoscopies, however no organism or abnormality was detected. Echocardiogram showed preserved left ventricular function&no evidence of pulmonary hypertension. A diagnosis of Bronchiolitis Obliterans was made&it was felt that this may be related to her underlying renal disease. The patient was assessed at a tertiary Lung transplant centre with view to potential combined lung/kidney transplant. She received a trial of steroids with minimal benefit.

Discussion: This young patient has already received 8 years of HD treatment, undoubtedly impacting on her length of life. She has a chronic irreversible lung condition, which has shown some stability in the last6years. Whilst she remains functionally better than investigations would suggest, the lung transplant team do not feel she is in need of urgent lung transplantation due to risk/benefit factors. Whilst systemic complications of IgA GN are uncommon, cases of interstitial pneumonitis, pulmonary haemosiderosis&bronchiolitis obliterans have been reported and an increased index of suspicion for multi-organ disease is needed in this patient group.



PUB585

Renal Thrombotic Microangiopathy: A Rare Complication of Castleman's Disease

Derian Lai,[1] Prejith P. Rajendran,[1] Sehrish Ali,[2] Jose J. Perez.[1] *[1]Baylor College of Medicine, Houston, TX; [2]BCM Nephrology, Sugar Land, TX.*

Introduction: Castleman's disease (CD) is a lymphoproliferative disorder characterized by excessive cytokine production. It is classified based on the extent of lymph node involvement, histologic features and associated diseases (HHV8). The pathogenesis of Castleman's disease involves excess IL-6 production in response to viruses, autoinflammation, or neoplasms. We present a rare case of renal thrombotic microangiopathy secondary to CD.

Case Description: A 51-year-old female presented with three months of worsening fevers, ascites and pedal edema. She was recently hospitalized for abdominal pain and imaging revealed multifocal circumferential colonic masses with diffuse abdominal and pelvic lymphadenopathy. Colonoscopy was completed two weeks prior to presentation, and there were no intraluminal abnormalities or evidence of malignancy. On admission she was noted to have acute kidney injury with serum creatinine 3.95mg/dL (baseline 1mg/dl) and non-nephrotic range proteinuria without active sediments. Lab findings notable for anemia (Hb 8.6 g/dL) and thrombocytopenia (platelets 26,000/uL), without evidence of hemolysis. Secondary workup revealed elevated ANA titers. Complements and other autoimmune serologies were normal. HIV and Hepatitis studies were negative. Fine needle aspiration of a supraclavicular lymph node returned as lymphoid tissue with polyclonal plasmocytosis. On Day 4, renal biopsy was performed, and histology revealed acute glomerular thrombotic microangiopathy. She was empirically treated with 5 sessions of therapeutic plasma exchange (TPE) with improvement in renal function (serum creatinine 1.2mg/dL). ADAMSTS13 eventually returned as equivocal (>32%) and genetic complement testing was unavailable. Bone marrow biopsy and peripheral blood smears were negative for a myeloproliferative process. On Day 20, she underwent excisional biopsy of cervical lymph node, which confirmed HHV8 negative Castleman's disease, mixed hyaline vascular and plasmocytic type. She was referred to hematology clinic for treatment but unfortunately lost to follow up.

Discussion: Multicentric Castleman's disease can present with a wide range of symptoms. Our patient presented with TAFRO syndrome (a unique subtype of idiopathic MCD) characterized by Anasarca, Fever and thrombocytopenia. Clinicians should be aware that CD can be a rare cause of thrombotic microangiopathy.

PUB586

Promising Treatment of Membranous Nephropathy Followed by Anti-Glomerular Basement Disease

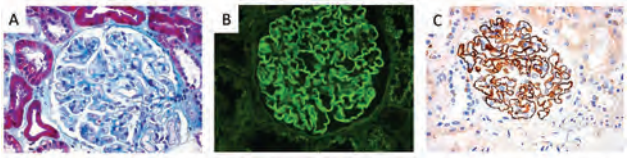
Claudius Speer,[2] Christian Nusshag,[1] Florian Kälble,[2] Christian Morath,[2] Matthias Schaier,[2] Claudia Sommerer,[2] Martin G. Zeier.[2] Zeier *[1]University Hospital Heidelberg, Heidelberg, Germany; [2]University Hospital of Heidelberg, HEIDELBERG, Germany.*

Introduction: Until now, a few studies reported evidence that both, simultaneous and consecutive occurrence of MN and anti-GMB disease can appear. The pathogenesis is still unclear and there is no algorithm in therapy. Here, we discuss a case of anti-GBM disease following MN with respect to clinical presentation and treatment options.

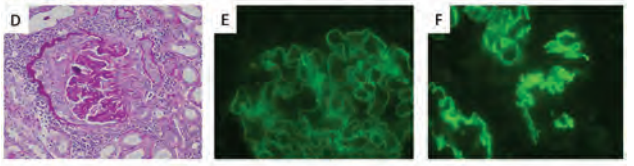
Case Description: We report a 55-year-old man with biopsy-confirmed MN 6 years ago and a base-line creatinine (Cr) of 1.3 mg/dl. The first kidney biopsy showed a MN with immune complex deposits (Figure 1A-C). Currently, the patient was admitted with new onset limb edema. Serum Cr level was 4.1 mg/dl and the protein/Cr ratio 119 g/molCr. Except the anti-GBM antibodies (titer 1:2560), the immunological screening was inconspicuous. In summary, we made the diagnosis of a rapidly progressive glomerulonephritis (GN). Thus, a second kidney biopsy was performed and the diagnosis of an anti-GBM GN superimposed on pre-existing MN could be established (Figure 1D-F). Immediately, therapy with i.v. methylprednisolone (MP) and cyclophosphamide (CYC) once per week in a dose of 250 mg for 3 times was started. Further, immunoadsorption (IA) was conducted 18 times. As a maintenance therapy, oral MP combined with another three times CYC 750 mg monthly was scheduled. Under therapy, the renal function improved and the serum Cr recovered to 1.6 mg/dl after 2 months.

Discussion: In a few cases with MN followed by anti-GBM, different therapy strategies were administered, having a poor patient outcome in common. For the first time, we report a patient with a favorable follow-up. An early biopsy-proven diagnosis followed by an immediate regimen of immunosuppression containing i.v. MP and CYC combined with IA seems to be encouraging. This case report underlines the fact that an early second biopsy should be considered in MN patients with an unusual clinical course.

Figure 1



The first renal biopsy in 2009 revealed a typical MN with thickening of glomerular basement membranes in the Masson-Trichrome stain (A), diffuse granular IgG deposits in subepithelial localization (B), and PLA2R-psotivity (C).



The current biopsy in 2017 disclosed an active crescentic GN (D, PAS stain)), with finely granular (E) and co-existing linear (F) IgG deposits along the GBM on immunohistology.

PUB587

Great Masquerade: Para-Neoplastic Pauci-Immune Glomerulonephritis

Sayee Sundar Alagusundaramoorthy, Laura J. Maursetter, Tripti Singh. *University of Wisconsin, Madison, WI.*

Introduction: Pauci-immune glomerulonephritis associated with neoplasia has been described in the literature. Fain et al reported the largest case series of 60 patients with malignancy and vasculitides and found 23.3% renal involvement. The most common cancer described in this series were hematologic followed by solid tumors. We describe a case series of 4 patients who presented with pauci-immune glomerulonephritis diagnosed by renal biopsy and four different malignancies which have not been commonly associated with pauci-immune glomerulonephritis.

Case Description: Three patients had diagnosis of malignancy and pauci-immune glomerulonephritis during the same hospital visit. One patient had cancer approximately 18 months after diagnosis of pauci-immune glomerulonephritis (Table 1). Only one patient recovered renal function leaving three patients dialysis dependent. Malignancy was treated in all patients without any recurrence to date.

Discussion: Malignancy should be considered at the time of diagnoses of antineutrophil cytoplasmic antibody associated pauci-immune glomerulonephritis as an ideopathic cause is often thought responsible. Physicians need to be vigilant to perform a thorough history and physical examination to identify the presence of clinical cues for any associated malignancies. Renal outcomes for patients with paraneoplastic pauci-immune glomerulonephritis are poor as in our case series. Nephrologists need to continue to strive to determine the best treatment when a combination diagnosis is present.

Table 1: Details about patients with Paraneoplastic pauci-immune glomerulonephritis

Abbreviation: IFTA, PLEX, CyBorD

Age & Sex	Serum Creatinine at presentation (mg/dl)	Antibody Positivity & Titer at time of diagnosis (units)	Renal Biopsy findings	Malignancy associated	Time interval between diagnosis of GN & Malignancy	Treatment (Malignancy and GN)	Renal function
50 years, Female	12.42	ANCA, MPO titer 26	Glomeruli 8/17 with cellular crescents, 2/17 globally sclerosis, 30% IFTA	Invasive ductal Carcinoma of right breast	Simultaneous	Prednisone + Cyclophosphamide + PLEX	Dialysis dependent
54 years, Female	1.59	ANCA, MPO 51	Glomeruli 6/17 fibrous crescents, 3/27 globally sclerosis, 20% IFTA	Malignant Melanoma of Left ear lobe	18 months	Methotrexate + Prednisone pre-biopsy – transitioned to Rituximab post biopsy	Renal function recovered completely
73 years, Female	5.41	ANCA, PR3 55	Glomeruli 2/6 with fibrinoid necrosis (inadequate specimen)	Adrenal Carcinoma	Simultaneous	Prednisone + PLEX, Rituximab	Dialysis dependent
75 years, Female	7.10	ANA 6.2, Anti DsDNA Ab 87.9 ANCA negative	Glomeruli 5/17 cellular crescents, 1/17 segmental fibrinoid necrosis, 7/17 global sclerosis, 70% IFTA	Multiple Myeloma (IgG Lambda)	Simultaneous	Prednisone + CyBorD	Dialysis dependent

PUB588

Treatment Options for Relapsing ANCA Associated Crescentic Glomerulonephritis (GN)

Golriz Jafari,[1] Raghu Konanur venkataram,[2] Anita Kamarzarian.[3] *[1]UCLA-Olive View Medical Center, Los Angeles, CA; [2]Olive View- UCLA Medical Center, Porter Ranch CA; [3]UCLA -Olive View Medical Center, La Canada, CA.*

Introduction: KDIGO 2012 guidelines recommends treatment of first episode or severe ANCA associated GN with cyclophosphamide and corticosteroids and alternatively the use of rituximab and corticosteroids in patients without severe disease or in whom cyclophosphamide is contraindicated. According to the RAVE TRIAL, neither treatment is superior for induction of remission in severe ANCA associated vasculitis and that perhaps rituximab may be ***superior in relapsing disease***. This case looks at the clinical application of these findings.

Case Description: A 26 year old female with history of ANCA (MPO) crescentic GN 2 years prior presents to ophthalmology clinic with a red eye and is found to have scleritis. Labs work reveals a Cr 1.62 mg/dl, Uprt/Ucr 4.4gm and UA >182 WBCs, >36 RBCs. Her initial episode of GN was treated with cyclophosphamide and steroids and she achieved remission with a Cr 0.70 and proteinuria 0.3 gm. She was maintained on and compliant with azathioprine until this second episode. Repeat kidney biopsy showed relapse of ANCA GN with 30% active crescents and secondary focal and segmental sclerosis. Anti-MPO titers increased from 4 to 31.4 and PR3 Ab negative. After discussion of therapy with cyclophosphamide and its potential risks of infertility vs. rituximab, patient opted for rituximab 375 mg weekly for 4 weeks with plan for biannual rituximab maintenance. Cr was 1.2 and proteinuria 2gm after 2 months.

Discussion: Cyclophosphamide with glucocorticoids has been the mainstay of therapy for ANCA associated vasculitis for many years. Most nephrologists are more comfortable with its use due to experience especially in very severe cases. The data does shows that rituximab is as effective as cyclophosphamide in treating ANCA associated vasculitis and maybe more effective for relapsing disease. After deciding to use rituximab for this patient's relapse, she questioned why we didn't use it for her first episode as she would have preferred a therapy that would not potentially affect her fertility. Although the study did not look at the fertility aspect, this is an advantage that rituximab haswhen choosing therapy. It is standard that we discuss all risk and benefits however we sometimes sway patients that cyclophosphamide might be better for severe disease. However clinically for younger female patients with severe disease, rituximab may be the superior option.

PUB589

Catastrophic Antiphospholipid Syndrome Presenting with Subacute Renal Thrombotic Microangiopathy

Shweta Punj, Ameesh Dara, Shikha Wadhwani. *Northwestern University Feinberg School of Medicine, Chicago, IL.*

Introduction: Renal thrombotic microangiopathy (TMA) can be the initial presentation of various systemic diseases including catastrophic antiphospholipid syndrome (CAPS).

Case Description: A 28-year-old Caucasian woman with history of asthma presented with two weeks of abdominal pain and new-onset jaundice, anorexia, and gross hematuria. Labs revealed a creatinine of 4.6 mg/dL (baseline 0.5 mg/dL), direct hyperbilirubinemia, hypoalbuminemia, leukocytosis, and elevated LDH. Extensive imaging was notable only for hepatosplenomegaly. Hepatitis panel, anti-nuclear antibody, and complement levels were unremarkable. Her renal failure worsened despite supportive measures and hemodialysis was initiated. A renal biopsy was performed, and she was transferred to our institution. The patient developed progressive anemia and thrombocytopenia with rare schistocytes seen on peripheral blood smear. Hematology recommended against empiric plasmapheresis given lack of clear evidence for microangiopathic hemolytic anemia and platelet count of 69 K/μL. Renal biopsy demonstrated glomerular endocapillary hypercellularity and segmental mesangiolysis, but no obvious fibrin thrombi or fibrinoid necrosis. Immunofluorescence staining was unremarkable and electron microscopy showed subendothelial widening concerning for subacute TMA. ADAMTS13 level and Shiga toxin PCR later returned normal. A liver biopsy was planned but the patient became encephalopathic and hypotensive following a platelet transfusion. She developed pressor-dependent shock and passed away hours later from cardiac arrest. On the day of death, her lupus anticoagulant resulted positive (anticardiolipin and anti-beta-2 glycoprotein antibodies negative). Autopsy findings included cerebral, adrenal, omental, and renal thrombi by CD61 staining, consistent with CAPS.

Discussion: The diagnosis of CAPS requires laboratory confirmation of the presence of antiphospholipid antibodies (APLA), thromboses in three or more organs in less than one week, and histopathologic confirmation of TMA. We describe an atypical case of a patient with rapid clinical deterioration in the absence of imaging consistent with thrombosis or infarction, delayed APLA positivity, and renal biopsy without active fibrin thrombi. Given the very high mortality rate associated with CAPS, a high index of suspicion is needed in patients with subtle features of TMA on renal biopsy.

PUB590

A Breathless Herring: Goodpasture's Presenting as Chronic Pulmonary Fibrosis

Ruth E. Campbell,[1] Kristin M. Olson,[2] Robert N. Smith.[3] *[1]Mercy Medical Center, Des Moines, Des Moines, IA; [2]Mercy Medical Center Internal Medicine Residency Program, West Des Moines, IA; [3]Associates In Kidney Care, West Des Moines, IA.*

Introduction: Goodpasture's syndrome involves rapid progressive glomerulonephritis and diffuse alveolar hemorrhage due to anti-glomerular basement membrane (anti-GBM) antibodies. We describe a case of Goodpasture's that presented as chronic pulmonary disease prior to renal involvement and was co-positive for anti-GBM and MPO/ANCA.

Case Description: A 73-year old man presented for 2 weeks of progressive weakness and oliguria. He had a 10-year history of pulmonary fibrosis, which did not require treatment or supplemental oxygen. On exam, he had asterixis and bibasilar crackles. Labs revealed a creatinine 23.7 mg/dL, BUN 256 mg/dL, potassium 7.0 mEq/liter and sedimentation rate (ESR) 98 mm/hr. Chest x-ray showed bibasilar fibrosis, in a usual interstitial pneumonia pattern, with superimposed edema. He became tachypneic with frothy hemoptysis, requiring intubation, and emergent continuous renal replacement therapy was started. Methylprednisolone was empirically started and ANCA, PR3, MPO and anti-GBM antibody labs were ordered. Anti-GBM antibodies and MPO/ANCA were positive. Plasmapheresis and cyclophosphamide were initiated. The patient improved and was extubated. Renal biopsy revealed necrotizing and crescentic glomerulonephritis with positive linear IgG basement membrane staining by immunofluorescence, confirming Goodpasture's syndrome. The patient was discharged on plasmapheresis, cyclophosphamide, prednisone and hemodialysis, with plans to switch to peritoneal dialysis.

Discussion: Goodpasture's has an estimated incidence of 1 case per million per year. However, Goodpasture's presenting as chronic pulmonary fibrosis prior to renal disease with anti-GBM, MPO/ANCA positivity is rare; as of 2017, only 7 cases had been reported. The significance of this presentation is unclear but may relate to the development and prognosis of the disease. While the trigger for Goodpasture's is unknown (proposed risk factors include hydrocarbon fumes and smoking), previous studies suggest MPO/ANCA positive pulmonary fibrosis may induce anti-GBM antibodies. The average 1-year survival rate of these 7 cases was 29%, in contrast to Goodpasture's 5-year survival rate of 50%. In either case, mortality rates improve with early treatment. Thus, early recognition of Goodpasture's presenting as chronic pulmonary fibrosis is key to improved outcomes.

PUB591

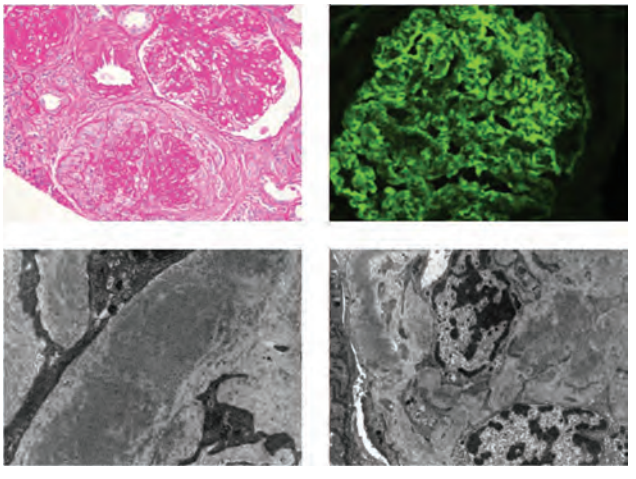
A Rare Case of Crescentic Fibrillary Glomerulonephritis

Kothai divya Guruswamy sangameswaran,[1] Muna Hale,[2] Narottam Regmi.[1] OU Tulsa *[1]OU -Tulsa School of Community Medicine, Tulsa, OK; [2]Oklahoma State University, Broken Arrow, OK.*

Introduction: Fibrillary glomerulonephritis (FGN) is a rare, primary, progressive glomerular disease that was first described by Rosenmann in 1977. Glomerular deposition of polyclonal IgG in the form of random fibrils of 15-20 nm size is pathognomonic of FGN and is distinguished from amyloidosis by negative congo red staining. We report a rare case of FGN in a middle-aged female with progressive renal failure and crescents on biopsy.

Case Description: A 58-year-old woman with hypertension was admitted with pneumonia and creatinine of 1.4 mg/dl with hematuria and 1.9 grams proteinuria. Extensive serological work up for secondary causes was negative. A diagnostic renal biopsy revealed FGN and patient was treated conservatively with ACE-inhibitor therapy, given stable renal function. A year later, she had steady rise in creatinine and a repeat biopsy showed FGN with active crescents. Repeat serological work up was unrevealing and patient was initiated on immunosuppression with cyclophosphamide and prednisone in anticipation of a favorable outcome.

Discussion: Patients with FGN are typically middle-aged and present with proteinuria, hematuria and renal insufficiency. FGN carries a poor prognosis with progressive renal disease and ESRD in over 50% of patients. Older age, higher creatinine and higher percentage of globally sclerotic glomeruli are poor prognostic indicators. FGN is a morphologically defined entity and without electron microscopy, it can be indistinguishable from other deposition diseases. Due to its rarity and diagnostic difficulty, there are not many clinical trials evaluating treatment efficacy. Immuno-staining with DNAJB9, a heat shock protein with >98% sensitivity and specificity for FGN has shown promise. With increased awareness and testing with DNAJB9, there can be hope of identifying viable treatment options for patients with FGN.



PUB592

Treating Antineutrophil Cytoplasmic Antibody Associated Vasculitis (AAV) with Rituximab: A Double-Edged Sword

Shenthuraan Tharmarajah,[2] Timothy C. Martin,[1] Loay H. Salman,[1] Swati Mehta,[1] Rafia I. Chaudhry.[1] *[1]Albany Medical Center, Albany, NY; [2]Albany Medical College, Albany, NY.*

Introduction: Rituximab is a monoclonal antibody directed against the CD20 antigen of B-lymphocytes used for the treatment of AAV. B-cell depletion with rituximab in AAV results in decreased production of pathogenic antibodies but also renders the patient immunocompromised. We report here a case of Invasive Pulmonary Aspergillus (IPA) after rituximab administration for AAV.

Case Description: A 27-year-old male with recently diagnosed AAV (based on anti-PR3 level of 528 AU/mL and pulmonary cavitary lesions on chest CT) s/p IV rituximab (375 mg/m^2 weekly x 4 doses) plus prednisone (60 mg q day), was transferred to our hospital. Four weeks after initial diagnosis, the patient continued to have persistent cough, anemia (Hb 8.7 g/dL, Plts 497 10^3/ uL) and leukocytosis (wbc 25.7 10^3/ uL), plus microscopic hematuria, and proteinuria (2.9 gm/ 24 hrs), with preserved renal function (Cr 0.91 mg/dL), and undetectable CD 19(+) B cells. Bronchoscopy was performed and bronchoalveolar lavage was positive for *Aspergillus*. Renal biopsy was done 6 weeks after the first dose of rituximab to determine the degree of activity of AAV and was consistent with pauci-immune focal segmental necrotizing (2/22 glomeruli) and crescentic glomerulonephritis (4/22 glomeruli with fibrocellular crescents). Voriconazole was started for IPA, followed by cyclophosphamide for active vasculitis despite induction therapy with rituximab. The patient had improvement in pulmonary symptoms and stable renal function, with resolution of microscopic hematuria but persistent proteinuria (2.2 gm/24 hr).

Discussion: AAV is an aggressive small vessel vasculitis that needs urgent treatment with immunosuppressive agents i.e. rituximab and cyclophosphamide, which increase the risk of opportunistic infections. Additional risk factors for infections in patients receiving rituximab include corticosteroids > 15 mg/day, creatinine clearance ≤ 45 mL/min, low IgG level, and low CD19(+) B cell count. Undetectable CD19(+) B cells (utilized to monitor B cell subset depletion after rituximab) in our patient implies that rituximab associated immunosuppression may have increased the risk of IPA. Therefore, while persistent pulmonary symptoms in patients with AAV can be due to active vasculitis, opportunistic and fungal infections such as *Aspergillus* must be ruled out.

PUB593

ANCA-Positive Crescentic Glomerulonephritis with Associated IgA Nephropathy

Gabriela C. Segura,[1] Luiza Lapolla,[1] Gerard F. Sales,[1] Tomas D. Ferreira,[1] Paula S. Mesquita,[2] Lectícia Jorge.[2] *[1]Hospital das Clínicas University of São Paulo (USP), SÃO PAULO, Brazil; [2]University of São Paulo, São Paulo, Brazil.*

Introduction: IgA nephropathy (IgAN) can present with positive ANCA in 10% of cases. Most of them are considered as false positives. The proposed mechanism is that pathogenic IgA immunocomplexes would predispose to ANCA positivation. Those patients with ANCA positive IgAN have poorer outcomes compared to those ANCA negative. Otherwise, in crescentic IgAN, ANCA correlates with better outcome.

Case Description: A 38-year-old Bolivian male patient presented malaise, vomits, oliguria and uveitis. He had a rapidly worsening renal function, from baseline serum creatinine (sCr) 0.84 mg/dL to admission sCr 11.06 mg/dL. His general condition deteriorated and emergency haemodialysis was initiated. He also showed hematuria (86 erythrocyte /c), which was present for the last 5 months, subnephrotic proteinuria (0.15 g/day) and severe anemia (7.0 gr/dL). Other relevant exams were normal Complement (C3 137mg/dL; C4 36 mg/dL), positive c-ANCA antigen (1/320), ANA 1/160, positive anticardiolipin IgG antibody (14.93 GPL U/mL), positive rheumatoid factor (61.8 UI/mL) and negative Anti-DNA. Kidney biopsy sample included twenty-eight glomeruli, eighteen of which were globally sclerotic, eight containing cellular glomerular crescents, two with fibrinoid necrosis and segmental cellular proliferation. Light microscopy demonstrated necrotizing glomerulonephritis with ANCA-associated pattern. Immunofluorescense revealed IgA mesangial diffuse granular staining (3+), suggesting IgA glomerulonephritis.

Discussion: We report a rare association between ANCA-associated vasculitis and IgAN. The previous finding of hematuria suggests that our patient could have IgAN as a previous undiagnosed condition. We could speculate that IgAN may trigger an immunologic response for developing an ANCA-associated vasculitis. More studies are needed to determine if this overlap would define a new condition, its physiopathology as well as the best therapeutic approach.

PUB594

Drug Resistant Focal Segmental Glomerulosclerosis (FSGS)

Jana Havranova,[1] Abbas Raza,[2] Dhaval Sureja.[3] *[1]St. Luke's University Hospital, Bethlehem, PA; [2]St. Luke's University Hospital, Bethlehem, PA; [3]St. Luke's University Hospital, Bethlehem, PA.*

Introduction: Focal Segmental Glomerulosclerosis (FSGS) accounts for approximately 40% of cases of nephrotic syndrome in adults. Most cases of FSGS are primary while others include genetics, infection/inflammation associated, or drug induced. The initial treatment of idiopathic FSGS is corticosteroid therapy. For steroid resistant FSGS, KDIGO guidelines recommend therapy with cyclosporine or Mycophenolate Mofetil (MMF) with corticosteroids. About 40% of the patients relapse after the initial therapy of FSGS. Relapses occur less frequently in those who have complete remission. We present a case of idiopathic FSGS resistant to multiple therapies.

Case Description: A 59-years-old male with medical history of CAD, hypertension, diabetes mellitus type 2, chronic obstructive pulmonary disease presented with proteinuria. Initial kidney biopsy confirmed FSGS thought to be primary. Patient could not tolerate steroid therapy due to side effects and was started on cyclosporine to which he responded well after prolonged therapy but relapsed after it was discontinued. At this time, repeat kidney biopsy was preformed showing predominantly FSGS with mild diabetic glomerulosclerosis. After reinstituting cyclosporine, he had an episode of Acute kidney Injury (AKI) requiring hospitalization and cyclosporine was changed to prednisone in combination with MMF for 12 months. Patient did not respond with worsening proteinuria. Patient was again restarted on cyclosporine with persistent nephrotic range proteinuria. Eventually therapy with corticotropin was also attempted but failed to show any benefit and had significant side effect of weight gain. Patient continues to be treated with cyclosporine.

Discussion: Our patient failed to show response with multiple immunosuppressive regimens and remains a challenge to achieve remission. Another option with Rituximab was also considered but with given underlying CKD, history of multiple AKI episodes and failure to show response with multiple regimens, we thought not to pursue Rituximab given lack of strong evidence. Larger studies and research is needed to better understand this disease and develop more effective therapeutic options.

PUB595

A Unusual Case of Nephrotic Syndrome Post Allogenic Bone Marrow Transplant (aBMT) Secondary to Focal Segmental Glomerular Sclerosis (FSGS)

Rhea Thurston,[1] Nicoleta Radoianu,[1] Claude Bassil,[1] Ajay Bhandari,[1] Liying Fu.[2]
[1]University of South Florida, Wesley Chapel, FL; [2]Tampa General Hospital, Tampa, FL.

Introduction: Allogenic bone marrow transplantation is a widely used treatment modality for many hematological diseases. Nephrotic syndrome post allogenic bone marrow transplant is extremely rare with an incidence of 1%. The development of nephrotic syndrome usually happens in the late post-transplant period of more than six months. When present, membranous nephropathy is the typical microscopic finding in 2/3 of cases followed by minimal change disease. In general, this develops after the cessation or tapering of immunosuppressive therapy, which suggests that nephrotic syndrome could be a manifestation of chronic graft versus host disease.

Case Description: A 75-year-old gentleman had a history of hypertension, prostate cancer and myelodysplastic syndrome with transformation into acute myeloid leukemia. He underwent matched unrelated donor allogenic bone marrow transplant as part of his treatment. Ten months later, the patient presented with symptomatic nephrotic range proteinuria (edema and hypoalbuminemia). A spot urine protein creatinine ratio was 12g and 24hr urine collection was 18g protein. Serologic workup was positive for ANA with negative ANCA, anti GBM, anti dsDNA, Smith, RNP, SSA, SSB. Free kappa lambda was elevated with normal ratio. The serum and urine protein electrophoresis reflected the presence of intensely stained bands in the beta-gamma region which may have represented a monoclonal protein. PLA2R was negative. Kidney biopsy revealed acute tubular injury with cytoplasmic vacuolization on light microscopy. Immunofluorescence had no specific immunoglobulin or complement deposition. Electron microscopy showed podocyte injury with diffuse foot process effacement and no electron dense deposits. These findings were suggestive of focal and segmental glomerulosclerosis, primary or secondary. After steroid treatment proteinuria improved to 1.5g/g.

Discussion: We presented this case of nephrotic syndrome post bone marrow transplant, with FSGS as microscopic evidence, because it was distinct from the most commonly found lesion. Further studies are needed to determine if FSGS might represent a chronic graft versus host phenomenon. Single agent steroid use was successful in this patient and ultimately this case expanded our knowledge on renal complications post bone marrow transplantation.

PUB596

Fulminant Acute Renal Failure in IgA Nephropathy

Hanning You,[1] Duncan B. Johnstone.[2] *[1]Temple University School of Medicine, Philadelphia, PA; [2]Temple University School of Medicine, Philadelphia, PA.*

Introduction: IgA nephropathy (IGAN) has been described as a disease with invariable histopathologic findings but highly variable clinical outcomes (Rodrigues JC et al, CJASN, 2017). Here we describe a patient a new diagnosis of IGAN that caused fulminant acute renal failure.

Case Description: A 20-year-old Hispanic woman with childhood epilepsy presented with two days of right flank pain, nausea and vomiting. Current medications were levetiracetam and topiramate. Physical exam was normal except for obesity. Abdominal CT scan was unrevealing. She was admitted without an explanation for her symptoms, which rapidly improved, but her serum creatinine rose from 0.88 mg/dL to 11.8 mg/dL with oliguria in one week. Nephrology was consulted. Urine sediment showed a few granular casts with numerous WBCs and RBCs. Urine culture grew E.coli > 100K. Ultrasound showed normally sized kidneys with increased echogenicity. Initial serologic tests were negative. She was treated with antibiotics for cystitis, dialyzed twice and then underwent kidney biopsy. Microscopy revealed mesangial hypercellularity, no crescents or fibrinoid necrosis, and a large number of red cell casts within tubules along with epithelial flattening. In addition there was a diffuse lymphoplasmacytic infiltrate with eosinophils. IF showed 3-4+ mesangial and glomerular capillary staining for IgA, C3 and fibrinogen. EM showed numerous mesangial dense deposits. MEST-C score: M0, E1, S1, T1, C0. Her interstitial nephritis was treated by changing her anti-epileptic medication and also with 1 month prednisone 60mg. Dialysis was held, and within a week she was discharged with improving renal function. Four weeks later in clinic her creatinine was 0.88mg/dL.

Discussion: Our patient had a new diagnosis of IGAN with acute renal failure due to intra-tubular obstruction from RBC casts. This rare variant of IgA is not incorporated into the Oxford classification. The prognosis is excellent because renal function recovers once RBC casts start degenerating. How glomerular hematuria becomes sufficient to cause cast obstruction is unclear. Similar to other case reports (Friedlaender MM et al, Isr J M Sci 1986; Lee HS et al, AJKD, 1988; August C et al, J Neph, 2001) our patient's infectious trigger was cystitis rather than a URI, a correlation that bears further consideration.

PUB597

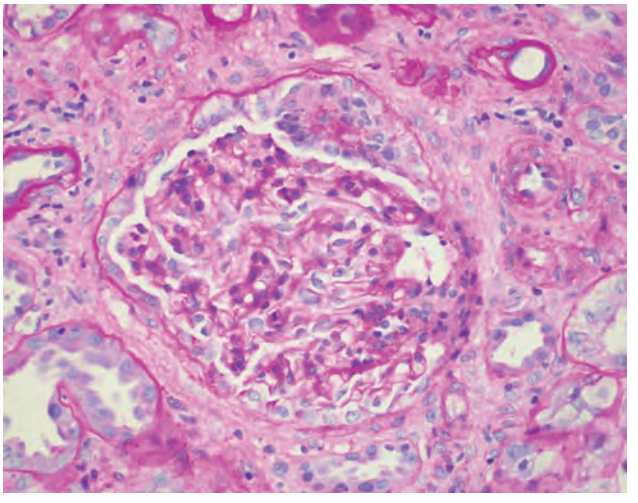
Crescentic IgA Nephropathy in an African American Man on Warfarin

Luis C. Segura,[1] Roberto L. Collazo-Maldonado.[2,1] *[1]Nephrology, Methodist Dallas Medical Center, Dallas, TX; [2]Dallas Nephrology Associates, Dallas, TX.*

Introduction: Immunoglobulin A Nephropathy (IgA Nephropathy) is a mesangial proliferative glomerulonephritis characterized by diffuse mesangial deposition of IgA.Its more commonly seen in Asians, caucassians and hispanics but the prevalence of IgAN is very low among African Americans. Anticoagulant related nephropathy is more common in patients with IgA Nephropathy.

Case Description: This is a 57 y/o AA man with a past medical history of thromboembolic disease on warfarin therapy, hypertension, and CKD stage 3 presented to our hospital with foot pain and gross hematuria with no other symptoms. On exam he was afebrile with a B/P of 140mm/hg with clear lungs and no edema. His admission labs showed a creatinine of 15.17mg/% (baseline 1.6mg/%), BUN of 100mg/% with a HCO3 of 14meq/dl. U/A showed large blood, with RBC casts and nephrotic range proteinuria of 4.1gms. His serologic work up was normal. His INR was 3.8. A renal ultrasound showed echogenic kidneys without hydronephrosis. After reversing the anticoagulation a Kidney Biopsy was done and is was consistent with IgA nephropathy with cellular crescents and moderate interstitial fibrosis. The patient was treated with methylprednisolone 1gm/daily for 3 days. He was then started on Prednisone 60 mg daily. He also received 1gm of cyclophosphamide, with recommendations to continue cyclophosphamide once a month for 6 months. His creatinine improved throughout his admission from 16.15mg/% to 6.60mg/% on discharge without the need for dialysis. The patient was discharge on Apixaban instead of Warfarin.

Discussion: Anticoagulant related nephropathy (ARN) is defined as an acute increase in serum creatinine of >0.3 mg/dl within 1 week of an INR >3.0. Chronic kidney disease and particularly patients with IgA Nephropathy are risks factor for ARN. We must be aware of the relationship of these two conditions and include IgA nephropathy in the differential diagnosis of glomerulonephritis in African American patients.



PUB598

Nephrosarca Causing Anasarca in an Elderly Male with Minimal Change Disease

Arun Rajasekaran,[1] Elpidio Abreu,[2] Pran M. Kar.[3] *[1]University of Central Florida College of Medicine, Kissimmee, FL; [2]Nephrology Associates of Central Florida, Ocoee, FL; [3]VA Medical Center Orlando, Orlando, FL.*

Introduction: Minimal Change Disease (MCD) rarely presents with nephrotic range proteinuria and acute kidney injury in adults. Nephrosarca, or severe edema of the kidney, has been proposed as a pathophysiological mechanism for this.

Case Description: A 75 year old male with chronic back pain (on long-term NSAIDs) presented with generalized body swelling, 10 kg weight gain, progressive dyspnea and decreased urine production worsening over a week. Vital signs were stable, and clinical exam revealed anasarca. Serum BUN (96 mg/dl) and creatinine (8.7 mg/dl, baseline 1 mg/dl) were elevated. Serum electrolytes, calcium, phosphorus, and magnesium were normal. Total protein was 5.3 mg/dl and albumin was 1.1 mg/dl. UA revealed 4(+) protein. A 24 hr. urine collection showed 5.9 g of protein, mainly albumin, and a creatinine clearance of 10 ml/min. SPEP and UPEP demonstrated hypoalbuminemia and hyperalbuminuria respectively. Serological workup including RF, ANA, ANCA, anti-dsDNA/anti-MPO/anti-GBM/anti-proteinase-3 antibodies, Hepatitis B & C panel, HIV, cryoglobulins, RPR, and complements C3/C4 was negative. Serum immunoglobulins levels were normal. Renal ultrasound showed kidneys' of normal size and echogenicity, but with moderate perinephric fluid. Renal biopsy depicted extensive and global foot process effacement with significant interstitial edema, consistent with MCD (likely secondary to chronic NSAID use). High doses of intravenous diuretics were ineffective, and early hemodialysis aided in achieving evolemia. He was started at 60 milligrams of prednisone per day, and his proteinuria and renal function improved in 4 weeks. Repeat renal ultrasound revealed no perinephric fluid.

Discussion: *Lowenstein et al.* proposed the theory of nephrosarca as a root cause in the pathophysiology of MCD by physically abetting vascular and tubular occlusion, consequently causing filtration failure. Our patient's nephrosarca and AKI did not revert by prompt reinstitution of euvolemia alone, but was temporarily concomitant with proteinuria remission in response to corticosteroids. Interestingly, our patient's nephrosarca resolution was captured on repeat renal imaging, which has not commonly been cited in the medical literature so far.

PUB599

Oxalate Nephropathy Leading to Acute Renal Failure

Meghana Chalasani,[1] Josephine Abraham,[1] Mazdak A. Khalighi,[2] Aylin R. Rodan.[1] *[1]University of Utah, Salt Lake City, UT; [2]Oregon Health and Science University, Portland, OR.*

Introduction: Hyperoxaluria is implicated in the development of nephrolithiasis and nephrocalcinosis and has also been shown to cause renal parenchymal disease with progression to end-stage renal disease. We present a patient with underlying CKD and pancreatic insufficiency who developed AKI secondary to oxalate nephropathy.

Case Description: A 75-year old man with a history of CKD IV and pancreatic adenocarcinoma s/p pancreaticoduodenectomy nine months ago presented to the emergency room complaining of nausea, fatigue, shortness of breath, and leg swelling for two weeks as well as decreased urine output for four days. Initial work-up revealed creatinine 11 mg/dL (baseline 2.5 mg/dL), hyperkalemia 6 mmol/L, and metabolic acidosis. Patient reported that since surgery he had been eating spinach daily and taking an herbal supplement containing kelp, thistle, rhubarb, and spinach. In addition, he stopped taking his pancreatic enzymes two months ago. He had also avoided dairy intake for many years. He has a history of kidney stones with analysis showing calcium oxalate, calcium phosphate, and uric acid. Urine microscopy was notable for pyuria, WBC casts, and muddy brown casts. Urine culture was negative. Patient underwent a percutaneous kidney biopsy which revealed acute tubular injury with extensive tubular calcium oxalate deposition and diffuse interstitial inflammation consistent with oxalate nephropathy. His diet has been adjusted to a low-fat, low-oxalate, high-calcium diet in addition to restarting pancreatic enzyme replacement. Patient has remained anuric requiring regular hemodialysis.

Discussion: Secondary hyperoxaluria often results from enteric hyperoxaluria (due to increased intestinal absorption), endogenous production, and/or increased dietary intake. Enteric hyperoxaluria results when intestinal oxalate is absorbed and is excreted in the urine, where it binds with calcium and deposits in the tubules. Renal parenchymal disease secondary to hyperoxaluria manifests as diffuse tubular deposition of calcium oxalate crystals and interstitial inflammation. Our patient, along with underlying CKD, also had malabsorption due to a pancreaticoduodenectomy as well as high oxalate and low calcium intake. Oxalate nephropathy has a poor prognosis and in this case the patient became dialysis-dependent. This case highlights the importance of gathering dietary habits as part of routine history-taking.

PUB600

Cocaine Induced Perinephric Hematoma

Geeta Bhagia, Rishi Raj, Samrah Zaigham, Wael Ghali. *Monmouth Medical Center, Long Branch, NJ.*

Introduction: Cocaine causes devastating effects on multiple organ systems. Renal complications range from kidney injury from rhabdomyolysis, progression of atherosclerosis, hypertensive nephrocalcinosis, end stage renal disease to rarely renal infarction. We present a rare case of perinephric hematoma associated with cocaine abuse in a young patient

Case Description: A 37-year-old Hispanic female with history of depression, hepatitis C and polysubstance abuse presented with left flank pain that started few hours after using intravenous cocaine. Pain was intermittent, colicky, 10/10 in intensity, aggravated by deep inspiration without any nausea or vomiting. On physical examination, she was febrile but hemodynamically stable, had left lower quadrant and costovertebral angle tenderness. Laboratory studies revealed leukocytosis with normal liver, renal and pancreatic function tests. Urinalysis revealed numerous RBCs. Renal ultrasound showed enlarged kidneys bilaterally with decreased echogenicity in left capsule without any evidence of hydronephrosis, tumor or calculi. Computed tomography (CT) of abdomen and pelvis with contrast showed large fluid collection surrounding left kidney originating from parenchymal defect in the inferior pole. Patient underwent CT guided aspiration of hematoma and aggressive blood pressure control. She was eventually discharged to rehabilitation facility

Discussion: Perinephric hematoma is defined as collection of blood in the subcapsular and perinephric space. It is a rare condition associated with renal neoplasms(renal cell carcinoma, angiomyolipoma), vasculitis, pyelonephritis, kidney stone, preeclampsia, eclampsia or coagulation disorders but it is a common complication of percutaneous nephrolithotripsy. Perinephric hematoma is rare complication seen in cocaine abusers. Most likely mechanism could be from severe hypertension associated with sympathetic stimulation in patients with cocaine abuse. The morbidity and mortality associated with this condition is high. CT scan is the diagnostic modality of choice. Conservative management with close follow-up is the mainstay of treatment but patients with associated tumor or those with uncontrollable hemorrhage are treated with nephrectomy. Our patient presented with left perinephric hematoma without any evidence of hemodynamic compromise or findings suggestive of malignancy. We managed our patient conservatively with frequent hemoglobin and hematocrit monitoring and fluid resuscitation

PUB601

A Case of Renin-Mediated Hypertension

Nitzy N. Munoz casablanca, Joselyn Reyes Bahamonde, Ana I. Velazquez. *Mount Sinai Beth Israel, New York, NY.*

Introduction: Renin-secreting tumors are a known rare cause of secondary hypertension with hypokalemia and metabolic alkalosis. Evaluation is remarkable for elevated plasma renin activity (PRA) and, in most cases, secondary hyperaldosteronism. Treatment options are limited with variable effectiveness data on the use of renin angiotensin aldosterone system blockers, making tumor resection the definite treatment. Our case highlights the importance of early recognition of reversible causes of hypertension, and its potential reduction of cardiovascular risk.

Case Description: A 23-year-old female with history of hypertension and hypokalemia, presented with 2 weeks of dyspnea on exertion, decreased exercise capacity, and mid-sternal sharp chest pain exacerbated by dry cough. On admission, her blood pressure was 195/144mmHg and she had jugular venous distention with clear lungs and no evidence of peripheral edema. Labs showed K 2.9mmol/L, CO2 29mmol/L, Cr 0.88mg/dL, pH 7.46, BNP 1492.3pg/mL, and UA >500 protein. EKG showed left ventricular hypertrophy. Chest x-ray revealed cardiomegaly and mild pulmonary edema. Findings were suggestive of new onset heart failure (HF) thus she was treated with aggressive diuresis. TTE confirmed left ventricular systolic and diastolic dysfunction. Evaluation of secondary causes of hypertension included Renal US and CT Abdomen/Pelvis which revealed an enhancing well-circumscribed 2.8cm renal mass arising from the left kidney. US doppler and CT angiogram showed no signs of high-grade renal artery stenosis or fibromuscular dysplasia. PRA was elevated to 29.794ng/mL/hr and aldosterone 52.4ng/dL. 24hr urinary collection of catecholamines and metanephrines was negative. A diagnosis of hypertension with end-organ damage due to renin-secreting tumor was made and our patient was referred for surgical tumor removal.

Discussion: Approximately 5% of patients with hypertension have reversible secondary causes. Renin-secreting tumors are considered a rare cause of secondary hypertension that should be considered in patients with concomitant hypokalemia and elevated PRA, especially when renovascular disease is ruled out. Our patient presented with HF and proteinuria in the setting of a suspected renin secreting tumor. Timely evaluation and treatment of secondary causes of hypertension is paramount to avoid mechanical injury, oxidative stress, and fibrosis along the renal and cardiovascular system.

PUB602

Amyloid Cast in a Case of Multiple Myeloma

Ping Lan, Liyi Xie, Jia Lv. Nephrology department, The First Affiliated Hospital of Xi'an Jiaotong University *Nephrology Department, First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China.*

Introduction: Cast nephropathy is the most frequent pathologic pattern of renal involvement in Multiple myeloma (MM), characterized with distal tubular casts that are composed of monotypic light chains. Here we present a case of MM with unusual cast.

Case Description: A 74-year-old Chinese male was referred to our hospital with complaint of extremities edema and fatigue for 4 months. He denied fevers, rashes, joint pain or weight loss. On admission, blood test showed WBC count 71600 with no shift, and platelets count 18000, and hemoglobin 98g/L. Urine test showed trace protein with no hemauria. Total urine protein in 24 hours was 12.43g/d with serum albumin 41g/L and normal renal function. ANCA, anti-GBM antibody, PLA2R antibody, autoantibodies and hepatitis virus were negative. Serum protein electrophoresis showed 5% M-protein. Both serum and urine immunofixation electrophoresis showed a band of lambda light chain. Bone marrow aspirate and biopsy confirmed multiple myeloma with 51% plasma cell. Renal biopsy: The specimen for light microscopy contained renal cortex with 10 glomeruli without globally sclerosis. The GBMs were almost normal without endocapillary hypercellularity or mesangial proliferation. No fuchsinophilic deposition was found. Tubular lumina contained several casts, and the interstitium was edematous with focal inflammation cells infiltration, mostly lymphocytes and monocytes. Arteries were almost normal. Congo Red and Oxide-Congo Red were only positive for several casts, with spicule formation at the rims. No immunoglobulin or complement components were positive by immunofluorescence microscopy (IF). Immunohistochemistry (IHC) test revealed lambda positive for certain casts. Electron microscopy (EM) showed 1glomeruli without any sign of amyloidosis or light chain deposition disease, but no casts were found. There were no electron dense immune complex deposits. This case was diagnosed Multiple myeloma (Stage III, lambda type), with amyloid cast nephropathy. He received PAD therapy (Bortezomib + Pirarubicin + Prednisolone) and revealed a good response.

Discussion: Cast nephropathy is characterized with casts of monotypic light chains. But there are rare cases showing amyloid casts, with spicule formation at the rims. Congo red staining, IHC and EM are helpful to confirm the diagnosis.

PUB603

Myeloma Cast Nephropathy in Elderly Patient Presenting as AKI

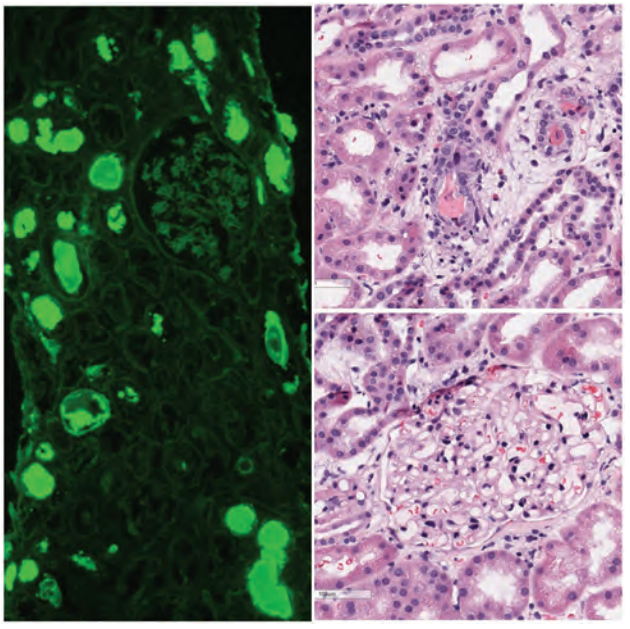
Sushma Edara, Madhu Kandarpa. *Kidney care specialists, Beavercreek, OH.*

Introduction: Multiple myeloma can present with various renal manifestations. Here we present a patient with acute kidney injury diagnosed as Myeloma cast nephropathy on kidney biopsy.

Case Description: 90-year-old healthy female with a history of treated endometrial cancer and osteoarthritis presented with creatinine of 7mg/dl (baseline creatinine 0.7mg/dl) and potassium 5.3mmol/l on routine laboratory testing done by her primary care physician. Urine is clear with specific gravity of 1.010. Renal ultrasound is normal with no hydronephrosis or renal artery stenosis. Complement levels are normal, c-ANCA negative and p-ANCA positive 1:320. Despite adequate hydration her creatinine improved only to 6.4mg/dl. Kidney biopsy showed Acute tubular necrosis and myeloma cast nephropathy with normal glomerulus. Protein electrophoresis demonstrated monoclonal lambda light chains in serum and free lambda light chains of 10934mg/l in urine. Bone scan showed lytic lesions suggestive of multiple myeloma. Bone marrow biopsy is diagnostic of monocytic lambda-expressing plasma cell neoplasm (65.6% plasma cells) with coexpression of CD56, CD38 and CD138. Patient is requiring hemodialysis and is being considered for specific regimen to treat myeloma.

Discussion: Despite increased risk of bleeding at her age, kidney biopsy was performed as diagnosis is unclear. The diagnosis of cast nephropathy is based on the demonstration of

tubular casts in distal nephron that are composed of immunoglobin light chains. Light chain casts generate intense inflammation via the activation of c-Src and NF-κB, and subsequent chemotaxis of immune cells further damaging the kidney tubules. If the obstruction is not eliminated, the damage becomes irreversible. Patients who are promptly diagnosed with myeloma cast nephropathy and rapidly commenced on disease-specific therapy have better outcomes.



PUB604

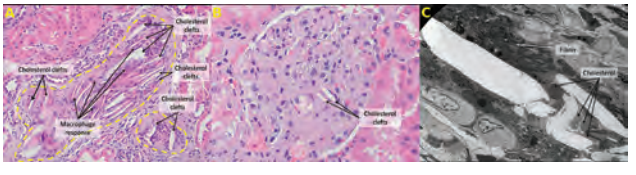
Severe Atheroembolic Renal Disease (AERD) Contributing to Renal Failure

Vidhit Puri,[1] Pridvi Kandagatla,[1] Nishant K. Puri,[1] Gunjan Garg,[1] Tina Nigam,[1] Sowmya Goranta,[2] Evan A. Farkash,[1] Rachel Perlman.[3] *[1]University of Michigan, Ann Arbor, MI; [2]Hurley Medical Center, Canton, MI; [3]UM Health Center, Ann Arbor, MI.*

Introduction: AERD is the occlusion of renal arterioles by cholesterol crystal emboli. These emboli often originate from atherosclerotic plaques along major arteries. They can circulate after an endovascular procedure or the initiation of anticoagulation. We present a case of severe AERD with an unusually extensive cholesterol burden associated with remarkably notable histopathological findings.

Case Description: A 74 year old male presented with weakness, anorexia, and low urine output. His recent history was notable for iliac artery stenting four months prior for claudication, and an interval ICU admission for burns, sepsis, and AKI. At admission, exam findings were significant for eschars on bilateral great and fifth toes. Lab values showed leukocytosis (16.9 x 10^9/L), eosinophilia (13%), and creatinine of 4.37 mg/dL (baseline 1.2). Work-up revealed bland urine sediment, minimal proteinuria, and normal renal US and complement levels. Despite fluid resuscitation, his renal function declined with no clear etiology. A renal biopsy revealed cholesterol clefts with a phagocytic reaction in the arcuate and intra-lobular arteries, arterioles, and glomerular capillaries across multiple tissue cores. Electron microscopy (EM) also showed occluded arteries with crystalline voids and intact cholesterol crystals. Imaging demonstrated an unstable aortic dissection presumed to be source for the atheroemboli. Not being a surgical candidate, his renal function continued to deteriorate, and hemodialysis was initiated.

Discussion: AERD can be challenging to diagnose; it requires a biopsy, the clefts can mimic processing artifacts, and it is frequently an incidental finding. Our case uniquely illustrates not only some of the common clinical findings associated with this entity, but it also exemplifies severe manifestations of this disease on pathology. Extensive cholesterol emboli involving vessels of multiple sizes, including documentation of cholesterol crystals by electron microscopy (Fig.1), is truly a rare presentation of this disease.



Cholesterol emboli present in multiple arteries in multiple cores: Large Intralobular Artery and Branches (A), Glomeruli (B), and EM (C).

PUB605

Cryofibrinogen-Associated Glomerulonephritis in a Patient with Rheumatoid Arthritis: A Rare Disease Without Immune Complex Type Electron Dense Deposits, but with Fibrillary Organized Deposits

Saeko Hatanaka,[1] Kentaro Koike,[1] Nobuo Tsuboi,[1] Ryuji Ohashi,[2] Tetsuya Kawamura,[1] Akira Shimizu,[3] Takashi Yokoo.[1] *[1]Division of Nephrology and Hypertension, Department of Internal Medicine, The Jikei University School of Medicine, Setagaya-ku, Japan; [2]Department of Diagnostic Pathology, Nippon Medical School Musashikosugi Hospital, Kanagawa, Japan; [3]Department of Analytic Human Pathology, Nippion Medical School, Tokyo, Japan.*

Introduction: Cryofibrinogen (CF) is a cryoprecipitate produced during the process of plasma refrigeration via the structural alteration of serum fibrinogen. To date, there are only a few reported cases of glomerulopathy associated with CF, and thus its clinicopathological aspects remain uncertain. Herein, we present a case of membranoproliferative glomerulonephritis (MPGN), characterized by the absence of immunoglobulin deposits and the presence of organized electron dense deposit (EDD), suggestive of CF-induced glomerulonephritis associated with rheumatoid arthritis (RA).

Case Description: A 72-year-old man, who had been followed-up for RA, visited our hospital with proteinuria and microscopic hematuria lasting over the last 1 year. At presentation, his serum creatinine (Cr) level was 1.69 mg/dL, and urinalysis found protein excretion of 4.6 g/day and many red blood cells. By laboratory work-up, all autoantibodies were negative except anti-cyclic citrullinated peptide antibody, and plasma cryoglobulin or M-protein were not present. Renal biopsy found MPGN, accompanied by glomerular basement membrane (GBM) rupture with fibrin exudation. By immunofluorescence microscopy, no immunoglobulin, or light or heavy chain deposition was found; however, subendothelial and subepithelial EDD were observed along GBM by electron microscopy. Of note, fibrillary materials with luminal diameter ranging from 50 to 100 nm were focally recognized within EDD. Those histological findings were suggestive of CF-associated glomerulonephritis. Subsequently, the patient was treated with corticosteroid, and the serum Cr decreased and the hematuria and proteinuria resolved in 12 weeks.

Discussion: CF-associated glomerulonephritis is an extremely rare disease as only a few cases are reported in the English literature. In the present case, we speculated that CF was produced in association with the patient's long standing RA. Our findings may provide insight into the underlying etiology and further help reveal morphological spectrum of this unique disease entity.

PUB606

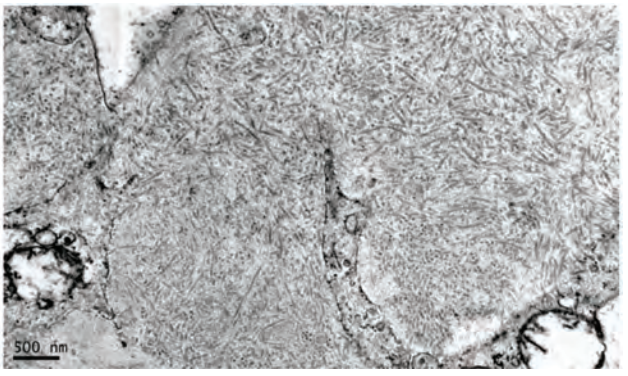
Fibrillary Glomerulonephritis (GN) with Amyloid-Like Fibrils Confirmed by Mass Spectrometry

Sylvester Barnes,[1,2] David J. Leehey,[1,2] Maria M. Picken.[1] *[1]Loyola University Medical Center, Maywood, IL; [2]Hines VA Hospital, Hines, IL.*

Introduction: Fibrillary GN is a nephritic syndrome characterized by Congo red negative glomerular fibrillary deposits. On electron microcopy (EM) the fibrils are oriented randomly, lack hollow centers, and are generally 16-24 nm in diameter. DNA heat shock protein family member B9 (DNAJB9) has been identified as a potential protein marker for this disease on biopsy.

Case Description: A 54 YOF was seen in clinic because of elevated serum creatinine (2.1 mg/dL). She was obese with uncontrolled hypertension but no evidence of diabetes. UA revealed 3+ protein with 3 RBCs/hpf. The UPCR ratio was 4.94 g/g with UACR of 3.3 g/g. Biopsy yielded 16 glomeruli; 5 showed mild mesangial expansion, 3 segmental sclerosis, and 8 global sclerosis. Congo red staining was negative. No glomeruli were present in tissue sent for IF. EM showed non-branching fibrils measuring between 8.8 - 15 nm in width localized in the mesangial matrix (Figure). Since the fibril size overlapped with that seen in amyloid, laser microdissection-tandem mass spectrometry (LMD-MS/MS) was used to determine the composition of the fibrils. This yielded abundant protein corresponding to DNAJB9. There was no evidence of monoclonal gammopathy. Renal function has continued to deteriorate and she is being evaluated for renal transplantation.

Discussion: Fibrillary GN is a rare cause of GN. Traditionally, Congo red stain and EM are used to distinguish between fibrillary GN and amyloid deposits; however, amyloid deposits may show variable affinity for Congo red stain. By EM, amyloid fibrils are typically 8-12 nm wide while fibrils in fibrillary GN are usually twice this size (16-24 nm), although there is considerable overlap with amyloid. Before interpreting fibrillary deposits as amyloid in specimens where Congo red stain is negative additional testing is prudent. Studies have shown that DNAJB9 is found in almost 100% of fibrillary GN by LMD-MS/MS and immunostains. In view of the absence of IF data, LMD-MS/MS demonstrating DNAJB9 protein was used to verify the diagnosis of fibrillary GN in this patient.



EM

PUB607

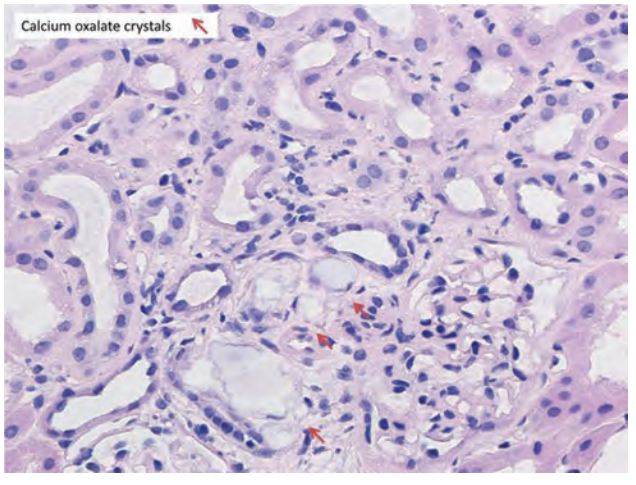
An Unexpected Cause of Acute Oxalate Nephropathy – or Is It?

Ambreen Azhar,[2] Steven D. Smith,[1] Mubasshar Rehman.[2] *[1]Icahn School of Medicine at Mount Sinai/St Luke's-Roosevelt Hospital Center, New York, NY; [2]Mount Sinai Saint Luke's and mount Sinai West, NYC, NY.*

Introduction: Acute oxalate nephropathy may result from increased intestinal absorption of oxalate due to: 1) excessive oxalate intake 2) fat malabsorption syndromes enteric hyperoxaluria or 3) alterations of gut flora depleting oxalate degrading bacteria including the obligate anaerobe Oxalobacter formigenes. During small bowel transplantation (SBT) the gut microbiome is destroyed and the new gut flora with ileostomy is composed of facultative anaerobes.

Case Description: 55 y/o female with h/o SMA rupture requiring SBT and ileostomy presented with multiple episodes of non-oliguric AKI 1yr post txp attributed to high stoma output with volume depletion. Baseline cr pretxp was 0.7mg/dl, peaked at 3.3 and improved to 1.44mg/dl with IVFs but never returned to baseline. U/A and abd CT w/o contrast unremarkable. A small intestinal biopsy ruled out rejection. After the third episode of AKI a native renal biopsy was performed that revealed ATN with calcium oxalate crystals suggesting a possible dx of acute oxalate nephropathy. The patient was treated with increased fluid intake, low oxalate diet, calcium supplementation with meals and a low fat diet. Another clinician questioned how a patient with an ileostomy could develop acute oxalate nephropathy since most oxalate absorption occurs in the large bowel. A relook at the biopsy revealed only sparse crystals in the tissue not refractile under polarized light (as would be expected with calcium oxalate). A von Kossa stain (which picks up phosphate) was not performed. The dx of acute oxalate nephropathy was deemed unlikely contrary to the initial preliminary report.

Discussion: Nephrology remains a fascinating field because it demands that we understand pathophysiology and that things "make sense". This case illustrates that nephrologists must use their clinical knowledge of the patient and be skilled in interpreting renal biopsies even if they are not pathologists. This includes being aware of the limitations and possibilities that a biopsy may offer.



PUB608

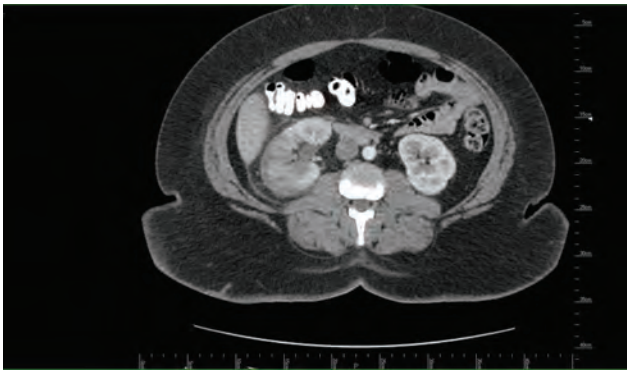
Acute Renal Infarction – A Diagnostic Challenge in a Young Female

Goni Katz Greenberg,[1] Ummerubab Syeda,[2] Rakesh Gulati.[2] *[1]Thomas Jefferson University and Hospital, Philadelphia, PA; [2]Thomas Jefferson University Hospital, Philadelphia, PA.*

Introduction: Acute renal infarction is a rare but serious event that continues to present a challenge in diagnosis and treatment.

Case Description: A 37-year-old morbidly obese female was admitted to an outside hospital with acute onset of severe right flank pain with nausea and vomiting. Past medical history was notable for dysfunctional uterine bleeding, migraine and psoriatic arthritis. Medications included Topiramate and OCP (high estrogen content) that were started 6 weeks prior to presentation. No history of miscarriages, but family history was significant for SLE. Physical exam was remarkable for mild hypertension, BMI 50, and RLQ tenderness. Laboratory tests: Cr 1.19mg/dL, LDH 2124 and normal PTT. CT scan showed right renal multifocal peripheral areas of decreased enhancement, consistent with infarction, confirmed by CT angiography. She was discharged on enoxaparin injections, and presented 3 months later for a second opinion. Livedo reticularis was noted on lower extremities. Echocardiogram was normal. Laboratory tests: normal LDH, platelets $289x10^9$/L; anti cardiolipin, anti b2 glycoprotein-1, lupus anticoagulant, anti-ds DNA, ANA, C3/C4, were all WNL. Repeat testing at 12 weeks was all negative.

Discussion: Although the most common etiology for renal infarction is thromboembolic originating from the heart or aorta, obesity, high estrogen OCP, or a hypercoagulable state can be associated with in situ thrombosis. In this reported case, clinical findings point to the diagnosis of antiphospholipid syndrome: history of migraines, no cardiac pathology, presence of livedo reticularis and thrombocytopenia during acute presentation. However, auto antibodies (anti-cardiolipin, anti b2 glycoprotein and lupus anticoagulant) were negative. The etiology of renal infarct was therefore attributed to morbid obesity and high estrogen OCP. Long-term aspirin use was recommended by hematology. Conclusion: With negative cardiac source and APLS workup, morbid obesity and high estrogen OCP should be considered in the differential diagnosis for acute renal infarction.



PUB609

Adenovirus Associated Acute Interstitial Nephritis (AIN) in a Patient with Follicular Lymphoma

Jessica M. Nelson, Isabelle Ayoub, Sergey V. Brodsky, Jason Prosek, Salem Almaani. *Ohio State Wexner Medical Center, Columbus, OH.*

Introduction: Adenovirus is a non-enveloped, double-stranded DNA virus known to cause upper respiratory, gastrointestinal, and conjunctival infections in healthy individuals. However, more significant disease is commonly observed in immunosuppressed patients. Those with renal allografts commonly develop adenoviral urinary tract infections. Patients can have disseminated disease, but this is quite rare. Bendamustine-Rituximab combination is a therapy option for the treatment of Follicular Lymphoma. Bendamustine is an alkylating agent that causes DNA damage. Its action is more pronounced in rapidly proliferating cells such as lymphocytes, causing rapid and sustained depletion. This case describes an unusual presentation of pyelonephritis secondary to adenovirus in a patient without a history of transplantation.

Case Description: A 70-year-old Caucasian female presented to our medical center for evaluation of persistent unilateral flank pain with radiological evidence concerning for pyelonephritis. Her medical history is significant for a recent diagnosis of stage IV follicular lymphoma the previous year, treated with 6 months Bendamustine-Rituximab that she completed 6 weeks prior to presentation. She had sought medical care weekly for three weeks, with right flank pain sans dysuria. She described one episode of gross hematuria at her initial presentation but no further episodes. CT and PET scans revealed unilateral perinephric stranding, concerning for pyelonephritis, that persisted on repeat imaging despite adequate antibiotic therapy. Renal biopsy was performed to rule out renal lymphoma. Renal biopsy was consistent with adenoviral interstitial nephritis. At the time of presentation her CD4 count was 86 cells/mm3. Her serum adenoviral load was 4696 copies/mL, urine 96,631 copies/mL. She was treated with Cidofovir. Current serum and urine viral loads are less than 500 copies/mL, or within normal limits.

Discussion: Bendamustine is a chemotherapy agent known to cause prolonged lymphocyte depletion. Therefore, these patients are at a higher risk for the development of common bacterial and viral infections including CMV, EBV, and adenovirus. Physicians

should be vigilant about the prolonged immunosuppressive effects of chemotherapeutic agents, and keep a low index of suspicion for unusual culprits of infection in this population.

PUB610

Know Your HBsAg Testing Method

Karthik Kovvuru, Prakrati C. Acharya, Pradeep Vaitla, Divya Monga. *University of Mississippi Medical Center, Ridgeland, MS.*

Introduction: Center for Medicare and Medicaid services (CMS) requires isolation of Hepatitis B surface antigen(HBsAg) positive patients on dialysis. We encountered a unique situation with our patient's (pts) positive screening HBsAg, negative confirmatory HBsAg and negative Hepatitis B (Hep B) PCR.

Case Description: 41 Yr old male with HIV (on Rx, undetectable HIV RNA, CD4 - 186)) and untreated Hepatitis C (viral load 3,500,000) was admitted to the hospital for worsening CKD requiring initiation of dialysis. He reportedly received last dose of Hep B vaccination series 3 months prior to admission and his screening HBsAg turned positive both immediately and a month after the vaccination series with a negative confirmatory HBsAg and Hep B PCR. Dialysis was initiated and Hep B status re-checked to help with outpatient dialysis placement. His screening HBsAg came back positive again with negative results for confirmatory HBsAg, Hep B antibody and Hep B PCR twice. His placement became challenging as our lab reported that his screening HBsAg is positive despite his confirmation test being negative. We requested CDC assistance and sent them blood samples. Meanwhile we arranged outpatient dialysis at our hospital with a dedicated machine and chair, in accordance with CMS regulations. CDC reported that the surface antigen and Hepatitis B PCR are negative and he was subsequently placed in a non isolation chair at outpatient dialysis center.

Discussion: Our lab uses Abbott architect which tests for HBsAg in two steps "HBsAg Qualitative" and "HBsAg Qualitative confirmatory". The first test is highly sensitive and gives false positive results when Hepatitis C viral load is high or other antibodies are present. The second test uses a reagent to neutralize the false positives and is specific. Our pt had very high Hepatitis C viral load and this was responsible for the false positive screening test. Due to the multiple testing modalities used (CDC uses Ortho Clinical Vitros HBsAg) we should learn how to interpret the local lab and incorporate into clinical practice. Also we need broader guidelines from CMS so that these tests can be interpreted without confusion.

PUB611

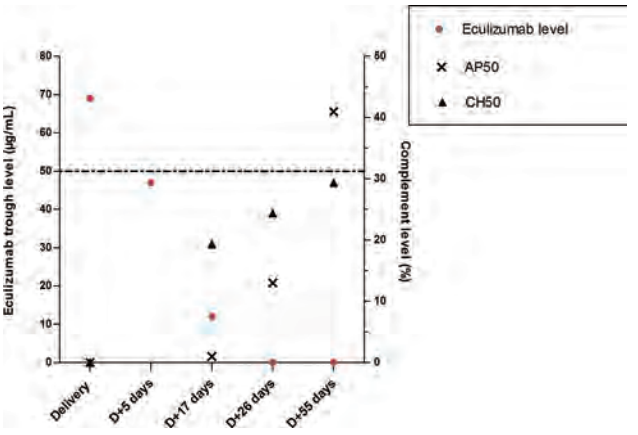
Placental Passage of Eculizumab and Complement Blockade in a Newborn

Caroline Duineveld,[1] Kioa L. Wijnsma,[2] Elena Volokhina,[3] Nicole Van De Kar,[2] Jack F. Wetzels.[1] *[1]Department of Nephrology, Radboudumc, Nijmegen, Netherlands; [2]Department of Pediatric Nephrology, Amalia Children's Hospital, Nijmegen, Netherlands; [3]Department of Laboratory Medicine, Radboudumc, Nijmegen, Netherlands*.

Introduction: Atypical hemolytic uremic syndrome (aHUS) and paroxysmal nocturnal hemoglobinuria (PNH) are rare complement mediated disorders, often affecting women of childbearing age. Because of severe maternal and fetal morbidity and mortality, pregnancy used to be discouraged. The introduction of the complement inhibitor eculizumab has contributed to successful pregnancies. Eculizumab can cross the placenta, and thus may inhibit the complement system of the newborn.

Case Description: A 30 year-old mother, known with aHUS and without treatment, presented at 8 weeks of gestation, with a rise in serum creatinine (from 100 µmol/L to 219 µmol/L), progressive proteinuria and evidence of thrombotic microangiopathy (thrombocytes $91x10^9$/L, undetectable haptoglobin and LDH 309 U/L). Treatment with eculizumab was started (900 mg weekly for four weeks, followed by 1200 mg biweekly), resulting in normalization of hematological parameters and improvement in renal function. At 36^{+1} weeks, after a spontaneous vaginal delivery, a healthy infant of 2010 gram was born. The mother had received her regular eculizumab dose 1 day before delivery. The eculizumab trough level was 262 µg/ml. Eculizumab was detectable in the cord blood of the newborn: free eculizumab level was 69 µg/ml. Evaluation of the complement cascade revealed complete blockade (Figure). Recovery was slow, and lasted > 3 weeks. The newborn was prophylactically treated with amoxicillin until normalization of the complement.

Discussion: Passage of eculizumab resulted in a therapeutic eculizumab level and full complement blockade in the newborn. During follow-up the alternative complement pathway remained blocked for several weeks while eculizumab levels decreased. This may be the result of physiologically low neonatal complement levels. Based on our observation we recommend assessment of drug levels and complement activity in newborns from eculizumab-treated mothers. Prophylactic treatment of newborns with antibiotics should be considered.



PUB612

Complement Factor I Gene Mutation with Normal Factor I Activity in a Child with ESRD Secondary to Atypical HUS

Kathleen E. Altemose,[1] Asha Moudgil,[2] Meredith A. Atkinson.[1] *[1]Johns Hopkins University School of Medicine, Baltimore, MD; [2]Children national Medical Center, Washington, DC.*

Introduction: Complement factor I (CFI) regulates the deleterious cytotoxic and inflammatory activity of the alternate complement pathway. CFI deficiency is a rare cause of atypical HUS (aHUS). We report a child diagnosed with ESRD secondary to aHUS who was found to have a CFI gene mutation with normal CFI activity.

Case Description: Our patient is a 10 yo boy with history of an encephalocele, seizures and hypertension who presented with hypertensive urgency and acute deterioration of renal function (serum creatinine 8.7 mg/dL) requiring CRRT. Following admission, his hemoglobin and platelets declined, requiring multiple blood product transfusions. Work-up for causes of acute on chronic renal failure were negative, including duplex US without renal artery stenosis, negative renal angiography, and negative serologies (ANA, anti-double stranded DNA and hepatitis panel). C3 was low at 64 mg/dl and C4 was normal on admission. Renal biopsy was significant for global glomerulosclerosis and tubular atrophy. HUS evaluation showed elevated LDH, normal haptoglobin, smear with schistocytes, and a normal ADAMTS13. Whole exome sequencing (GeneDx, OPKO Health) showed heterozygosity for a G119R variant classified as "likely pathogenic" in the CFI gene inherited from the paternal side. TMA complement panel (Cincinnati Children's Hospital) revealed normal Factor H and B activity. Factor I activity was also normal at 3.2 mg/dl (reference range 2.4-4.9 mg/dl). The patient received a deceased donor renal transplant ~10 months after initial presentation. Due to genetic mutation in CFI, he has been treated with IV eculizumab at time of transplant and every 2 weeks since transplant. He had one episode of anemia requiring blood transfusion but has maintained his platelets in normal range with excellent allograft function (creatinine 0.5 mg/dl).

Discussion: In this patient with a known variant in the CFI gene and a history of ESRD, Factor I activity as measured on a TMA complement panel was within normal range. However, clinical presentation is consistent with aHUS, and he has remained stable on biweekly IV eculizumab infusions -post-transplant. This case supports the value of genetic investigation for causes of aHUS, even in the setting of normal factor H and/or I levels, in order to prevent disease recurrence after renal transplantation.

PUB613

Acute Antibody-Mediated Rejection in a Zero Mismatch Living Donor Pediatric Kidney Transplant Due to an Anti-HLA-DP Donor-Specific Antibody

Neha D. Pottanat,[1,3] Hiren P. Patel,[1] Rose M. Ayoob,[1] Peter B. Baker,[4] Hemant K. Parekh.[2] *[1]Nationwide Children's Hospital, Columbus, OH; [2]Ohio State University Wexner Medical Center, Columbus, OH; [3]Riley Hospital for Children/Indiana University, Indianapolis, IN; [4]Nationwide Childrens Hospital, Columbus, OH*.

Introduction: Donor-specific antibodies (DSAs) against human leukocyte antigens (HLA), particularly anti-HLA-DP, have been associated with development of acute/chronic rejection in highly sensitized (due to a previous transplant) HLA-matched renal allografts recipients. We present a case of a 6 year-old male with **no** prior sensitization, who received a zero mismatch living-related donor kidney transplant from his mother and developed acute antibody mediated rejection (AMR) due to an anti-(HLA)-DP DSA.

Case Description: The recipient and donor were a 10/10 antigen match for HLA-A, B, C, DR, and DQ and the flow cytometric T- and B-cell crossmatches were negative. The recipient was given induction immunosuppression with five daily doses of antithymocyte globulin (total dose of 4.7 mg/kg) and steroids tapered over 6 days. Maintenance immunosuppression included mycophenolate mofetil (MMF) and tacrolimus every 12 hours. Our maintenance immunosuppression protocol targets the following goal tacrolimus troughs: 7-12 ng/mL for months 0-3 and 5-10 ng/mL for months 4-6. Due to our recipient's low immunological risk, we reduced the goal to ≥5 ng/mL for months 0-3. Furthermore, his MMF dose was reduced during this time due to neutropenia. No DSAs were identified in

the first 6 months. Over the next year, the recipient had a slow increase in serum creatinine from 0.4 mg/dL to 0.6 mg/dL. He developed a *de novo* DSA to HLA-DPB1(MFI = 8377) at 14 months post-transplant. Pathology met Banff 2013 criteria for acute AMR. He received two doses of 1 g/kg intravenous immunoglobulin (IVIG) and one dose of 375 mg/m2 Rituximab. His serum creatinine has remained stable and unchanged after treatment.

Discussion: Due to low immunological risk (10/10 HLA antigen match) our patient received reduced maintenance immunosuppression for the first 3 months post-transplant. However, despite being a *pediatric* non-sensitized recipient with an apparently well-matched renal allograft and receiving complete induction immunosuppression, the patient developed acute AMR after developing DSA against the mismatched HLA-DP antigen. This report highlights a role for evaluating DP antigen mismatch before making adjustments to immunosuppression protocols.

PUB614

Arginine Induced Metabolic Acidosis and AKI

Rami Batarseh. Texas Tech University Health and Science Center - Permian Basin *Texas Tech University health and science center - Permian Basin, Odessa, TX.*

Introduction: Arginine (Arg) among multiple OTC supliments used for various medical conditions. Under appropriate dose and chemical form it is not toxic to cells**,** high doses >9 gm/day are associated with adverse effects in some subjects.

Case Description: 65 years old female patient self treating her hypertension with OTC Arg, for 10 years with poor efficacy, increased her dose gradualy to a total of 45 – 60 mg/day. Presented confused, lab workup showed a Non Anion Gap Metabolic acidosis, with elevated Creatinine, Arg over dose revealed from history and the patient was started on NaHCO3 infusion and hydration, condition improved gradually till completely resolved.

Discussion: Arginine is available in different structures, among which is Arg-HCL, HCL group is added to improve solubility, Side effects are largely related to the HCl group resulting in rapid drop in pH causing metabolic acidosis leading to hyperkalemia, Arginine markedly impairs bicarbonate reabsorption in the proximal convoluted tubules, hence inducing proximal renal tubular acidosis with hypophosphatemia without a renal phosphate leak. Infusion of Arg-HCL causes profound impairment of bicarbonate reabsorption. Management is mainly supportive with IV NaHCO3 and hydration with correction of electrolyte abnormalities. Fatal dose have been reported in pediatric population

Table 1: Patient's Abnormal lab results on admission and on discharge

	Reference	Admission	Discharge
pH	7.32 – 7.45	7.15↓	
PCO2	35 – 45 mmHg	14↓	
HCO3:	22 – 24 mmol/L	<5↓	35
creatinine:	0.6-1.3 mg/dL	2.4↑	1.0
Blood Urea Nitrogen	7-21 mg/dL	87↑	40
Na	136-144 mmol/L	143	145
K	3.6-5.1 mmol/L	3.4↓	2.6
Anion Gap	5.5-14.6 mmol/L	14	7
Phosphorus	2.3 – 7 mg/dL	5.3	3.5
Mg	1.8-2.5 mg/dL	2.9↑	1.8
Glucose	70-100 mg/dL	L 143↑	123

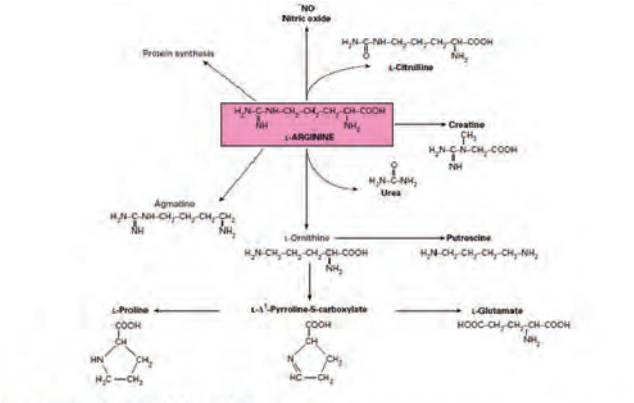


Figure 1 Metabolic fates of arginine in mammalian cells

The five enzymes on which the central fluxes of the pathways are based include tetrahydrobiopterin from the rapid nitric oxide synthase (NOS), arginine:glycine amidinotransferase, arginase, ornithine decarboxylase and arginyl-tRNA synthetase.

PUB615

Hepatorenal Failure with Mushroom (Amanita) Poisoning

Huiwen Chen. *University of Pittsburgh Medical Center, Pittsburgh, PA.*

Introduction: Toxic mushroom ingestions can lead to many symptoms including gastroenteritis, seizures and multiorgan failure depending on the toxins involved. Here, we describe a case of acute hepatorenal failure secondary to amatoxin.

Case Description: A 75-year-old male with hyperlipidemia presented to the emergency department (ED) with nausea, vomiting, and diarrhea for two days following ingestion of wild mushroom. Symptoms started 24 hours after a plateful of cooked mushrooms from his backyard. He also complained of inability to urinate. Temp 36.4 C, BP 116/87, Pulse 97, RR 24, Sao2: 99% room air. Physical exam did not have any gross abnormality. Foley yielded 400 cc urine. Labs: hemoglobin19, hematocrit 54.1, platelet 155, sodium 127, Potassium 4.6, chloride 91, bicarbonate 16, bun 75 and creatinine 5.48 Aspartate aminotrasferase 4879, Alanine aminotransferase 9212, Total bili 2.6. Patient had normal kidney function at baseline per his recollection. Given the patient's hepatic injury and unknown mushroom type, he received N-acetylcysteine to reduce potential toxic conversion in the liver, methylprednisolone for potential interstitial nephritis, silymarin to interrupt the enterohepatic circulation of amatoxin, charcoal to absorb the toxin, and penicillin G to increase renal toxin excretion. Plasmapheresis was performed given case reports of successful toxin removal in amatoxin ingestions. Dialysis was initiated given profound azotemia, and he was set up for outpatient hemodialysis (HD) prior to discharge. Amanita virosa was identified based on photos.

Discussion: Amatoxin manifests with symptoms of nausea, vomiting and diarrhea occurring within 24 hours after ingestions followed by multiorgan failure, most notably fulminant hepatic failure and rarely renal failure. Amatoxin is a peptide with molecular weight 900 DA, and it has a high affinity for charcoal as well as polymers found in hemoperfusion cartridges and HD. The best way to remove amatoxin would be hemoperfusion or HD because of its small molecular weight and large volume of distribution. Plasmapheresis in theory would not provide any benefit. Teaching point: It is important to note that the efficacy of treatments of mushroom toxicity is based on small series and there are no randomized controlled trials to address the efficacy of treatments. Given the uncertain role of extracorporal support in toxin management, one should carefully weigh the risks and benefits of these procedures.

PUB616

Appearances Should Not Deceive the Nephrologist

Gajapathiraju Chamarthi, Abhilash Koratala. *University of Flroida, Gainesville, FL.*

Introduction: Hydroxocobalamin causes reddish discoloration of the urine, mimicking hematuria. Clinicians should be aware of this common side effect of the rarely used drug to prevent unnecessary consultations and work up. Additional benign causes of red urine include foods such as beets, rhubarb and medications such as rifampin, phenazopyridine.

Case Description: A 70-year-old woman with a history of multiple abdominal surgeries in the past was admitted for incisional hernia repair and adhesiolysis. The procedure was complicated by bowel injury leading to peritonitis and refractory septic shock with a mean arterial pressure less than 60 mmHg. A trial of intravenous Hydroxocobalamin 5g was given, in an attempt to improve the blood pressure as a last resort, as she was hypotensive despite being on multiple vasopressors. Subsequently, she developed reddish discoloration of the urine, which appeared to be gross hematuria [Figure]. However, urine microscopy was negative for red blood cells and the chromaturia was due to hydroxocobalamin administration.

Discussion: Hydroxocobalamin is the hydroxylated active form of vitamin B12, which is approved for the treatment of cyanide poisoning. Approximately 18-28% of healthy subjects receiving hydroxocobalamin develop elevated blood pressure as a side effect. This moderate pressor effect is likely due to its nitric oxide scavenging effects and this drug is sometimes used as an off-label treatment for vasoplegic syndrome. Hydroxocobalamin can impart reddish to purple color to the urine, which can persist for up to 35 days following intravenous infusion. While this side effect is benign, it is important to note that it can alter colorimetric laboratory measurements and interfere with hemodialysis by triggering a false blood leak alarm.

PUB617

The Ups and Downs of Diarrhea

Krystahl Z. Andujar, Ileana E. Ocasio Melendez, Fatima B. Cintron-Rosa. *Nephrology, University of Puerto Rico - Medical Sciences Campus, San Juan, Puerto Rico*.

Introduction: Despite increased intestinal transit times, a paradoxical rise in tacrolimus levels is a rare complication in diarrheal illness. We present the case of a renal transplant patient on a stable dose of tacrolimus that had to be adjusted after the onset of severe diarrhea.

Case Description: A 70-year-old man with end stage renal disease secondary to hypertension status-post renal transplant in 2007 presented to the emergency department with more than 20 episodes of watery diarrhea, anorexia and abdominal pain. He had travelled from Massachusetts to Puerto Rico two days prior and had been treating his symptoms unsuccessfully with oral hydration. He had no sick contacts and onset of symptoms occurred hours after consuming a sandwich containing mayonnaise during his flight. Long term immunosuppressive regimen included tacrolimus 2 mg every 12 hours, mycophenolate mofetil (MMF) and prednisone. Upon evaluation, he had dry mucous membranes, tachycardia and a tender abdomen. Laboratory results demonstrated severe metabolic acidosis and creatinine levels of 7.3 mg/dL from his baseline creatinine of 2 mg/dL. He was started on intravenous (IV) isotonic fluids and bicarbonate; however, due to refractory metabolic acidosis, intermittent hemodialysis (HD) was started. HD was placed on hold after one session and IV hydration was continued for hypovolemia. Tacrolimus trough levels were supratherapeutic at 37.9 ng/dL and dose was decreased. MMF was placed on hold. Stool and blood cultures, fecal leukocytes, clostridium difficile toxin and CMV titers were negative. After the resolution of diarrhea, tacrolimus trough levels were subtherapeutic and dose was readjusted. He was discharged with stable dose of tacrolimus and baseline renal function.

Discussion: Due to intestinal metabolism by cytochrome P450 (CYP3A4) and active secretion from enterocytes into intestinal lumen by P-glycoprotein, tacrolimus has low oral bioavailability. In the setting of diarrhea, enterocytes are damaged, leading to both increased absorption and decreased gut metabolism of tacrolimus. The impaired gut mucosa leads to increased drug levels despite increased transit times. As the gut heals, CYP3A4 and P-glycoprotein begin to function normally, and tacrolimus levels fall. Therefore, as tacrolimus trough levels may abruptly rise and fall during diarrhea, their intense monitoring is recommended.

PUB618

Hypernatremia and Neurosurgery: Not Always What It Seems

Keysha Lopez vega, Ileana E. Ocasio Melendez, Krystahl Z. Andujar, Stephanie Colon Lopez, Mariela Marquez Pantoja, Carlos G. Rivera-Bermudez, Fatima B. Cintron-Rosa. *Nephrology, University of Puerto Rico - Medical Sciences Campus, San Juan, Puerto Rico*.

Introduction: After a neurosurgical procedure, the expected etiology of hypernatremia would be central diabetes insipidus (CDI). However, in a patient with psychiatric illness, poor water access may reveal another culprit for electrolyte disturbance. We present the case of nephrogenic diabetes insipidus (NDI) in a patient on chronic lithium use.

Case Description: A 63-year-old woman was admitted to the neurosurgical unit following a left temporal lobe mass resection. Nephrology service was consulted two days after surgery for a sodium of 172 mEq/L. Medical history was significant for bipolar disorder on chronic lithium therapy for more than 20 years. A direct medical history could not be obtained due to altered mental status but her son reported that she had complained of thirst, increased fluid intake and urinary frequency. Upon evaluation, patient had dry mucous membranes. Urine output was charted at 5 liters per day (L/d). Laboratories showed hypernatremia that followed an increasing trend with associated low urine osmolality of 176 mOsm/kg. Despite lithium discontinuation upon admission and fluid repletion, patient persisted with severe hypernatremia. A water deprivation test was not performed. Desmopressin administration failed to elevate urine osmolality above 300 mOsm/kg, which confirmed NDI. A thiazide diuretic was started to increase urine osmolality by reducing distal water delivery and upregulate aquaporin receptors. Patient showed significant improvement, decreasing urinary output to 3 L/d and reaching normal sodium levels. A positive response to the thiazide diuretic without further symptoms or electrolyte disturbances was observed in the outpatient follow up.

Discussion: NDI is a rare condition that can become irreversible in patients with chronic lithium use. This case highlights the importance of thorough history taking and differential diagnosis formulation; as in our patient, the etiology of hypernatremia was lithium use and not brain mass or surgery. It is important for patients on chronic lithium to be monitored closely for medication complications.

PUB619

Multisystemic Manifestations of Lithium Therapy

Andrea G. Del toro diez,[2] Ileana E. Ocasio Melendez,[1] Nicolle M. Canales-Ramos,[2] Fatima B. Cintron-Rosa,[1] Krystahl Z. Andujar,[1] Carlos G. Rivera-Bermudez.[1] *[1]Nephrology, University of Puerto Rico - Medical Sciences Campus, San Juan, Puerto Rico; [2]University of Puerto Rico, Medical Sciences Campus, San Juan, PR.*

Introduction: Chronic lithium use has been associated with multiple complications, including nephrogenic diabetes insipidus (NDI), hyperparathyroidism, thyroid disease and dysrhythmias. Patients on chronic lithium therapy experience at least one episode of toxicity during treatment. Unfortunately, lithium concentrations may not correlate with signs of toxicity.

Case Description: A 53-year-old woman with bipolar disorder was admitted to the Internal Medicine Ward due to acute changes in mental status. She was diagnosed with bipolar disorder 20 years prior and was treated with risperidone and lithium. Laboratories showed leukocytosis, sodium 164 mEq/L, calcium 11.3 mg/dL, creatinine 2.6 mg/dL and BUN 36 mg/dL. Brain imaging and lumbar puncture ruled out any acute pathology to explain symptoms. Nephrology service was consulted due to hypernatremia and kidney disease. Upon evaluation, patient reported increased thirst, dry mouth and urinary frequency. She was oriented only to person and had dry mucous membranes. Additional workup revealed lithium levels 1.4 mmol/L, serum osmolarity 325 mOsm/kg, urine osmolarity 104 mOsm/kg and PTH 191 pg/mL. Urinalysis showed decreased specific gravity 1.003. Renal ultrasound was remarkable for left non-obstructive nephrolithiasis and findings of renal parenchymal disease. Suspecting NDI, lithium was discontinued. Patient was volume repleted and intravenous fluids were then changed to hypotonic dextrose solution, which resulted in a steady decline in sodium and calcium levels.

Discussion: Lithium leads to NDI by inhibiting aquaporin insertion into the apical membranes, which affects urine concentration and decreased parathyroid gland sensitivity to calcium resulting in an increased incidence of adenomas and hyperplasia. The mainstay of therapy is discontinuation of lithium. Although our patient had only mild elevation of lithium levels, she had a unique presentation with three simultaneous complications from lithium therapy: NDI, hyperparathyroidism and chronic kidney disease. As the unusual multisystemic manifestations of lithium therapy may be observed regardless of its levels, close monitoring for possible complications is of utmost importance during therapy with this drug.

PUB620

An Extended Lithium Saga

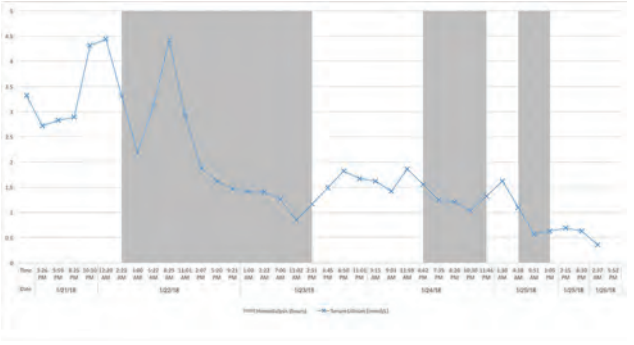
Caroline L. Matchett,[2] Laura J. Maursetter.[1] *[1]University of Wisconsin School of Medicine & Public Health, Madison, WI; [2]University of Wisconsin School of Medicine and Public Health, Madison, WI.*

Introduction: Despite its narrow therapeutic window and toxic effects, lithium continues to be an effective treatment for bipolar disorders. Severe lithium intoxication (levels > 2.5 mEq/L) can cause altered mentation, seizures or death and almost universally requires hemodialysis for removal if renal function is compromised. Proper management is essential

to avoid permanent complications. We present a case of acute on chronic lithium toxicity that necessitated a total of 45 hours of hemodialysis to appropriately reduce lithium levels.

Case Description: A 29-year-old male with bipolar disorder presented with altered mental status, emesis, and tachycardia following an intentional overdose with 470 tablets of lithium carbonate 300 mg extended release. Initial lithium level was 3.32 mEq/L. After 2 liters of saline administration, repeat lithium levels were improving to 2.72 mEq/L therefore a decision to track levels instead of starting hemodialysis was made. Intermittent hemodialysis (IHD) was initiated 12 hours after the presentation when patient's UOP decreased and QT began to prolong. Repeat lithium level had increased to 4.4 by the start of dialysis. After 36 continuous hours of hemodialysis a lithium level of 0.85 mEq/L was achieved. Rebound lithium levels necessitated two additional sessions of dialysis, with an additional 9 hours in total. Upon discontinuation of IHD, the lithium level remained below 1 mEq/L.

Discussion: This case illustrates the therapeutic role of prolonged IHD in extended release lithium intoxications. Realizing the pharmacokinetics of extended release lithium, the care team astutely continued tracking lithium levels even after they were noted to be decreasing. It is imperative for practitioners to understand the pharmacodynamics of lithium, including the changing volume of distribution for chronic use in comparison to acute overdose. It is also important to understand how extended release formulations might alter predictions on how to best provide intoxication management.



PUB621

Glass Green Colored Urine: Is It Benign or a Cause for Alarm!

Karan Puri,[1] Sangita Bista,[1] Yuvraj S. Chowdhury,[1] Balaji Yegneswaran.[2]
[1]Internal Medicine, SPUH/RWJ, New Brunswick, NJ; [2]Saint Peter's University Hospital, New Brunswick, NJ.

Introduction: Urine analysis is an integral part of the evaluation of any illness. A change in the urine color always makes a clinical contemplate. The cause could be an underlying illness or simply a new medication or dietary changes. We present an interesting case of green urine which developed after propofol.

Case Description: A 22-year-old male was admitted with an acute onset of difficulty in breathing that started 3 hours prior to admission and was debilitating to the extent that he couldn't speak in full sentences. On examination, he was tachypneic, breathing at 34 breaths per minute and required oxygen 6L/minute to maintain>90% saturation. He was subsequently intubated. Propofol5mcg/kg/min and Fentanyl25mcg/hr were used for sedation. Propofol was gradually increased to 20mcg/kg/min to achieve RAAS score of -2. On the day 2, his condition improved and he was extubated. Interestingly, during this period his urine bag showed glass green colored urine. Initially, urine infection was suspected. Although clinically he was normal. All his sedations including Propofol were stopped.6 hours after discontinuation, the green color cleared and his urine returned to a pale yellow color.

Discussion: Propofol is extensively used in intensive care medicine for sedation. It is metabolized in the liver and predominantly excreted in urine as phenolic metabolites. The green discoloration of urine is attributed to these phenolic metabolites and is reversible on discontinuation. Total dosage or length of infusion does not correlate with discoloration. The total dose of propofol leading to green urine may range from 200 mg to 14,000 mg. Our patient received total 3035mg over 34 hours. Some of the other causes of green color urine could be urine infection or drugs like promethazine, thymol etc. Therefore, urine color should be interpreted with an acumen considering all benign and pathological conditions so as not to miss a disease and also avoid unnecessary diagnostic evaluation.

PUB622

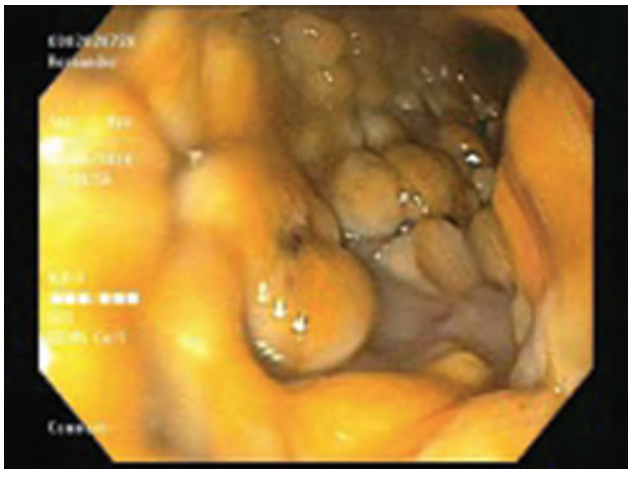
Systemic Absorption of Oral Vancomycin in C. difficile Colitis

Allison Bigeh,[1,2] Leonor A. Echevarria.[3] *[1]University of Arizona College of Medicine, Phoenix, AZ; [2]Internal Medicine, Banner University Medical Center, Phoenix, AZ; [3]Infectious Diseases, Banner University Medical Center, Phoenix, AZ.*

Introduction: Oral vancomycin is generally considered safe to use in patients with kidney disease due to its minimal absorption in the gut <5%. This has led to a widespread approval of the oral form of the drug in treating *Clostridium difficile* infection (CDI). Some case reports indicate unpredictable absorption in renal failure. Here we report a case of nearly supratherapeutic levels in a patient with severe CDI and stable renal function.

Case Description: 50-year-old female with hypertension, diabetes, and CKD 4 presented to the hospital with chief complaint of diarrhea and abdominal pain. After completing two weeks of levaquin developed profound loose, watery stools. Labs showed a leukocytosis 25k and stable CKD (Cr~3.0). CDI tests were positive for toxin and GDH antigen. Oral vancomycin and IV metronidazole were started immediately, however, symptoms persisted one week later. Vancomycin dose was increased and given both oral and rectally with only mild improvement in symptoms. Prolonged vancomycin taper was initiated. Trough levels were measured 19 mg/L. Due to concern for nephrotoxicity the dose was not increased. Flexible sigmoidoscopy showed diffuse pseudomembranes indicating severe CDI refractory to antibiotics. Fecal transplant was performed 35 days into admission and diarrhea resolved.

Discussion: IDSA guidelines recommend oral vancomycin for treating several stages of CDI. This case raises the question of whether inflammatory states or altered bowel anatomy (rectal ulcers in this case) and renal insufficiency play roles in unpredictable vancomycin levels. Few case reports have been published on this matter, most report detectable drug concentrations when vancomycin is used at high doses >2 g/day and long durations >10 days. Currently there are no guidelines for monitoring serum vancomycin levels when given orally. Serum drug monitoring in patients with severe or fulminant CDI is an area necessitating further research and may reveal an issue of toxic absorption.



sigmoid pseudomembranes

PUB623

Cefepime Induced Non-Convulsive Status Epilepticus in ESRD Patients

Gargi S. Priamvada,[1] Usman A. Khan,[2] Syeda maria Muzammil,[3] Usman Z. Bhutta.[3] *[1]university of oklahoma health sciences center, OKLAHOMA CITY, OK; [2]University of Oklahoma College of Medicine, Oklahoma City, OK; [3]OUHSC, OKC, OK.*

Introduction: Cephalosporin induced neurotoxicity is well described in the literature but it remains an under-recognized phenomenon clinically. Studies have shown that up to one-third of patients (pts) on hemodialysis (HD) are prescribed a drug at an inappropriate dose resulting in adverse reactions. Cefepime is predominantly cleared by renal excretion; impaired renal function increases the risk for cefepime-induced neurotoxicity leading to an array of symptoms including slurred speech, tremors, confusion, coma, and non convulsive status epilepticus (NCSE). We present a case of a pt with ESRD who developed NCSE from cefepime toxicity and aim to highlight the importance of medication adjustment in patients with renal failure.

Case Description: A 60 year old woman, with ESRD on HD, was transferred to our facility for management of persistent encephalopathy while being treated at an outside hospital for health care associated pneumonia (HCAP). She was receiving cefepime at the regular dose rather than the ESRD -adjusted dose. Imaging excluded acute intracranial abnormalities and CSF studies were unrevealing. Continuous EEG monitoring showed 2Hz generalized periodic discharges (GPD), a pattern characteristic of NCSE. The patient was dialyzed daily for several days with high flux dialyzer. Gradually, GPD were replaced with generalized rhythmic delta activity, marked improvement in neurological status was noted and eventually the pt was extubated.

Discussion: Physicians need to be aware of the importance of medication dose adjustment in patients with renal failure. This case highlights a common neurotoxic effect of cefepime due to high levels in an ESRD pt but a similar scenario can be envisioned with any medication that needs renal adjustment, if they are not dosed properly. To prevent such adverse events, we suggest the use of eGFR calculators in all electronic medical records, involvement of clinical pharmacists on the inpatient teams as well as increased vigilance on the part of the inpatient pharmacy along with early involvement of nephrology team. Keeping in view the shortage of fellows opting for nephrology resulting in a decrease of qualified physicians to care for the ever increasing population with ESRD, it is imperative to stress this issue when residents rotate on the nephrology service since they will often be on the frontlines to treat such patients.

PUB624

Recurrent Proliferative Glomerulonephritis with Monoclonal IgG Deposits in a Renal Allograft - Still a Dilemma

Manini Vishwanath,[1] George P. Bayliss,[2] Basma O. Merhi.[3] *[1]Rhode Island Hospital/Brown University, Providence, RI; [2]Alpert Medical School, Brown University, Providence, RI; [3]Nephrology, East Greenwich, RI.*

Introduction: Proliferative glomerulonephritis with monoclonal immunoglobulin G deposit (PGNMID) is a recently described pathological entity of native kidneys which falls in the spectrum of monoclonal immunoglobulin deposition disease, whose clinical course resembles glomerulonephritis. Occurence in renal allografts is exceedingly rare and appears as a recurrent or de novo disease.

Case Description: A 56 year old Caucasian female with history of End Stage Renal Disease due to biopsy proven membranoproliferative glomerulonephritis 12 years ago on dialysis, underwent a deceased donor kidney transplant on maintenance prednisone, tacrolimus and myfortic with baseline allograft function at 0.9mg/dl, presented 4 months later for a routine visit and was found to have worsening allograft function with serum creatinine at 1.35 mg/dl. Urinalysis showed 3+ blood and >500 protein. Urine sediment revealed dysmorphic red blood cells with urine protein/creatinine ratio of 1.5 g/g. Complements C3/C4, SPEP, UPEP and serum immunofixation were normal, prompting a diagnostic allograft biopsy. Findings were consistent with endocapillary proliferative and exudative glomerulonephritis accompanied by diffuse glomerular immune deposits comprising IgG, kappa light chain and C3 localized to capillary walls and mesangial areas confirming the diagnosis of PGNMID. Bone marrow biopsy was negative. She was treated with 4 doses of Rituximab 3.75mg/ m2 given 2 weeks apart, and prednisone 60mg. 5 months after treatment, repeated urinalysis still showed 3+ blood and 100 protein with improving allograft function and serum creatinine at 1.1 mg/dl.

Discussion: Our patient has recurrent PGNMID in allograft due to its rapid appearance after transplant, supporting the theory that it recurs within 2 years after transplant due to circulating abnormal IgGs in patient sera. Diagnosis is based on electron microscopy and immunofluorescence of biopsy specimen as it can be misdiagnosed as transplant glomerulopathy. There is no definite treatment yet. Amongst case reports of PGNMID of native kidneys, the most successful outcomes were with Rituximab perhaps because it targets plasma cells secreting these abnormal immunoglobulins. Hence, we chose this treatment option in our patient. A follow up biopsy may be helpful to assess the pathological response to Rituximab.

PUB625

Primary Nonfunction of a Renal Allograft Secondary to Primary Hyperoxaluria and Systemic Oxalosis

Nawal Habib,[1] David J. Widmyer,[3] Imara Dissanayake,[1] Gitana Bradauskaite,[2] Astha Gupta,[2] Manjula Balasubramanian.[2] *[1]Einstein Medical Center Philadelphia, Philadelphia, PA; [2]Einstein Medical Center, Philadelphia, Philadelphia, PA; [3]Associates in Nephrology, LTD, Boardman, OH.*

Introduction: The primary hyperoxalurias are rare genetic abnormalities of the hepatic enzymes involved in glyoxylate metabolism leading to overproduction of oxalate which is renally excreted. There is deposition of calcium oxalate in various tissues, primarily the kidney, leading to nephrolithiasis, nephrocalcinosis and ESRD.We present a case of primary nonfunction of a renal allograft due to primary hyperoxaluria type 1 (PH1).

Case Description: 52 yo M with ESRD due to recurrent staghorn calculi s/p DDKT remained dialysis dependent. Allograft biopsy showed an eosinophilic infiltrate, interstitial nephritis and acute tubular necrosis (ATN). There were a few crystals under polarized light but no interstitial fibrosis/rejection. Two months later he still required dialysis so a second biopsy was done. This showed marked ATN with casts and birefringent crystals enhancing under polarized light. Immunofluorescence and electron microscopy were negative for light chains and the amyloid stain. He remained anemic despite erythropoietin and transfusions. The erythropoietin level was 459 mIU/mL.A bone marrow biopsy showed normocellular marrow, oxalate crystals, myelodysplasia of the megakaryocytes and erythroid precursors that was classified as refractory cytopenia with multilineage dysplasia. FISH markers for myelodysplastic syndrome were negative.With evidence of oxalate crystals on the kidney/ bone marrow biopsies and history of recurrent nephrolithiasis, primary hyperoxaluria was worked up. Genetic tests showed an alanine-glyoxylate aminotransferase gene mutation consistent with PH1 causing primary nonfunction of his renal allograft.

Discussion: Systemic oxalosis causes deposition of oxalate crystals in the kidneys, blood vessels, bones, heart and central nervous system. The earliest manifestations are renal due to direct tubular toxicity from the crystals, nephrolithiasis, infection and nephrocalcinosis. Once the GFR <30-45 mL/min, serum oxalate levels rise and deposit in tissues. Bone marrow involvement causes ineffective erythropoiesis, resistance to erythropoietin, other cytopenias and hepatosplenomegaly. PH with ESRD requires daily dialysis along with nocturnal peritoneal dialysis. Oral pyridoxine is helpful as a suppressive therapy in PH1. Definitive treatment with liver-kidney transplantation supplies the missing enzyme for glyoxylate metabolism.

PUB626

CNS Aspergilloma Mimicking Pituitary Adenoma in a Renal Transplant Recipient

Nawal Habib,[1] Mustafa Saidi,[2] Daranee Chewaproug,[2] Imara Dissanayake,[2] Gitana Bradauskaite.[2] *[1]Einstein Medical Center Philadelphia, Philadelphia, PA; [2]Nephrology Department Albert Einstein, Philadelphia, PA.*

Introduction: Fungal infections of the CNS are frequently seen immunocompromised hosts however, CNS Aspergillomas are rare. Aspergillosis commonly presents as a primary opportunistic infection of the lungs/paranasal sinuses with systemic hematogenous spread. Primary CNS infection without extracranial involvement is rare. MRI Brain and CT sinuses are essential for diagnosis. Surgical resection with voriconazole are the best treatment. We present a case of an isolated CNS Aspergilloma mimicking a pituitary adenoma in an immunosuppressed kidney transplant recipient.

Case Description: 68 yo F with HTN, DM, ESRD s/p DDKT with CKD due to allograft nephropathy, maintained on immunosuppression, presented with frontal headache. She did not exhibit neurological deficits. Labs showed baseline Cr 2 mg/dL.Brain MRI showed a sellar mass consistent with a pituitary macroadenoma. She had no clinical findings of an endocrinopathy. Due to limitations of contrast administration given her CKD imaging was limited. Later she presented with sudden onset decreased vision and L sided proptosis. Repeat imaging showed increased size of the lobulated sellar mass with supra-sellar extension, optic chiasmatic compression and invasion of the L cavernous sinus. Trans-sphenoidal resection showed a fibrous and purulent mass. Frozen section biopsy revealed necrotizing granuloma, septate fungal hyphae and conidia consistent with aspergilloma. Fungal cultures were also positive. She was treated with IV amphotericin B and voriconazole and was maintained on lower immunosuppression. However she suffered a stroke and renal allograft dysfunction post-operatively. Given her complex condition the family decided to withdraw care.

Discussion: CNS aspergillosis is an uncommon infection seen in immunocompromised hosts. Manifestations include focal deficits, cranial nerve palsies, strokes, and intra-cranial hemorrhage. Radiographic findings include sino-nasal disease, intracranial mass lesions and cavernous sinus invasion. Biopsy reveals branching septate hyphae and conidia of Aspergillus. Sellar space occupying lesions can be confused with pituitary adenomas and endocrine involvement must be considered. Craniocerebral aspergillosis is treated with Voriconazole which has been shown to have good CNS penetration in combination with surgical resection. Mortality rates are higher in immunosuppressed patients with intracerebral involvement.

PUB627

Azathioprine and Allopurinol Combination Therapy in Renal Transplantation

Robert S. Niznik, Andrea G. Kattah. *Mayo Clinic, Rochester, MN.*

Introduction: Azathioprine is rarely used in renal transplant recipients outside of pregnancy, but options for immunosuppression are limited in this setting. Thiopurine-allopurinol co-therapy represents an alternative treatment strategy in the setting of azathioprine-associated hepatotoxicity in women with transplants who desire pregnancy

Case Description: A 32 year old female with a history of ESRD secondary to unknown etiology received a preemptive unrelated renal transplant in 2014. She received Campath induction and was on tacrolimus and mycophenolate mofetil. She was initially prednisone-free; however, was transitioned off mycophenolate mofetil to azathioprine in anticipation of desired pregnancy. Thiopurine methyltransferase (TPMT) activity was normal. Unfortunately, soon after the initiation of azathioprine she developed hepatotoxicity with transaminitis and biliuria. She subsequently had normalization of her liver function tests after the azathioprine was switched back to mycophenolate mofetil. She was then found to have a borderline cellular rejection on protocol biopsy, necessitating steroid treatment. After another year of therapy with stable graft function, she again wanted to discuss the possibility of pregnancy and different options were considered for immunosuppression, including prednisone and tacrolimus dual therapy or sirolimus in place of mycophenolate mofetil. Finally, a third alternative was chosen of using low-dose azathioprine in combination with daily allopurinol to minimize the hepatotoxicity of azathioprine

Discussion: Thiopurine-allopurinol co-therapy has been successfully used as immunosuppressive strategy in renal transplant recipients, but is rarely used now due to risks of bone marrow suppression. Azathioprine is metabolized to 6-MP, which is metabolized to form 6-thioguanine nucleotides (TGN), the main therapeutic metabolites. 6-MP can also be deactivated by TPMT to form 6-methylmercaptopurine (MMP). High levels of 6-TGN are associated with disease remission, but also with myelosuppression when in excess, whereas high levels of 6-MMP are associated with hepatoxicity. TPMT activity does not predict hepatoxicity in the same way that it predicts myelosuppression. Approximately 15% of patients will preferentially metabolize 6-MP to 6-MMP instead of 6-TGN. Allopurinol helps circumvent this hypermethylation and will reduce 6-MMP levels and increase 6-TGN levels

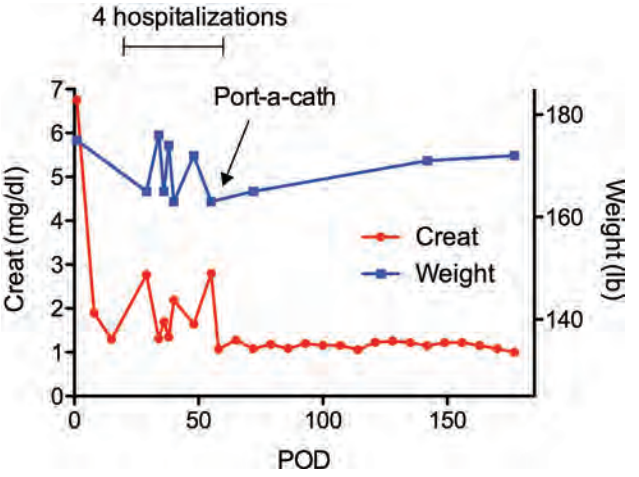
PUB628

Daily Self-Administered Intravenous Fluids Prevent Recurrent Acute Kidney Allograft Dysfunction in a Patient with Short Bowel Syndrome

Ankit B. Patel, Alex Cuenca, Hannah M. Gilligan, Nahel Elias, David Wojciechowski, Kassem Safa. *Massachusetts General Hospital, Boston, MA.*

Introduction: Short bowel syndrome (SBS) is a relative contraindication for kidney transplantation (KT). Few cases of dual kidney and intestinal transplantation are reported, whereas there are no data to help manage similar patients who end up receiving KT alone.

Case Description: A 59 y/o man with ESRD on HD for 10 years in the setting of Crohn's disease and SBS (150 cm of small bowel, subtotal colectomy), underwent a deceased donor KT. He received basiliximab induction and maintenance mycophenolate, tacrolimus, and prednisone; discharged on POD 4, after requiring one session of HD for hyperkalemia. Subsequent course was complicated with recurrent acute kidney injury (AKI) from diarrhea, with stool output >3.5L at times, and weight loss before each AKI, despite aggressive oral hydration. A kidney biopsy showed acute tubular injury with rare tubular oxalate crystals. Despite transition to azathioprine, aggressive motility inhibition including DTO, he continued to have high output diarrhea and required 4 hospitalizations (average length of stay was 5 days) for work up and volume expansion, which on every occasion led to the swift resolution of the AKI. Eventually, he received an internal jugular port-a-cath and was discharged on a daily 1L Ringer's lactate infusion. This resulted in a sustained recovery up to 7 months after transplantation (at the time of this report) with steady serum creatinine and weight, no additional hospitalizations, and return to work full time (figure).



Discussion: We report for the first time stable kidney allograft function in a patient with SBS with self-administered daily IV fluids. Although this case is short-termed, the trend is meaningful and shows that select patients with SBS, could still undergo kidney transplant, but will rely on daily parenteral volume expansion, which can be done at home safely and consistently.

PUB629

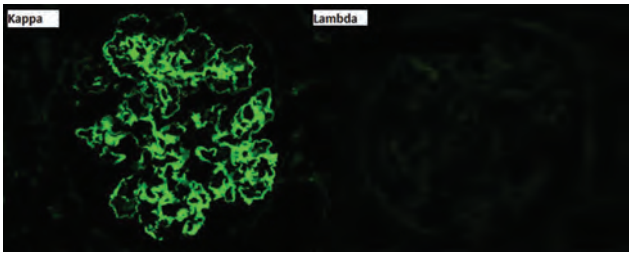
Recurrent MGRS in a Renal Transplant: Importance of Knowing the Primary Disease

Hema V. Sheelvanth, David J. Cimbaluk, Vasil Peev, Roger A. Rodby. *Rush University Medical Center, Lincolnshire, IL.*

Introduction: The term monoclonal gammopathy of renal significance (MGRS) was developed to encompass renal lesions associated with a monoclonal immunoglobulin (mIg) that do not fit the typical lesions of cast nephropathy and AL amyloidosis etc. While some are associated with a mIg in the serum or urine, some are identified only on renal biopsy by demonstrating light chain restriction indicating an abnormal cellular clonality. These lesions have a high recurrence rate in allografts and the clonal cell line should be treated prior to transplantation. We present a case of MGRS that was identified as such only after recurrence in the renal transplant.

Case Description: A 61 year-old woman presented with nephrotic-range proteinuria and creatinine (Cr) of 0.8 mg/dl. Renal biopsy revealed MPGN with IgG kappa restriction (Figure 1). This was not appreciated to be a MGRS and was treated with cyclophosphamide (CP) and steroids. Three years later, she presented with ESRD. A renal biopsy was identical but with advanced fibrosis felt to be ESRD secondary to idiopathic MPGN and she remained on hemodialysis without further treatment. After 5-years she received a cadaveric renal transplant (CRT). At 4 months post CRT, her Cr was 2.1 mg/dl. An allograft biopsy showed mesangial hypercellularity with glomerular IgG kappa restricted deposits and her disease was finally clinically recognized as a MGRS. Serum and urine immunofixation failed to show a mIg and a bone marrow with flow cytometry could not identify an abnormal cell clone. Despite this, she was treated with bortezomib, dexamethasone and CP. An allograft biopsy 4 months later had persistent mIg deposits but her Cr improved to 1.2 mg/dl. Due to concern for failure of first line therapy and future allograft loss, second line therapy with Daratumumab vs. autologous stem cell transplant is being considered.

Discussion: MGRS has high allograft recurrence rates and needs to be identified and treated prior to renal transplantation. This patient appears lucky in that the clonal production of mIg was indolent enough that treatment post CRT may be successful.



PUB630

Discovery of Functioning Native Kidneys with a Failed Renal Allograft 5 Years After a Simultaneous Liver Kidney Transplant (SLKT)

Amanda A. Karasinski, Jaime A. Baynes-Fields, Lissa B. Levin Mizrahi, Sandeep Aggarwal, Karthik M. Ranganna. *Drexel University, Philadelphia, PA.*

Introduction: Renal function has been found to recover in 11.5% of single organ liver transplant recipients who required pre-transplant renal replacement therapy for more than 90 days. There are reports of SLK recipients regaining significant native kidney function post transplantation. We report a discovery of native renal function in a patient with renal allograft failure 5 years after SLKT who required pre-transplant renal replacement therapy for 5 months.

Case Description: A 70-year-old man with a PMH of end stage liver disease from HCV cirrhosis, HCC, HTN, T2DM and HRS pre-transplant, requiring hemodialysis, who received a SLKT in 2013. His post-transplant course was complicated by acute cellular

rejection of the liver in 2013 which was successfully treated. Five years post transplant, patient developed AKI with creatinine rising to 2.0mg/dl. See figure 1 for the trend of creatinine post transplantation. US revealed an atrophic renal allograft with significant cortical thinning and abnormal doppler waveforms of the main renal artery that was consistent with a failed renal allograft. US of the renal allograft performed 2 years prior was normal in size but increased in echogenicity. Biopsy revealed chronic inflammation, 60% globally sclerosed glomeruli with severe interstitial fibrosis and tubular atrophy. MAG3 furosemide renal scan was performed to investigate native renal function which revealed left kidney, 55.2% and right kidney, 44.8% without activity in the renal allograft.

Discussion: We discovered renal allograft failure which resulted in the unmasking of native renal function as demonstrated by the furosemide renal scan 5 years after SLKT. This patient met UNOS criteria for dual organ transplantation, having sustained AKI requiring hemodialysis for 5 months prior to SLKT. More studies are warranted to investigate better predictors of native renal recovery in SLKT in the era of the new UNOS policy.

A Case with Muir-Torre Syndrome: Concurrent Sebaceous Carcinoma with Multiple Visceral Malignancies in a Kidney Transplant Recipient

Masahiro Tomonari,[1] Yasuyuki Nakada,[2] Izumi Yamamoto,[3] Takafumi Yamakawa,[4] Haruki Katsumata,[1] Aki H. Mafune,[5] Akimitsu Kobayashi,[1] Yudo Tanno,[1] Hiroyasu Yamamoto,[6] Takashi Yokoo,[1] Makoto Sagasaki,[3] Mayuko Kawabe,[7] Ai Katsuma.[8] *[1]The Jikei University School of Medicine, Tokyo, Japan; [2]The Jikei University of Medicine, Tokyo, Japan; [3]Division of Nephrology and Hypertension, Department of Internal Medicine, The Jikei University School of Medicine, Tokyo, Japan; [4]Division of Nephrology and hypertension, The Jikei university school of medicine, Tokyo, Japan; [5]Jikei University School of Medicine, Tokyo, Japan; [6]Division of Nephrology and Hypertension, Department of Internal Medicine, Jikei University School of Medicine, Tokyo, Japan; [7]the Jikei University School of Medicine, Tokyo, Japan; [8]The Jikei University school of Medicine, Tokyo, Japan.*

Introduction: Sebaceous carcinoma (SC) is a rare but progressive malignant skin cancer, and the incidence is approximately five times higher in post-transplant patients. SC is sometimes found concurrently with visceral cancers and a genetic abnormality called Muir-Torre syndrome (MTS).

Case Description: The patient was a 43-year-old woman who had received a living kidney transplantation from her father at the age of 33 due to end-stage kidney disease caused by IgA nephropathy. The transplanted kidney function was stable, with a serum creatinine of 1.5 mg/dl. Ten years after transplantation, a rapidly enlarged skin tumor developed in the left occipital region, which was totally resected. The tumor was diagnosed as SC. In addition, subsequent examination revealed the development of multiple visceral malignancies, including sigmoid colon cancer, rectal SC, and cervical cancer. Immunohistochemical study revealed the absence of mismatch repair (MMR) proteins and the development of microsatellite instability in the SC, suggesting MTS. DNA sequence analysis for MMR genes revealed a genetic mutation of 1226_1227delAG in the MSH2 Exon 7 lesion, which confirmed MTS.

Discussion: SC is relatively common in transplant recipients with visceral malignancies due to MTS. Our case suggests that careful and frequent follow-up and thorough evaluation by a dermatologist is important for an accurate diagnosis in transplant recipients.

PUB632

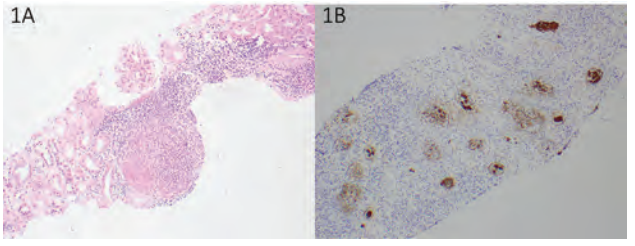
Adenovirus Nephritis in the Transplanted Kidney

Imad Razzak, Mohamad A. Hanouneh, Teresa K. Chen, Sami Alasfar. *Johns Hopkins University School of Medicine, Division of Nephrology, Baltimore, MD.*

Introduction: Adenovirus infection can manifest as disease involving the upper respiratory tract, gastrointestinal, ophthalmologic, genitourinary, and/or neurologic systems. Most cases are self-limited; however, serious and disseminated infections can occur in immunocompromised patients.

Case Description: We report the case of a 69-year old male with end-stage renal disease attributed to diabetic nephropathy who underwent a deceased donor kidney transplant six years prior and presented with weakness, fever, chills, and gross hematuria. Laboratory work-up revealed acute kidney injury with a serum creatinine of 2.1 mg/dL, up from his baseline of 1.3 mg/dL. Urine studies were notable for >1000 red blood cells/high-power field and proteinuria of 0.58 g/g. Cystoscopy showed clots in the bladder, cystitis, and bloody efflux from the ureteral orifice of the transplanted kidney. Adenovirus DNA was detected in the urine by PCR and serum adenovirus viral load was elevated at 1630 copies/mL. An allograft kidney biopsy was performed, which demonstrated diffuse and severe interstitial inflammation with tubulitis and vague granulomas on light microscopy (Figure 1A). Immunostaining for adenovirus showed numerous foci of nuclear and cytoplasmic staining of tubular epithelial cells (Figure 1B). Given these findings, the patient was diagnosed with adenovirus nephritis and treated with intravenous cidofovir 2.5 mg/kg twice a week for 3 weeks. The dose of his mycophenolate was also reduced by 50%. With this treatment, his hematuria resolved, serum creatinine returned to baseline, and serum adenovirus viral load became undetectable.

Discussion: Adenovirus is an opportunistic infection frequently seen in kidney transplant recipients. Clinical manifestations of adenovirus involving the genitourinary system include hemorrhagic cystitis and, rarely, tubulo-interstitial nephritis. A kidney biopsy is necessary for definitive diagnosis of adenovirus nephritis. Treatment includes antiviral therapy and reduction of immunosuppression.



PUB633

Rituximab Success in Management of Recurrent GVHD of the Kidney Post Allogeneic SCT

Omar Mamlouk,[1] Hanan A. Khairalla,[4] William F. Glass,[2] Ala Abudayyeh.[3] *[1]University of Texas Health Science Center at Houston, Houston, TX; [2]University of Texas – Houston Medical School, Houston, TX; [3]The University of Texas MD Anderson Cancer Center, Houston, TX; [4]University of Texas, Houston, TX.*

Introduction: GVHD of the kidney is a rare complication post allogeneic stem cell transplant usually manifests clinically as a nephrotic syndrome after around 6-12 months of transplant. It is estimated that the incidence of the nephrotic syndrome in adult recipients ranges 0.4-6 %. Majority of the cases has evidence of Mimimal change disease(65.5%), followed by membranous (19%) then FSGS (7.7%). Steroids used alone or in combination with calcineurin inhibitor reported to induce favorable response in around 75% of the cases. Rituximab had good outcome in management of GVHD with membranous nephropathy. There is a very limited data about the incidence and treatment of recurrent GVHD of the kidney after initial remission. We present a case of FSGS as a presentation of GVHD of the kidney with three relapses who has failed tacrolimus and steroids in the past and successfully treated with rituximab each time with full remission.

Case Description: 66 year old hispanic male with history of hypertension, non-ischemic cardiomyopathy and Mantle cell lymphoma status post allogenic SCT (7 years ago) with renal GVHD at 1 and 3 years post-transplant. Renal biopsy consistent with Minimal change disease and FSGS respectively, treated successfully with rituximab. Patient presented with volume overload with anasarca. Urine analysis was positive for hematuria and pyuria. Proteinuria peaked at 11g and albumin of 2.2 g/dl. Patient had AKI on admission with creatinine was of 3.3 mg/dl (with baseline 1.4 mg/dl, 5 months prior to admission) patient was started on empiric therapy with 1m/kg of prednisone daily and underwent renal biopsy with finding of FSGS. He was started on weekly dose of rituximab 375 mg/m^2 but his creatinine peaked at 7.7 mg/dl and underwent dialysis for three weeks at which point he had improved urine output, creatinine decreased to 1.0 mg/dl, and UPC decreased from 11g to 1g.

Discussion: Renal GVHD after stem cell transplant can be of a recurrent nature, even after 7 years of transplant. Rituximab successfully induced remissions in patient with FSGS despite severe AKI that required. A possible theory on how B cells can contribute to chronic GVHD is that the reconstituted B cells after myeloablative conditioning may have impaired immune tolerance of peripheral B cells, leading to the production of autoantibody in chronic GVHD.

PUB634

A Case of High Output Heart Failure Secondary to an Arteriovenous Fistula in a Renal Transplant Patient

Divya Raghavan,[1] Josephine Abraham,[2] Fuad S. Shihab,[3] Isaac E. Hall,[1] Faris A. Ahmed.[2] Divya Raghavan *[1]University of Utah, Salt Lake City, UT; [2]University of Utah, Salt Lake City, UT; [3]University of Utah Health Science Center, Salt Lake City, UT.*

Introduction: The presence of an arteriovenous (AV) fistula in a patient leads to decreased systemic vascular resistance and a compensatory increase in cardiac output which may result in clinical heart failure.

Case Description: A 72-year-old lady with history of end stage renal disease secondary to ANCA vasculitis post renal transplant 2 weeks ago was admitted with worsening

peripheral edema and dyspnea on exertion. She had gained 19 kg since transplant. She was on tacrolimus, mycophenolate sodium and prednisone. Physical examination showed elevated jugular venous pressure, bilateral crackles, 2+ pitting lower extremity edema, 1+ pitting upper extremity edema, greater on the right side, and a right brachiocephalic arteriovenous fistula with thrill and bruit. Echocardiogram showed an ejection fraction of 63%, diastolic dysfunction, an elevated pulmonary artery systolic pressure of 53 mmHg and a dilated inferior vena cava. Right upper extremity duplex was negative for deep vein thrombosis. Serum creatinine (SCr) was 1.64 mg/dl, (baseline 1 mg/dl). She was treated with intravenous (iv) furosemide and improved clinically. She was transferred to inpatient rehab after 5 days, by which time SCr was down to 1.2 mg/dl and she had lost 2 kg. In rehab, she lost another 10 kg. 2 weeks after transfer, she developed worsening hypoxia and was transferred back to the floor. She received iv diuresis and was discharged after 5 days. She was readmitted 3 weeks later for volume overload, and her weight was up by 9 kg. Labs showed SCr of 2.34 mg/dl. Vascular duplex of AV fistula showed a high flow rate of 2.7 L/min. She was treated with iv furosemide. The patient lost 12 kg and underwent right heart catheterization. Her cardiac output was 8.6 L/min at baseline and decreased to 6.6 L/min after right arm fistula occlusion. Her fistula was ligated 4 days later. At the time of clinic visit 2 weeks post-discharge, SCr was down to 0.6 mg/dl, and the patient had lost another 3 kg and was back to her pre-transplant weight.

Discussion: High output heart failure secondary to an AV fistula can be confirmed by right heart catheterization with dynamic measurements. An elevated baseline cardiac output with a significant decrease upon transient fistula occlusion, such as in our patient, helps confirm the diagnosis.

PUB635

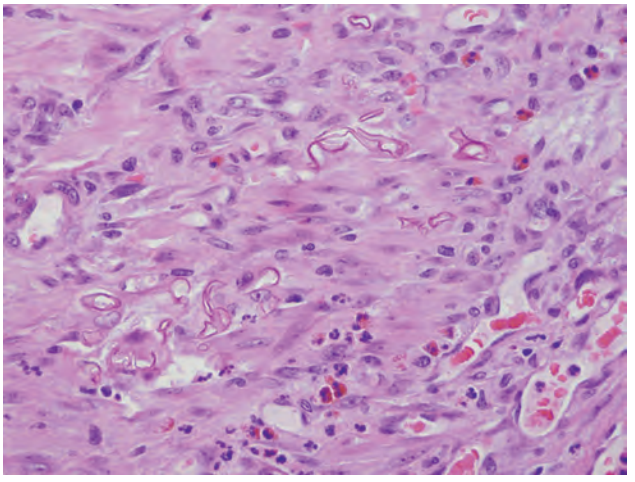
Invasive Mucormycosis Causing Gastrointestinal Bleed in a Renal Transplant Patient

Divya Raghavan,[1] Josephine Abraham,[2] Fuad S. Shihab.[3] Divya Raghavan *[1]University of Utah, Salt Lake City, UT; [2]University of Utah, Salt Lake City, UT; [3]University of Utah Health Science Center, Salt Lake City, UT.*

Introduction: Mucormycosis refers to a serious infection by fungi in the order Mucorales. It presents most commonly as rhino-orbital-cerebral and pulmonary infections. It predominantly affects patients with diabetes mellitus and immunocompromised patients.

Case Description: A 43-year-old lady with a history of end stage renal disease secondary to lupus nephritis post second kidney transplant (with alemtuzumab induction) 2 weeks prior to presentation was admitted with severe anemia. She was on tacrolimus, mycophenolate sodium and prednisone. She had blood tinged stools but stable vital signs. Hemoglobin was 5.6 g/dl for which she received two units of packed red blood cells. Colonoscopy revealed two large ulcers. Biopsies showed invasive mucormycosis. She was started on amphotericin therapy and subsequently underwent a subtotal colectomy with creation of an ileostomy. The resected specimen had multifocal ulcerations on gross examination. On histologic examination, the mucor invaded the muscularis propria and was associated with an extensive giant cell reaction, acute inflammation and ulceration. Her clinical course was further complicated by antibody mediated rejection after immunosuppression was decreased. She developed a pulseless arrest during plasmapheresis therapy necessitating resuscitation. She developed hypoxic brain injury and was eventually transferred to a long term assisted care living center with a tracheostomy.

Discussion: Invasive mucormycosis can rarely affect the gastrointestinal tract. The stomach is most frequently reported as a site of involvement, followed by the colon. The typical lesions seen are ulcers with necrosis. Opportunistic infections such as mucormycosis should be part of the differential diagnosis for solid organ transplant patients with gastrointestinal symptoms. There should be a low threshold to pursue definitive diagnosis with tissue biopsy.



Colon biopsy showing invasive mucormycosis

PUB636

Type III Hypersensitivity Reaction (HSR3) from Rabbit Anti-thymocyte Antibody (ATGAM) Induction

Roopa Sharadanant,[3] Gautam M. Phadke,[1] Adit S. Mahale,[1] Smaroula Dilioglou.[2] *[1]Medicine, Nephrology, Sanford Health, UND School of Medicine, Fargo, ND; [2]Sanford Health, Fargo, ND; [3]Internal Medicine, University of North Dakota School of Medicine, Fargo, ND.*

Introduction: We report a rare complication of thymoglobulin use and importance of its early recognition and treatement.

Case Description: A 38 year old male during his 3rd kidney transplant received 6 mg.kg of ATGAM for induction immunosuppression. He presented 1.5 weeks after last dose with 102 F fever and fleeting joint pains. Examination revealed tender joints with effusions. Day 2 of hospital admission, targeted question of jaw pain was elicited, which was positive. Clinical diagnosis of serum sickness due to ATGAM was made, empiric antibiotics discontinued and treatment with Solumedrol, daily plasmapheresis was initiated. Day 4 of treatment, all symptoms were resolved. Steroids were tapered over 2 weeks.

Discussion: Incidence of HSR3 or serum sickness due to ATGAM ranges 2-27%, but severe reaction needing treatment is rare. Prior ATGAM exposure, raising or ingesting rabbits, increase its incidence. Jaw pain is a distinct clinical symptom. No commercial diagnostic test is available in the US: personal communication, Sanofi. Complements may be low. IgM, IgG, but mainly IgG antibodies bind to the F(ab) part of IgG thymoglobulin forming immune complexes (IC). Excess IC escaping degradation by liver and Kupffer cells, precipitate in tissues. Fenestrated endothelial lining(synovial membrane)are most susceptible. Fc part of the IC binds to the Fcγ receptor on endothelial lining activating classical complement pathway, recruiting inflammatory cells, cytokines resulting in a systemic reaction. Corticosteroids, physical removal of IC by plasmapheresis is mainstay of treatment. Rapid resolution of symptoms after plasmapheresis, correlates with reduction of IC *in vivo*. Our case demonstrates need to identify this rare clinical syndrome due to ATGAM. Theoretically, reduced immunosuppressive potency of ATGAM due to IC formation may increase risk of early rejection; no such effect was observed in our case.

Deep Dermatophytosis in an Immunosuppressed Kidney Transplant Recipient: A Case Report

William Osborne,[2] Alireza Abdolrasouli,[1] Marina Loucaidou,[2] Rawya Charif,[2] James Carton,[1] Neill D. Duncan.[2] *[1]Imperial College NHS Healthcare Trust, London, United Kingdom; [2]Imperial College Renal and Transplant Centre, London, United Kingdom.*

Introduction: Dermatophytosis is a common, superficial skin, hair and nail infection caused by a diverse group of filamentous fungi. In contrast, deep dermatophytosis is a rare and invasive form, whereby deeper dermal structures are invaded and/or there is dissemination to other tissues (e.g. lymph nodes, brain and lung). Risk factors for this include CARD9 deficiency, human immunodeficiency virus infection and immunosuppression. We report a case of deep dermatophytosis involving the fungus, *Trichophyton rubrum*, in an immunocompromised patient.

Case Description: A 66 year-old man of Indian descent, presented to our rapid access clinic with fevers, left buttock pain, dry cough and a nodular lesion on his right leg. He had a recent diagnosis of type 2 diabetes mellitus and received a live unrelated donor kidney transplant one-year prior. He was on tacrolimus, mycophenolate and prednisolone therapy for antibody-mediated rejection. The patient had a fever (38.6ºC) and was temocillin and vancomycin for a presumed urinary tract infection. Admission blood testing revealed an elevated C-reactive protein (45.9mg/L), a high tacrolimus level (14.9 ug/L), graft dysfunction (creatinine 184 umol/L), normocytic anaemia (Hb 106g/L, MCV 89.4fL) and normal white cell count ($6.4x10^9$/L). EBV and adenovirus DNA were detected in blood. Biopsy of the nodular lesion demonstrated granulomatous inflammation and fungal hyphae within the granulomas. *Trichophyton rubrum* was isolated in culture. High-resolution CT imaging of the chest revealed progressive ground-glass opacities in the right peri-hilar region. Bronchoscopy was negative for malignant cells, *M. tuberculosis* and fungi. He was treated with liposomal amphotericin B and voriconazole, topical terbinafine and meropenem.

Discussion: This case highlights the plethora of opportunistic infections that immunosuppressed kidney transplant patients are at risk of. A high index of suspicion, thorough investigation and good dialogue between specialists are required to offer the best patient outcomes. In addition, we feel that any undefined skin lesion in this patient group warrants a skin biopsy.

PUB638

Recurrence of Hypertension and Hypokalemia Following Renal Transplant Uncovers Inadequately Treated Primary Hyperaldosteronism

Sadeem Ali, Christie P. Thomas. *University of Iowa College of Medicine, Iowa City, IA.*

Introduction: Persistent or recurrent primary hyperaldosteronism after renal transplant has only rarely been reported which makes this case unique.

Case Description: 49-year-old man received a deceased donor renal transplant in November 2016 after being on hemodialysis for 18 months. Potassium in blood was 4 on admission and he was on amlodipine 10 mg daily (changed to nifedipine late November to allow for up titration), carvedilol 25 mg twice a day, doxazosin 8 mg daily, furosemide 80 mg daily (later discontinued), and spironolactone 50 mg twice a day for blood pressure. He developed hypertension, 1 day after transplant up to 160s systolic blood pressure and manifested hypokalemia by day 52 post- transplant, despite being on tacrolimus, trimethoprim-sulfamethoxazole & heparin. Review of his prior records indicated that he had been diagnosed with primary hyperaldosteronism leading to ESRD. His CT scan in August, 2015 showed bilateral adrenal lesions, most likely simple adenomas, medullary nephrocalcinosis & concurrent renal atrophy, left greater than right. His aldosterone to renin ratio was 20 in 2013 & 71.9 in 2015. He had been treated with carvedilol 12.5 mg twice a day, doxazosin 8 mg daily and spironolactone 100 mg twice a day, until he developed ESRD. TTKG was 4.5, aldosterone 22 ng/dl, renin 0.7 ng/ml/h and renin to aldosterone ratio 31 on 11/28/17. He is currently more than 1.5 year out from renal transplant with an eGFR in ml/minute/square meter of 71 per MDRD. His hypertension is treated with spironolactone 50 mg twice a day, carvedilol 12.5 mg twice a day and doxazosin 16 mg daily. His last serum potassium level was 3.8 and blood pressure 140s/90s last checked at home.

Discussion: The cardinal manifestations of primary hyperaldosteronism may be lost or masked by the onset of ESRD because of end organ resistance to aldosterone and because maintenance dialysis can efficiently manage hypertension and disordered electrolytes. Since the abnormality arises from autonomous secretion of aldosterone, the successful replacement of renal function with a functioning renal transplant will inevitably lead to recurrence of the resistant hypertension & hypokalemia. Patients with a history of primary hyperaldosteronism should be recognized and appropriately managed prior to a kidney transplant and if pre-transplant cure is not possible, then recurrence should be anticipated

PUB639

Early Listeria Monocytogenes Infection Post-Kidney Transplantation

Shreemayee De,[1] Pooja Tanjavour.[2] *[1]Newark Beth Israel Medical Center, Edison, NJ; [2]Newark Beth Israel Medical center, Nutley, NJ.*

Introduction: *Listeria monocytogenes* is a facultative anaerobic, gram-positive bacillus commonly found in soil, water, sewage, animal feces and domestic animals. It most commonly affects immunocompromised individuals such as those with HIV, cancer, and those who are immunosuppressed. Invasive form of *Listeria monocytogenes* infection usually occurs during the intermediate phase of post-renal transplantation. However on rare incidences, it can affect recipients during early phase of post renal-transplantation.

Case Description: This is a 67-year-old female with history of end-stage renal disease secondary to type 2 diabetes mellitus who was admitted 9 days post deceased donor renal transplantation for symptoms of fever, diarrhea, nausea and lethargy. Patient had received 3 doses of anti-thymocyte globulin on Days 0-2 of renal transplantation, and was started on tacrolimus, mycophenolic acid and prednisone. Septic workup showed blood culture and cerebrospinal fluid study was positive for *Listeria monocytogenes*, and CAT Scan of the head was overall unremarkable. Thus, she was diagnosed with meningitis due to *Listeria monocytogenes* and was treated with parenteral ampicillin and gentamycin. Her course was complicated by acute hypoxic respiratory failure requiring brief intubation for 2 days, and an episode of tonic-clonic seizures. Her condition gradually improved and was discharged to rehabilitation with total 4 weeks course of ampicillin and gentamycin.

Discussion: This case highlights that even though opportunistic infections occur during intermediate phase of post-renal transplantation, they can manifest during early phase as it did with this patient who presented within 10 days of renal transplantation. In this case, it is presumed that patient had acquired *Listeria monocytogenes* prior to her transplantation since the average incubation period of *Listeria monocytogenes* is 11 days. The invasive form manifested earlier due to T cell activity suppression via anti-thymocyte globulin and tacrolimus. Such cases like this are rare but needs increased awareness when considering etiology of fever in transplant recipients.

PUB640

Successful Use of Ruxolitinib for Graft-versus-Host Disease in a Simultaneous Liver-Kidney Transplant Recipient

Ryan A. Kunjal,[3] Karthikeyan Venkatachalam,[1] Sadaf N. Sheikh,[2] Rowena B. Delos Santos.[3] *[1]Washington University School of Medicine, Saint Louis, MO; [2]Washington university St Louis MO, Valley Park, MO; [3]Washington University in St. Louis, Saint Louis, MO.*

Introduction: Graft-versus- host disease (GVHD) is a rare and lethal complication of solid organ transplants (SOT). It occurs more commonly from donor grafts with larger amounts of lymphoid tissue such as liver transplants. Its occurrence after simultaneous liver-kidney (SLK) transplant has not been described. We describe the first successful case of Ruxolitinib use in steroid refractory GVHD in SOTs.

Case Description: A 66 year old Caucasian male with end stage renal disease and non-alcoholic steatohepatitis related cirrhosis received a SLK transplant with Basiliximab induction and was maintained on tacrolimus, mycophenolate and prednisone. On post-transplant day (PTD) 14, he was readmitted for fever and abdominal pain due to an E. Faecium biloma which was treated with linezolid, cefepime and surgical drainage. At PTD 26, he developed a diffuse maculopapular rash and a biopsy showed interface dermatitis; initially thought to be due to drug eruption and was treated with 3 days of IV methyl prednisone (MP) at 1mg/kg then prednisone taper. His rash worsened, and he complained of nausea and watery diarrhea. Infectious workup was negative. Hepatic and renal function were normal and immunosuppression was continued. However on PTD 31, he was noted to be pancytopenic. Bone marrow biopsy revealed normocellular marrow without evidence of GVHD. Short tandem repeats (STR) enriched for CD3+ cells from peripheral blood showed mixed chimerism. His diarrhea became intractable, and a colon biopsy revealed Grade 1 GVHD. MP 2mg/kg/ day was started, but he became neutropenic requiring filgrastim. He had persistent mixed chimerism on repeat testing a week later. Ruxolitinib 5mg twice daily (a selective Janus kinase inhibitor used in steroid refractory GVHD, where it inhibits T cell activation) was added. 3 days later, leucopenia and thrombocytopenia resolved and diarrhea ceased. His rash improved and steroids were gradually tapered. 6 wks post treatment there was no evidence of peripheral blood donor chimerism.

Discussion: Knowledge of the clinical features of GVHD in SOT is limited and delayed diagnosis contributes to the high mortality. This case demonstrates the value of early recognition and initiation of treatment. The treatment however, is quite heterogenous and no guideline exists.

PUB641

First Report of Successful Kidney Transplantation in a Patient with Job's Syndrome

Samaya J. Anumudu,[2] Ahmed A. Awan,[2] Bhamidipati V. Murthy,[2] Biruh Workeneh.[1,2] *[1]MD Anderson Cancer Center, Houston, TX; [2]Baylor College of Medicine, Houston, TX.*

Introduction: Autosomal dominant hyper-IgE syndrome (AD-HIES), commonly referred as Job's syndrome, is a rare immune disorder associated with mutations in the STAT3 gene with high blood levels of IgE. Recurrent infections affecting multiple body systems characterize the disease. Little is known of the renal disease that occurs in patients with Job's syndrome; however, there have been documented reports of lupus nephritis and interstitial disease occurring in these patients. The survival of patients receiving hemodialysis (HD) is poor and can be decidedly improved with transplantation, but due to the high risk of infections kidney transplantation has not been generally considered as an option for patients with AD-HIES.

Case Description: A 26-year-old African American female with a history of Job's syndrome, asthma, and recurrent skin and lung infections developed end-stage renal disease (ESRD) due to immune-complex nephritis. She received HD for 5 years prior to accepting a living related kidney transplant from her mother. She received induction with thymoglobulin, and was subsequently placed on tacrolimus, mycophenolate, prednisone along with standard infection prophylaxis. She had immediate graft function and was discharged home on post-operative day 4 with a serum creatinine (SCr) of 1.26 mg/dL, down from a pre-transplant value of 11.73 mg/dL. Infectious complications during her post-transplant course included several urinary tract infections, an episode of influenza, CMV, BK, and EBV viremia. She also experienced periodic asthma exacerbations and pneumonia, which required brief hospitalizations. She developed acute kidney injury after some of the infectious complications, never requiring dialysis. After 14 months post-transplant she has not experiend allograft rejection and maintains good renal function, the most recent SCr was 1.08 mg/dL at the time of this report.

Discussion: We present the first and only case of successful kidney transplantation in a patient with Job's syndrome. Despite the various infectious episodes complicating her post-transplant course, she has been able to overcome them and her renal function remains excellent. The decision to transplant should be highly personalized with the involvement of experts who are familiar with the disease. Close monitoring for infectious complications and avoidance of over-immunosuppression would be advised.

PUB642

A Case of Myeloma Cast Nephropathy Unmasked by Volume Depletion in a Renal Transplant

Jason C. George, Prince Mohan. *Geisinger Medical Center, Danville, PA.*

Introduction: Acute kidney injury (AKI) in a renal transplant patient should prompt investigation for reversible causes, such as volume depletion, ureteral obstruction, or supra-therapeutic calcineurin inhibitor levels. If no clear cause is identified, allograft biopsy can help elucidate a diagnosis and potentially guide treatment decisions.

Case Description: A 51 year-old Caucasian female with Alport syndrome underwent deceased donor renal transplant at age 37. She had chronic allograft dysfunction with baseline creatinine 1.8-2.0 mg/dL. Medications included tacrolimus 2mg q12h, mycophenolate mofetil 500mg BID, and lisinopril 5mg daily. She presented with 5 days of profuse diarrhea and poor oral intake. Her daughter was recently sick with similar symptoms. Labs showed creatinine of 6.5 mg/dL, HgB 6.7 mg/dL, calcium 8.0 mg/dL, albumin 4.1 g/dL, and FK trough of 2.9. Stool infectious workup was unrevealing. Transplant ultrasound showed no evidence of hydronephrosis. She received IV fluids without improvement in renal function. Allograft biopsy showed numerous intra-tubular, periodic acid-Schiff-negative casts with surrounding cellular reaction and diffuse interstitial edema/inflammation. Moderate tubular atrophy/interstitial fibrosis were present. No glomerulitis/tubulitis, or crescent formation were seen. Staining for C4d was negative in peri-tubular capillaries. Bone marrow biopsy showed plasma cell infiltrate of 30% with associated kappa restriction, consistent with light chain myeloma. She was started on induction chemotherapy and plasmapheresis. She required hemodialysis due to progressive decline in renal function and associated hyperkalemia.

Discussion: Light chain cast nephropathy can be unveiled in certain settings, such as intravascular volume depletion or receipt of potentially nephrotoxic agents (iodinated contrast, NSAID's, etc.). Severe renal insufficiency at diagnosis is generally associated with worse overall survival. However, recovery of renal function with disease-specific therapy can have prognostic significance. Thus, it should remain a diagnostic consideration in patients with AKI that does not improve with conservative interventions, especially in the setting of volume depletion.

PUB643

Unusual Case of Encapsulated Sclerosing Peritonitis(ESP) in Renal Transplant Recipient

Sasmit Roy,[1] Kenneth A. Bodziak.[2] [1]*Renal Medicine, University of Massachusetts Medical School, Worcester, MA;* [2]*UMass Memorial Medical Center, Worcester, MA.*

Introduction: ESP is a rare complication of Peritoneal Dialysis(PD) with annual mortality 51%. Likely causes are prior episode of severe peritonitis, using acetate as dialysate buffer, prolonged exposure to glucose degradation products from glucose-containing solutions, withdrawal from PD and long duration of PD.

Case Description: 35 year old man admitted with intractable nausea(N), vomiting(V), odynophagia, abdomen distension and weight loss for few months. **PMH**:ESRD from FSGS s/p LRKT in 2003 failed due to noncompliance and recurrent FSGS, HTN, on PD for >10 years, DDKT12/2016. **P/E**:BP 90/50; weight loss 50 lbs ;tender distended abd, no guarding, sluggish bowel. **Labs**:K 5.4, HCT 35. Frequent readmission for abd pain, N&V.Multiple CT abd-loculated collections, large hemoperitoneum, no bowel obstruction. Ba swallow- delayed gastric emptying;bone marrow biopsy -neg. IR guided angiogram- no active bleeding or aneurysm. Managed conservatively and started on TPN. **Exploratory Laporotomy**:Dense fibrovascular tissue with chronic inflammation, hemorrhage, hemosiderin deposition and fibrin;fibrous tissue with fibrinous exudate and necrosis **Treatment:**Tamoxifen. Now tolerating po intake. Stable renal graft function on tacrolimus& prednisone.

Discussion: ESP cause extensive intraperitoneal fibrosis & encasement of bowel loops. It is associated with progressive loss of ultrafiltration, causing fluid retention and edema. It is slowly progressive, mostly asymptomatic. Presentations are abd pain, N&V, appetite loss, constipation, diarrhea, abdominal mass, ascites, weight loss and fatigue. CT abd shows peritoneal calcification, bowel thickening, bowel tethering and dilatation. Diagnostic confirmation with laparotomy/laparoscopy-characteristic peritoneal thickening that encloses intestinal contents. Histopathology: dense fibrocollagenous tissue +/- lymphocytic/plasma cell infiltration. Treatment is switching from PD to hemodialysis, bowel rest with TPN, immunosuppressive therapy (corticosteroids/azathioprine/tamoxifen)+/- surgery.

External Iliac Artery Stenosis Causing Resistant Hypertension and Acute Renal Allograft Dysfunction

Jason C. George,[1] Anil Kotru,[1] Amit B. Bansal,[3] Christine Du,[2] Prince Mohan,[1] Ashok Bhanushali.[2] [1]*Geisinger Medical Center, Danville, PA;* [2]*Geisinger Health System, Danville, PA;* [3]*Geisinger, Danville, PA.*

Introduction: Renal artery stenosis (RAS) in kidney transplant is a reversible cause of hypertension (HTN) and acute kidney injury. Although RAS usually presents between the first three months to two years after transplantation, it can manifest at any point during the post-transplant course. We present a rare case of external iliac artery stenosis presenting as transplant RAS.

Case Description: A 52 year-old man with end stage renal disease due to IgA nephropathy and diabetes underwent living unrelated renal transplant (right lower quadrant placement) 9 years prior to presentation. Baseline lab values showed creatinine of 1.4 mg/dL and urine protein/creatinine ratio of <500mg/g. His tacrolimus trough level was maintained at 6-7 ng/mL. Over the past several years he developed worsening HTN, for which he was treated with lisinopril but this required discontinuation on several occasions due to worsening renal allograft function. He developed worsening HTN and renal allograft function with creatinine as high as 2.7 mg/dL. On physical examination, a bruit was appreciated over the allograft. Renal ultrasound showed a parvus-tardus waveform. Angiography performed by Interventional Radiology showed high-grade stenosis of the right external iliac artery that was successfully stented with no residual post-procedural stenosis identified. No stenosis of the transplanted renal artery was seen. Prior to the procedure he disclosed worsening right leg claudication that improved after vascular intervention. His creatinine subsequently improved to 1.3mg/dL and blood pressure was controlled on minimal anti-hypertensive therapy.

Discussion: Stenosis of the transplanted renal artery is a common complication after renal transplantation. It can occur in up to 23% of patients and present as uncontrolled hypertension with AKI. Stenosis of the anastamosed external iliac artery, which can have similar hemodynamic effects on the renal allograft, can also occur but has rarely been reported. This case highlights the importance of thorough vascular examination in the renal transplant recipient to help identify signs of poor flow to the ipsilateral limb of the allograft. Such vascular changes can unmask a stenosis that is proximal to the renal artery and can have clinical manifestations of RAS.

PUB645

Cystic Degeneration of Metastatic Lymph Nodes in Renal Cell Carcinoma (RCC) in a Renal Transplant Patient

Hong loan T. Nguyen, Samaya J. Anumudu, Natasha N. Dave, Bhamidipati V. Murthy. *Baylor College of Medicine, Houston, TX.*

Introduction: Increased risk of malignancy is a major post-transplant complication. The incidence of *de novo* RCC is 4.6% in the renal transplant compared to 3% in the general population and 25% of which are incidentally discovered. We present a case of incidental RCC associated with rare cystic degeneration of metastatic lymph nodes in a renal transplant patient.

Case Description: A 53 y/o AAM with obesity and h/o kidney transplantation 5 years ago secondary to ESKD from hypertensive nephrosclerosis requiring prior hemodialysis was admitted with advanced renal failure. He presented with nausea, vomiting and anuria after defaulting on immunosuppression for few weeks and was found with blood pressure 220/100, creatinine 33.16 mg/dl, BUN 180 mg/dl, hyperkalemia, severe metabolic acidosis, and microangiopathic hemolytic anemia on workup. Allograft kidney biopsy revealed thrombotic microangiopathy, acute tubulitis, intimal vasculitis, and positive C4d staining consistent with acute antibody-mediated rejection (AMR). Hospital course was complicated by incidental finding of diffuse mediastinal and cervical lymphadenopathy with cystic degeneration. Cytology of the cyst aspirate revealed papillary cancer. Further imaging showed atrophic native kidneys with innumerable bilateral complex cysts and normal allograft kidney. Immunohistochemistry profile favored papillary RCC – likely arising from native kidneys. During AMR treatment, he developed life-threatening spontaneous hemorrhage from left native kidney needing percutaneous embolization.

Discussion: In renal transplant recipients, RCC is the most common urologic malignancy and multiple factors such as age, gender, race, dialysis duration, glomerular disease has been shown to affect RCC risk. However, most transplant guidelines either recommend against or do not include RCC screening recommendation citing limited cost-effectiveness of screening strategies. A regular post-transplant surveillance would have detected RCC in a much earlier stage with probable chance of cure. This case emphasizes the need for further awareness and clear cancer surveillance guideline with special attention to high risk post-transplant population. This case also highlights two other rare presentations – a cystic degeneration in metastatic lymph nodes, and spontaneous hemorrhage of RCC in a transplant recipient.

PUB646

De Novo Crescentic IgA Nephropathy Along with Antigen and Antibody Mediated Rejection in a Renal Allograft

Sandeep Padala, Imran Y. Gani. *Augusta University, Augusta, GA.*

Introduction: Acute rejection is the common cause of allograft dysfunction in a kidney transplant. Rejection can be either antigen or antibody mediated. De Novo IgA nephropathy can happen in tranplant kidney. We report a unique case of de novo crescentic IgA Nephropathy with both acute cellular and antibody mediated severe allograft rejection.

Case Description: 36-year-old male with history of ESRD secondary to recurrent AKI from sepsis related to MRSA hip osteomyelitis and contrast exposure s/p deceased donor kidney transplant in 2014, h/o biopsy proven cell and antibody mediated rejection in 2015 due to non-compliance with immunosuppressants which was successfully treated. He was admitted with nausea, diarrhea and dark colored urine. Labs revealed AKI with creatinine of 11 mg/dL (baseline 1.8), BUN of 96 mg/dL, CO2 of 11 mEq/L, K of 5.6 mEq/L and subtherapeutic tacrolimus level of 1.6 ng/ml. UA and microscopy revealed dysmorphic RBC's and protein without any infection. On exam, he had a systolic murmur and 1+ bilateral lower extremity edema. Pan cultures and ECHO were negative. Due to worsening acidosis and hyperkalemia, hemodialysis was initiated. Transplant ultrasound was normal. A kidney biopsy revealed mesangial expansion, IgA deposition, mesangial immune complex deposits, severe lymphoplasmacytic tubulointerstitial infiltration, transplant arteritis, positive C4d staining along peritubular capillaries consistent with both cell mediated as well as humoral rejection. Also crescents were seen. Donor specific antibodies were positive. Further workup revealed weakly positive anti-nuclear antibodies (1:160). C3, C4, ds-DNA, C-ANCA, P-ANCA, anti-GBM, HIV, hepatitis panel, RPR, EBV, CMV, Adenovirus, BK virus and Influenza were negative. Treatment was initiated with high dose steroids, thymoglobulin followed by plasmapheresis and IVIG. Cyclophosphamide was not used. Despite aggressive management, patient had no response and required hemodialysis as outpatient.

Discussion: Our case reports occurrence of de novo crescentic IgA nephropathy along with both cellular and antibody mediated rejection in a kidney transplant patient. IgA nephropathy with mesangial deposits only may have a favorable prognosis but presence of crescents heralds a bad prognosis. Crescentic IgA nephropathy along with transplant rejection is associated with worse prognosis.

PUB647

Successful Combined Liver and Kidney Transplant in a Patient with Primary Hyperoxaluria and Thrombophilia: A Management Conundrum

Sandiya Bindroo,[1] Simin Goral.[2] *[1]Crozer Chester Medical Center, Upland, PA; [2]University of Pennsylvania, Bryn Mawr, PA.*

Introduction: Primary hyperoxaluria (PH) is a rare autosomal recessive disorder caused by a deficiency of the liver-specific enzyme alanine: glyoxylate aminotransferase (AGXT). This is characterized by oxalate overproduction, leading to kidney failure due to nephrocalcinosis, and is eventually responsible for systemic oxalosis. We present a case of PH with known factor V Leiden and prothrombin 20210G mutation, who underwent combined deceased-donor liver and kidney transplant (CLKT).

Case Description: A 27-year-old Syrian female, with a history of PH type 1 (positive AGXT mutation), factor V Leiden and prothrombin gene mutation was scheduled for CLKT. Over the past 1 year, patient developed end-stage renal disease in the setting of nephrocalcinosis secondary to PH and was started on hemodialysis (HD). Preoperative laboratory tests showed serum creatinine, 5.63 mg/dL (0.6-1.2 mg/dl); international normalized ratio (INR), 1.1; and activated partial thromboplastin time (aPTT), 29 seconds. Model for End-Stage Liver Disease score was 21. Intermittent HD was done 6-24 hours before surgery to adjust electrolyte balance and to optimize intravascular volume. Continuous venovenous hemofiltration (CVVHD) was started after induction of anesthesia to remove oxalate crystals. She received methylprednisolone and thymoglobulin for immunosuppression. In view of the patient's history of prothrombin gene mutation and factor V Leiden mutation, she was maintained on a heparin infusion with an aim of maintaining the partial thromboplastin time in the range of 70-75. She remained stable throughout, maintaining a mean arterial pressure goal of > 80-85 mmHg after reperfusion. CVVHD was continued in post-operative period to enhance oxalate removal followed by intermittent daily HD. As per institutional policy she was on maintenance immunosuppression with tacrolimus, steroid taper and mycophenolate mofetil. The functions of both grafts remained stable throughout the entire 2-month post-transplant period.

Discussion: Inherited prothrombotic risk factors predispose to thromboembolic events and are significantly associated with acute vascular rejections. There is currently no consensus on optimal management for CLKT in the setting of prothrombin gene mutation. More prospective studies are needed to elucidate ideal treatment strategies for an uncommon, but important clinical scenario.

PUB648

A Case of PTLD 27 Years After Kidney Transplantation in a Failing Allograft

Maho Terashita,[1] Masahiko Yazawa,[2] Yugo Shibagaki.[1] *[1]Department of Nephrology and Hypertension, St. Marianna University School of Medicine, Kawasaki, Japan; [2]Division of Nephrology and Hypertension, Department of Internal Medicine, St.Marianna University School of Medicine, Kawasaki, Japan.*

Introduction: The deterioration of allograft function in kidney transplant recipients can lead to over immunosuppression due to relative immunosuppressant overdosing for kidney function. We report a case of EBV-positive post transplantation lymphoproliferative disorders (PTLD) 27 years after transplantation in a failing allograft, which immediately responded well only to withdrawal of immunosuppressant (IS).

Case Description: A 59-year-old female, who received an ABO-compatible living kidney transplantation 27 years ago, was admitted to initiate dialysis for allograft failure. Six months prior, she had developed pancytopenia, which was caused by bone marrow suppression from accumulation of mycophenolic acid and CMV infection, and was recovered by reducing mycophenolate mofetil (MMF). When admitted, she was found to have asymptomatic low-grade fever. Computed tomography (CT) showed multiple liver masses without lymphadenopathy or other organ involvement, which was not present six months before. We at first diagnosed it as liver abscess and treated her with antibiotics, only in vain. We then punctured the liver mass, which showed diffuse large B-cell lymphoma (DLBCL) with positive EBV in situ, leading to a final diagnosis of PTLD. MMF and cyclosporine were stopped immediately, and subsequently she became afebrile and the liver masses were completely disappeared within 4 months without requiring chemotherapy.

Discussion: Although there are a growing number of late-onset PTLD, most reported cases were occurred earlier than twenty years post-transplant and were not so associated with EBV, partly because ISs are usually reduced in very late phase. In these perspectives, our case seems exceptional. Teaching points in our case include that PTLD can occur even very long after the transplant, and that late onset PTLD can be associated with EBV. We speculate the pathogenesis of our case is over-immunosuppression not because of absolute IS overdosing but because of relative overdosing due to advanced allograft dysfunction, in which renally excreted MPA could accumulate. The fact that only IS withdrawal resolved the PTLD suggests the over-immunosuppression rather than dysregulated proliferation is the cause of PTLD in our case. In conclusion, failed transplant patients may have risk of PTLD due to relative IS overdosing, which may be prevented by therapeutic drug monitoring.

PUB649

Chronic Interstitial Nephritis with IgG Tubular Basement Membrane Staining in a Allogeneic Stem Cell Transplant Patient: Renal Graft vs Host Disease?

Hanan A. Khairalla,[1] Omar Mamlouk,[2] William F. Glass,[3] A. Bernard Collins,[5] Ivy Rosales,[5] Nina E. Tolkoff-Rubin,[5] Ala Abudayyeh.[4] *[1]University of Texas, Houston, TX; [2]University of Texas Health Science Center at Houston, Houston, TX; [3]University of Texas – Houston Medical School, Houston, TX; [4]The University of Texas MD Anderson Cancer Center, Houston, TX; [5]Massachusetts General Hospital, Boston, MA.*

Introduction: GVHD of the kidney is a rare complication post allogeneic SCT usually manifests clinically as a nephrotic syndrome. Renal GVHD can present as minimal change disease, membranous nephropathy, or FSGS. We are presenting an allogeneic SCT patient who developed tubulo-interstitial nephritis with IgG and C3 granular tubular basement membrane deposits with negative brush border autoantibodies. To the best of our knowledge, this is the first case report of renal GVHD associated with antibodies against an unknown tubular antigens in humans.

Case Description: 56-year-old woman with history of plasma cell leukemia who underwent an allogeneic SCT in 2016. Her transplant course was complicated by GVHD of the skin and GI tract, treated successfully with steroids and continued on prophylactic sirolimus. She has developed progressive renal dysfunction with creatinine increasing to 2.5mg/dl from baseline of 1mg/dl. She was noted to have proteinuria of 1g she underwent a renal biopsy that indicated chronic tubulo-interstitial nephritis with granular tubular basement membrane deposits. No evidence of BK Polyomavirus infection or IgG4 subtype. Patient had normal complements and lupus serologies. Based on a similar case report in a kidney transplant recipient with interstitial infiltrate and anti-brush border antibody we tested our patient's serum for ABBA; however, was negative. We have started patient on prednisone 1mg/kg to treat for the interstitial infiltrate with improved creatinine and have started her on Rituximab in hopes to help with the antibody mediated process.

Discussion: We postulate that autoantibodies to an unknown tubule antigen likely caused cellular injury in our patient with granular basement membrane deposits. Autoantibodies against proximal tubular brush border in mice with experimentally induced chronic GVHD has been reported, but no similar findings in humans. In recent studies, the presence of autoantibodies after allogeneic SCT in association with GVHD provides evidence for B-cell involvement. It has been shown in autoimmune disease that more than half of the developing B cells in the bone marrow express autoreactive B-cell receptors. This case presents yet another possible form of renal GVHD after allogeneic SCT.

PUB650

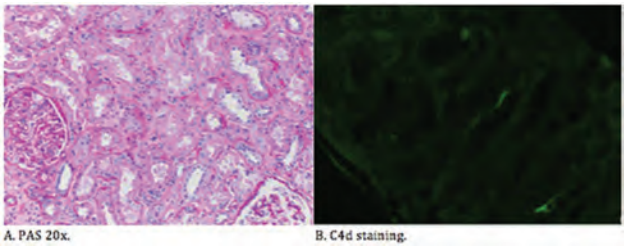
AT1R Antibodies: Time to Think Outside the HLA Box

Brittaini D. Bunce,[1,2] David N. Dado,[1,2] Yanli Ding,[4] Suverta Bhayana.[3] *[1]Nephrology, University of Texas Health Science Center, San Antonio, TX; [2]Nephrology, San Antonio Military Medical Center, San Antonio, TX; [3]Transplant, University of Texas Health Science Center, San Antonio, TX; [4]Pathology, University of Texas Health Science Center, San Antonio, TX.*

Introduction: In renal transplantation, elevated levels of anti-angiotensin II type 1 receptor (AT1R) antibodies have been associated with antibody-mediated rejection (AMR) in the absence of HLA (human leukocyte antigen) donor specific antibodies (DSA). The majority of these patients present early after transplantation with elevated serum creatinine (SCr) in the setting of accelerated hypertension. Renal biopsy typically shows C4d negative vascular rejection. Treatment with an angiotensin receptor blocker (ARB) has been successful in children but is not well-documented in adults.

Case Description: We present a unique case of a 29-year-old male with end-stage renal disease due to Alport syndrome who underwent a living related renal transplant with nadir SCr 1.2mg/dl. He received thymoglobulin induction with tacrolimus, mycophenolate mofetil, and corticosteroids maintenance therapy with an uneventful post-transplant course. At one year follow-up, urine protein-to-creatinine ratio (UPC) increased to 0.8, and lisinopril was started. Six weeks later, UPC was 2.24. Renal biopsy showed moderate glomerulitis and peritubular capillaritis (Image A) with minimal C4d staining of the peritubular capillaries (Image B) consistent with an AMR. Pre and post-transplantation sera were negative for HLA DSAs, so non-HLA antibody testing was sent. Anti-AT1R antibodies were detected at 33 U/ml (strong positive). Patient was switched to losartan and then treated with intravenous methylprednisolone 500mg for three doses followed by four sessions of plasmapheresis. The response to treatment was excellent with a decrease in UPC to 1.2 and in anti-AT1R antibodies level to 8U/ml (<10 normal). SCr and blood pressure remained well-controlled throughout the treatment.

Discussion: AMR in renal transplantation due to non-HLA antibodies, like anti-AT1R antibodies, has gained interest in recent years. The diagnosis is often missed or delayed, leading to more aggressive therapy and a poor prognosis. Our patient had an unusual presentation with proteinuria, but prompt diagnosis and early initiation of therapy achieved a good outcome with relatively modest immunosuppression.



PUB651

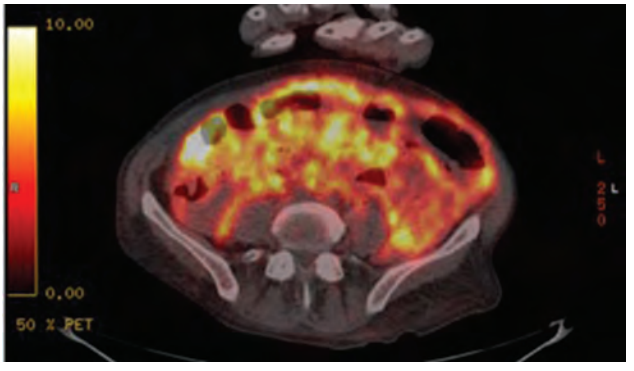
A Case of Serous Lymphoma Post Renal Transplant

Michelle Clince,[1] Hannah M. O'Keeffe,[2] Conall M. O'Seaghdha.[1] [1]*Beaumont Hospital, Dublin, Ireland;* [2]*Health Service Executive, Ireland, Galway, Ireland.*

Introduction: Post-transplant lymphoproliferative disorder (PTLD) is one of the most feared consequences of long term transplantation. We present a case occurring late in the post transplant period with an unusual distribution. The case highlights the utility of PET CT in facilitating diagnosis and guiding tissue diagnosis in suspected PTLD.

Case Description: Our case is a 62 year old man who presented with anorexia, weight loss, night sweats, fevers, and altered bowel habit. End stage renal disease was secondary to IgA nephropathy. He was a deceased donor transplant recipient from 2000 with early biopsy proven antibody mediated rejection. Maintenance immunosuppresion was Tacrolimus and Mycophenolate mofetil. Clinically he had ascites and lower limb oedema. CT-TAP showed dense ascites and small bowel thickening. Colonoscopy was normal. A large pleural effusion caused respiratory compromise and chest drain insertion was performed. Empiric cover for TB was added due to his clinical status and pending a tissue diagnosis. PET-CT showed extensive FDG avid peritoneal disease (Figure 1) as well as in the pleura and pericardium. Ascitic fluid had abundant inflammatory cells but no malignant cells. Pleural aspirate revealed atypical lymphoid cells positive for CD20 consistent with high grade B cell lymphoma. Peritoneal biopsy revealed atypical cells staining positive for CD20, CD10 and BC16. Immunosuppression was discontinued and he is being treated with R-CHOP with an excellent clinical response to date. Graft function remains stable

Discussion: Given the heterogeneity of PTLD presentations the clinician must maintain a high index of suspicion. This case demonstrates an unusual distribution of a post transplant lymphoma as well as highlighting the increasing utility of PET-CT in the work up of these patients. Earlier use of PET-CT in the work up of suspected PTLD may facilitate earlier instigation of treatment and improve prognosis.



PUB652

A Case of Lymphocele Associated Kidney Graft Impairment

Lucas A. Bastianelli, Valkercyo A. Feitosa, Igor Smolentzov, Luiz F. Souza, Andrés S. Bueno, Laura Onuchic, Flavio De paula. *Universidade de São Paulo, São Paulo, Brazil.*

Introduction: Lymphocele is well established as an early renal transplantation complication and may seriously impair graft function due to graft vessel compression. Venous compression may increase the pressure gradient and therefore cause kidney graft associated proteinuria.

Case Description: A 46 year-old male, on hemodialysis for the past 3 years due to hypertensive nephrosclerosis, was admitted for deceased donor kidney transplantation. We followed institutional protocols for surgery and immunossupression, with no apparent complications. At discharge, the patient serum creatinine was 1.53mg/dL and urine tests for proteinuria were negative. Four months after transplantation, the serum creatinine increased to 2.56 mg/dL and the protein/creatinine ratio rose to 4.3 (g/g), with no hematuria. Renal graft biopsy revealed interstitial fibrosis and mild focal tubular atrophy, BANFF grade I, and immunofluorescence for C4d was negative. Computerized tomography of the abdomen revealed two lymphocells, localized posterior to the graft (18.0 x 10.0 x 10.0 cm) and adjacent to the left iliac vessels (8.5 x 6.0 x 6.0 cm), leading to compression of the left external iliac vein close to the venous anastomosis of the renal graft. In this scenario, marsupialization of the lymphocele was performed due to worsening renal function and progressively ascendant protein/creatinine ratio (12.1 g/g). Two days after surgery, the patient evolved with reduction in proteinuria (protein/creatinine levels of 0.2g/g) and serum creatinine dropped to 1.98 mg/dL, suggesting early recovery.

Discussion: This is an atypical case of massive urinary protein loss secondary to lymphocele compression leading to high pressures in the renal vein. Graft rejection and glomerulopathy relapses are widely discussed as etiologies of proteinuria in transplant patients; however in this case we underscore the importance of including anatomical causes among the differential diagnosis.

PUB653

Acute Respiratory Distress in a Renal Transplant Recipient: Think Toxoplasmosis

Justin Lee Loy, Abhilash Koratala, Gajapathiraju Chamarthi, Kawther F. Alquadan. *University of Flroida, Gainesville, FL.*

Introduction: *Toxoplasma gondii (T. gondii),* an intracellular protozoan parasite is an important cause of opportunistic infection in transplant recipients associated with high mortality. Herein, we present a case where physicians' knowledge gaps and diagnostic difficulties resulted in unfavorable outcome.

Case Description: A 38-year-old man with ESRD due to congenital vesicoureteral reflux underwent deceased donor kidney transplant. Alemtuzumab was used for induction immunosuppression (IS), followed by maintenance IS consisting of mycophenolate mofetil, tacrolimus and prednisone. Inhaled pentamidine was used for post-transplant *P. jirovecii* prophylaxis instead of the standard therapy with trimethoprim-sulfamethoxazole (TMP-SMX) because of hyperkalemia. At 1-month follow up visit, he appeared ill and was febrile to 102 F, hypotensive and tachycardic. He was admitted to the hospital for further evaluation and soon after that, he developed acute respiratory distress requiring intubation, later extracorporeal membrane oxygenation and also dialysis requiring AKI. He was started on broad-spectrum antibiotics/antifungals and antivirals. Blood and urine cultures were negative. Respiratory viral panel, CMV, EBV and HSV serologies were negative. Clinical status deteriorated rapidly and he passed away. Autopsy revealed multiple intracellular organisms consistent with *T. gondii* in both lungs and the heart.

Discussion: The clinical presentation of toxoplasmosis in renal transplant recipients is variable. Fever is the most frequent clinical sign (80%), followed by pneumonia and headaches. It can be transmitted from a seropositive donor to a seronegative recipient or occur as a *de novo* infection or as a reactivation of latent infection. Our patient was seronegative prior to the transplant and donor was positive. Interestingly, post-mortem testing revealed both serologic and histologic positivity for *T. gondii*. The data on prevention of toxoplasmosis is sparse and TMP-SMX at a dose of 1 single-strength tablet daily is considered sufficient for both Pneumocystis and Toxoplasma prevention. Pyrimethamine + TMP-SMX may be considered in high-risk recipients. Toxoplasmosis should be considered in the differential diagnosis of pneumonia, culture-negative sepsis, and encephalitis in renal transplant recipients, especially when the history suggests inadequate prophylaxis.

PUB654

A Rare Case of JC Virus Nephropathy in a Kidney Transplant Recipient

Yan Zhong, Guang-Qian Xiao, Yasir A. Qazi, Thin Thin Maw, Miroslaw Smogorzewski. *Keck school of medicine-USC, Los Angeles, CA.*

Introduction: Acute kidney injury after renal transplantation is usually attributed to acute cellular or antibody medicated rejections or viral nephropathy (BKV). However rarely we can be confronted with the unexpected conditions. We are reporting a rare case of biopsy proven JCV nephropathy in a kidney transplant recipient.

Case Description: A 57-yo female, ESRD due to ADPKD, had deceased donor renal transplant (DDRT) in 2011. She was on azathioprine, tacrolimus and prednisone as the maintenance therapy with serum creatinine level 1.8 to 2.0mg/dL. In 2017 SCr elevated to 3mg/dL for 3 months without urinary symptoms. BKV PCR was negative in both serum and urine. Kidney biopsy show acute tubular injury, acute interstitial inflammation, and scattered prominent atypical tubular epithelial cells. SV40 stains was positive in many cells (figure 1). JCV DNA was detected by in situ hybridization in the allograft biopsy tissue. JCV DNA was also detected by PCR in both blood (81661copies/ml) and urine (>35000000 copies/ml). Spinal fluid was negative for JCV. MRI of the brain was unremarkable. JCV blood level became undetectable 4 months after reduction in tacrolimus dosage and initiation of iv IG. Prednisone and azathioprine were continued. Transplant kidney function remained stable with SCr 2.8mg/dL.

Discussion: Up to 36% of renal transplant recipients were found to be positive for JCV in their urine. Reactivation of JCV post-transplant could be associated with PML in immunosuppressed patients, but rarely causes JCV nephropathy. Less than a dozen cases of JCV nephropathy were ever reported in renal transplant recipients after the first case in 2003. Reduction in immunosuppression remains the mainstay of treatment for JCV nephropathy. Use of iv IG was reported to be helpful as well. It is important to look for JCV nephropathy in DDRT recipients with unexplained AKI.

PUB655

Native Kidney BK Nephropathy in Lung Transplant Patient

Rungwasee Rattanavich,[1] Joseph Gaut,[2] Andrew F. Malone.[1] *[1]Division of Nephrology, Department of Medicine, Washington University School of Medicine, St.Louis, MO; [2]Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, MO.*

Introduction: BK nephropathy (BKN) usually affects renal allografts and is rarely seen in non-renal solid organ transplant patients. We present the rare case of a lung transplant patient who developed BK nephropathy in the native kidney.

Case Description: 62 yo AAF with sarcoidosis received a bilateral lung transplant in 2007 complicated by bronchiolitis obliterans syndrome stage III and CKD stage IV secondary to calcineurin inhibitor toxicity. Her immunosuppression was sirolimus, mycophenolic acid, and prednisone. She presented with severe sepsis, Pseudomonas pneumonia, and acute kidney injury (AKI) Cr up to 4.3. Renal function did not improve despite improvement of pneumonia and sepsis. Native kidney biopsy showed tubulitis and viral nuclear inclusions and serum BK PCR was 8,000,000 copies/ml. Her renal function rapidly declined (Cr 6.8). She was treated for BKN with lower immunosuppression, IVIG and cidofovir. Her renal function improved without need for dialysis and her serum BK PCR decreased to 849,000 copies/ml. Three weeks after discharge, she was re-admitted with progressive acute respiratory failure and severe oliguric AKI requiring hemodialysis. BK levels increased back to 1,700,000 copies/ml and sepsis work up was negative. She was later transitioned to comfort measures per family wishes.

Discussion: The poorer outcomes seen with BKN in non-renal solid organ transplants maybe due to the lack awareness of native BKN and its relative rarity in this population. This leads to late diagnosis, advanced irreversible disease and poorer response to treatment. A higher suspicion for BKN in non-solid organ transplant patients with AKI seems warranted. Peripheral blood testing for BK virus and kidney biopsy for early diagnosis may avoid irreversible injury and yield a more favorable outcome.

PUB656

Preserved Renal-Allograft Function and Successful Treatment of Metastatic Merkel Cell Cancer Post Nivolumab Therapy

Priyamvada Singh,[1] Jon R. Von Visger,[1] Jason Prosek,[6] Thomas Olencki,[2] Deepali Pandey,[3] Brad H. Rovin,[4] Todd E. Pesavento.[5] *[1]The Ohio State University Wexner Medical Center, Columbus, OH; [2]The Ohio State University, Columbus, OH; [3]Saint Vincent Hospital, Worcester, MA; [4]Ohio State University Wexner Medical Center, Columbus, OH; [5]Ohio State University, Columbus, OH; [6]The Ohio State University Medicial Center, Columbus, OH.*

Introduction: Checkpoint inhibitors like Programmed cell death 1 (PD-1) inhibitors are found to be efficacious even in difficult-to-treat cancers, has fewer side-effects and sustained therapeutic benefit. PD-1 is a cell surface receptor that has a vital role in down-regulating the immune system and enhancing self-tolerance by suppressing T cell activity. The major shortcoming in Kidney transplant recipient is the severe rejection and immediate graft loss making it somewhat taboo to use these agents in this population.

Case Description: 71-year-old female, status post deceased donor Kidney transplant in 2004 for Autosomal Dominant Polycystic Kidney disease with coincident native nephrectomy received a 5/6 HLA-mismatched kidney, induction with ATG and steroid, and maintenance therapy of tacrolimus and myfortic. She was diagnosed with Merkel cell cancer in 01/2016 and underwent lateral neck dissection and radiation therapy (05/2016). Tacrolimus was discontinued, mycophenolate was reduced to half dose twice daily, and prednisone 5 mg daily was initiated. In April 2017, she was diagnosed with the metastatic disease to the liver and spine. Her prognosis was deemed marginal and she was initiated on Nivolumab and was maintained on 10 mg of Prednisone. She completed a total of 13 cycles of Nivolumab (240 mg based on a dose regimen of 3 mg/kg, every month) without any significant side-effects and significant improvement in the quality of life. Her renal function remained stable with the creatinine of 1.5 (egfr 35), absent donor-specific antibodies and no disease progression on subsequent imaging.

Discussion: To date, the literature reports five kidney transplant recipients treated with PD-1 inhibitors. To our knowledge, the case presented here is only the second case of a kidney transplant patient treated with a PD-1 inhibitor(s) who did not experience acute rejection. One similarity between our situation and previously reported case is the history of native nephrectomy. It is unclear if native Kidneys have a role to play in rejections and thus nephrectomy is giving an added benefit. Additionally, our patient was on a reduced frequency of Nivolumab (monthly compared to bi-monthly). If these drug regimens have any significant role to play in avoiding rejection, is again a topic for future research and debate.

PUB657

Stuck Between a Rock and a Hard Place - The Challenging Management of Metastatic Renal Cell Carcinoma in a Kidney Transplant Recipient Using Checkpoint Inhibitors

Manini Vishwanath,[1] Sara Syeda,[2] Basma O. Merhi.[3] *[1]Rhode Island Hospital/ Brown University, Providence, RI; [2]Brown University, Cranston, RI; [3]Nephrology, East Greenwich, RI.*

Introduction: The incidence of Renal Cell Carcinoma(RCC) in a renal transplant is 100 times higher than the general population. Metastatic RCC is a dreaded complication and currently there is no one specific agent used in its management. Due to marked success of immunotherapy and checkpoint inhibitors (CPIs) specifically the program cell death ligand inhibitors (PD-1)in treatment of melanomas, these agents have been proposed for metastatic RCC also. Their effects on organ transplant recipients are unknown.

Case Description: 58 y/o Caucasian male with h/o End Stage Renal Disease on hemodialysis for 2 years s/p Deceased donor kidney transplant 18 years ago, maintained on tacrolimus, azathioprine and prednisone, with excellent allograft function with baseline creatinine of 1.5 presented with shortness of breath. Medical history included bilateral nephrectomies performed 4 years ago with both kidney biopsied and showing RCC. A CT Chest this admission revealed multiple nodules to the lungs and a left sided pleural effusion. Surprisingly, a nodule biopsy was consistent with metastatic RCC. Oncologists initiated pazopinib(a tyrosine kinase inhibitor) but disease progressed on the drug. Hence, the decision to switch to Nivolumab(a PD-1L inhibitor) was made while decreasing dose of tacrolimus. Within 2 weeks of drug initiation, patient became oliguric and developed an acute kidney injury with a creatinine of 4.5. An allograft biopsy showed banff grade 2A/2B acute cellular rejection and dialysis had to be resumed. Unfotunately, patient could not tolerate dialysis due to hypotension, had recurrent admissions for pleural effusions and finally opted for inpatient hospice.

Discussion: Our case is unique in several ways. It is an exceedingly rare one where metastatic RCC was found even years after bilateral nephrectomy. It is also highlights the association of CPIs with acute cellular graft rejection. PD-1 ligand inhibitors increase effector T-Cell activity, promote tumor regression, but may also be responsible for the cell mediated rejection of the allograft, using the same pathway. Hence, it becomes necessary to weigh the risks of graft rejection with mortality benefit from immunotherapy in organ transplant recipients because of significant morbidity that follows.

PUB658

Nivolumab-Induced Kidney Transplant Allograft Rejection Requiring Nephrectomy

Vishwa C. Sheth, Kuang-Yu Jen, Brian Y. Young. *University of California, Davis, Sacramento, CA.*

Introduction: Many types of cancers have developed mechanisms to activate immune checkpoints in order to evade the immune system. Immune checkpoint inhibitors allow a patient's immune system to overcome such a blockade in order to target and eradicate tumor cells. Although checkpoint inhibition holds a promising future in cancer treatment, side effects can include severe autoimmune-mediated reactions, including against transplanted organs. We report a case of a patient treated with nivolumab who developed acute on chronic kidney allograft rejection necessitating nephrectomy.

Case Description: A 47-year-old female who had chronic kidney disease stage V secondary to renal dysplasia received a living donor kidney transplant and was maintained on prednisone, cyclosporine (CSA), and mycophenolate mofetil (MMF). Her creatinine post-transplant ranged from 1.8-2.5 mg/dl. She was diagnosed with anal squamous cell carcinoma 15 years later and underwent chemoradiation with simultaneous reduction of CSA and discontinuation of MMF. Her kidney function declined over this time. Unfortunately, her cancer recurred 2 years later and was deemed unresectable, prompting her oncologist to start nivolumab. In preparation for immunotherapy, the patient's prednisone and CSA were stopped. By then, her creatinine was 6.1 mg/dl. Shortly after she began maintenance hemodialysis for uremic symptoms, though she continued to make about a liter of urine per day. Two days after receiving her first nivolumab dose, she abruptly became anuric other than small streaks of gross hematuria. Five days post nivolumab treatment she was admitted to the hospital with fever and unrelenting allograft tenderness and swelling. Renal ultrasound showed an enlarged, echogenic allograft of 14 cm with abnormal perfusion, consistent with severe acute rejection. She initially underwent IR-guided embolization of the transplant but ultimately required surgical nephrectomy to control her inflammation.

Discussion: Literature is scarce on protocols for administration of immune checkpoint inhibitors to transplant recipients. We report an interesting case of nivolumab-induced rejection that acutely blossomed two days post-administration. Future studies should evaluate whether transplant nephrectomy should be considered prior to immune checkpoint inhibition, particularly in patients with planned minimization or withdrawal of immunosuppression.

PUB659

AKI from Aspergillus Triggering Antiphospholipid Syndrome

Adrian A. Ochoa,[1] Steven Chou,[1,2] Nagaraju Sarabu,[1] Aparna Padiyar,[1] Anne M. Huml.[1] *[1]Nephrology and Hypertension, University Hospitals Cleveland Medical Center, Cleveland, OH; [2]MetroHealth Medical Center, Cleveland, OH.*

Introduction: Thrombotic microangiopathy (TMA) is commonly encountered following kidney transplant, however anti-phospholipid syndrome (APS) causing TMA is rare. We present a case of transplant AKI from APS triggered by *Aspergillus*.

Case Description: 52 yo M with lupus nephritis status post kidney transplant on tacrolimus and MMF was admitted for 3 days of progressive cough and hemoptysis. Medical history significant for APS with stroke and DVT, paroxysmal a fib on chronic warfarin, HTN and thrombocytopenia. Initial EKG had a fib with RVR and CXR with multifocal pneumonia. Labs: BUN and cr of 32 and 1.9 mg/dL, plt 26 (baseline 80), hgb 12.7 g/dL and INR 1.9 with a PTT of 73. Urinalysis had 2+ protein and hyaline casts. Given IV levofloxacin, oral β-blocker, heparin drip, and platelet transfusions. On day 2, chest CT and bronchoscopy done. No evidence of DAH. CT revealed multifocal ground glass and peribronchial airspace opacities with bronchial thickening and bronchiectasis bilaterally; concerning for atypical fungal infection. Fibrinogen and D-dimer elevated, +ANA (1:160 titer) with normal C3, C4 and ds-DNA. Anti-microbials switched to meropenem and voriconazole. By day 3, renal function deteriorated (cr trend 1.9>4.4>9.8 mg/dL). Due to acute thrombocytopenia, a high concern for TMA even though initial labs not suggestive (LDH 144, hagptoglobin 189). Tacrolimus was held. DRVVT screen, anticardiolipin antibodies, beta 2 glycoprotein resulted very high titers. On day 5, transplant biopsy done and IV methylprednisolone given. Biopsy showed TMA and APS. The biopsy findings mimicked a severe antibody mediated rejection (DSA neg). He received 5- sessions of plasmapharesis (PP) and HD. Bronchoscopy cultures were negative and voriconzale stopped. On day 7, his galactomannan testing from BAL was positive. Given the high specificity of this test, CT findings, and hemoptysis, diagnosed with invasive pulmonary aspergillosis. Voriconazole restarted. 1g/kg of IVIG and 5 more PP was used for refractory thrombocytopenia. Over next 3 weeks, Cr improved, HD stopped, and he was discharged to rehab.

Discussion: This case of AKI induced by TMA and APS triggered by invasive aspergillosis had none of classical features of TMA. A low threshold for kidney biopsy and high suspicion of fungal infection were helpful to reach the diagnosis. The management of APS post-kidney transplant lacks evidence and trials are needed.

PUB660

Wondering Why It Wandered: Pacemaker Lead Perforation in a Renal Transplant Patient on Sirolimus

Gonzalo Matzumura,[1] Angelina Edwards.[2] *[1]University of Texas Health Science Center at Houston, Houston, TX; [2]University of Texas at Houston Health Science Center, Houston, TX.*

Introduction: Pacemaker lead perforation of the ventricle is a rare but potentially fatal event, we present the first reported case of pacemaker lead perforation in a renal transplant patient on sirolimus.

Case Description: A 63 year-old man, end stage renal disease from diabetes, status-post living-related renal transplant 17 years ago, on sirolimus and prednisone, presented to the hospital with dyspnea and flank pain. Medical history included bi-ventricular permanent pacemaker (PPM) 3 months prior. He was hemodynamically unstable, in respiratory distress, requiring intubation and vasopressors. Labs showed acute kidney injury, creatinine of 6.0 mg/dL (baseline 1.3) and hyperkalemia, requiring dialysis. Chest X ray revealed left pleural effusion and displaced right ventricular (RV) pacer lead. Thoracentesis showed hemorrhagic effusion and echocardiogram revealed perforated, thin-walled RV apex, with pericardial effusion. Hemopericardium was evacuated in the OR, RV perforation repaired, and PPM generator/leads were removed. Patient had a favorable post-operative course and underwent reinsertion of pacemaker with no complications. Renal allograft function returned to normal and immunosuppression was changed from sirolimus to tacrolimus. Outpatient follow-up confirmed stable PPM location and function.

Discussion: Ventricular perforation following PPM placement is rare and perforation greater than 1 month after implantation is infrequent. Predictors of perforation include steroid use, temporary pacemaker, active fixation of PPM lead and antiplatelet therapy. Proposed mechanisms include characteristics of the ventricular wall (thinner walls have increased risk of perforation) and intrinsic characteristics of PPM leads. No cases of RV perforation on mammalian target of rapamycin (mTOR) inhibitor therapy have been documented. It is well described that mTOR inhibitors impair fibrosis and wound healing. Furthermore, murine models show less fibrosis, hypertrophy and lower levels of TGF-β and collagen type I and III in rat myocardium on mTORs compared to controls. In this case, sirolimus may have favored conditions in the myocardium (less fibrosis and thinner wall) that allowed RV perforation to occur. This case highlights the importance of considering this infrequent complication in patients on mTOR inhibitor therapy to prevent potentially catastrophic consequences.

PUB661

Unusual Case of Abdominal Pain in Kidney Transplant Patient

Saed Shawar,[1] Osarhiemen A. Omwanghe,[2] Akosua A. Korboe,[2] Juan Pablo Arroyo,[1] Beatrice P. Concepcion.[2] *[1]vanderbilt medical center, ANTIOCH, TN; [2]Vanderbilt University Medical Center, Nashville, TN.*

Introduction: Gastrointestinal histoplasmosis is likely manifestations of disseminated disease but only rarely comes to clinical attention due to the lack of specific signs and symptoms. We report the unusual case of abdominal pain found to be histoplasmosis in duodenum in kidney Transplant patient

Case Description: 65 year female with history of ESRD Secondary to Alport's Syndrome s/p kidney transplant X2, last DDKT 9/2013. Presented to ED with generalized weakness, and abdominal pain, no change in bowel habit, no dysphagia or odynophagia. physical exam notable for abdominal tenderness. Labs notable for mild leukopenia wbc 3.2. Abdominal CT imaging demonstrated 'misty' mesenteric LAD, as well as some mild duodenal thickening. GI was consulted regarding CT findings and performed endoscopy noting some gastric erythema and nodular/polypoid mucosa of the duodenum.biopsy was done and Path returned notable for histoplasmosis at the duodenal biopsy site. no evidence of pulmonary involvement based on CT imaging and CXR. Serum histoplasmosis ag negative, urine histoplasmosis ag positive; She was started on PO liquid Itraconazole and tolerated it. Her abdominal pain has resolved.

Discussion: Disseminated histoplasmosis may involve the gastrointestinal tract in 70-90% of cases, nearly 90% of lesions involve the lower GI tract, most commonly the ileocecal region or colon. Given the risk of dissemination of histoplasmosis and the potential to lead to considerable mortality and morbidity if not identified in early, suggesting that clinicians should consider fungal infections as part of their assessment for transplant patients, presenting with non-specific symptoms, including abdominal pain to improve patient outcomes and prevent disease recurrence.

PUB662

Successful Treatment of Refractory Severe Acute Humoral Rejection (AMR) in a Renal Transplant with Double Filtration Plasmapheresis and Immunoadsorbtion

Martin Russwurm,[1] Joachim Hoyer.[2] *[1]Marburg University, Marburg, Germany; [2]Marburg Philipps-University, Marburg, Germany.*

Introduction: AMR is a major threat to renal allograft survival in the early transplant period as it accounts for up to 40% of graft losses within the first year. Although various immunomodulatory treatments are implemented to treat AMR, there is no golden standard. In every clinical situation regarding mismatch, serological follow-up, severity of AMR and long- and short-term adverse events of immunosuppressive treatment, careful consideration which therapy to choose is imperative. Here we present a case of severe, sustained early AMR, treated w/ the various immunomodulatory agents and techniques, eventually AMR being successfully resolved by an extensive plasmapheresis approach.

Case Description: Immunosuppressive treatment has been initiated w/ Cyclosporin, Methylprednisone and Mycophenolate. While the patient (pt.) developed no graft function postoperatively, she underwent the first renal transplant biopsy (Bx) at d6 which revealed severe AMR. Despite sequentially initiated treatment w/ a course of anti-thymocyte immunoglobulin, plasma exchange, Rituximab, Immunoadsorption (IA) and intravenous immunoglobulin, the pt. remained anuric still. We then decided to serial-connect the double filtration plasmapheresis (DFPP)- w/ an IA system, treating the pt. every other day. After the 2nd treatment the transplant developed excretory function, accompanied by significant decline in SCr. Follow-up Bx at d50 still showed AMR but w/ significantly lesser activity. The pt. was dismissed at d60 w/ improved and stable renal function. We performed DFPP+IA thrice weekly for 2 months and weaned the pt. over one year. The last SCr was 1,52 mg/dl (2,5y).

Discussion: The capability of DFPP+IA in clearing main effectors of AMR was the rational to adopt this approach in an experimental treatment intent. Although we cannot rule out the impact of long-term effects of the preliminary treatments, the chronological relationship of DFPP+IA initiation and renal recovery appears convincing. To our knowledge, this is the first report of DFPP+IA for treatment of severe AMR. Thus, we consider the implications of this case to be twofold: 1st, treatment of severe AMR could be successful in long-term graft dysfunction. 2nd, DFPP+IA should be considered a rescue-treatment option for selected high-risk pts. w/ proven severe AMR in which other treatments failed.

PUB663

Myeloma Cast Nephropathy in the Kidney Transplant: A Rare Reversible Cause of Kidney Transplant Dysfunction

Joana M. Dias. Kidney Transplant Team - Nephrology and Kidney Transplant Department - Hospital de Santa Maria *Centro Hospitalar Lisboa Norte, Lisboa, Portugal.*

Introduction: Multiple Myeloma (MM) is commonly associated with kidney injury through multiple mechanisms, most importantly cast nephropathy. Although kidney transplant recipients (KTR) have a higher incidence of malignancy, *de novo* MM is infrequent. Likewise, cast nephropathy is relatively frequent in the population with MM and kidney dysfunction (KD), but exceedingly rare as a cause of KD in the transplanted kidney.

Case Description: The authors present a case of a 62 year old men submitted to a deceased donor kidney transplant 12 years ago for end stage diabetic nephropathy, presenting a stable baseline serum creatinine (sCr) of 1.2mg/dL therafter. He presented to the clinic with mild progressive KD, with sCr increasing to 2.2mg/dL over a 5-month period. His laboratory workup was unremarkable except for mild anemia and borderline hypercalcemia. At this time his renal biopsy discarded rejection and was otherwise inconclusive. No other causes of KD were found. He maintained rapidly progressive RD over the next 4 months, to a maximum sCr of 8.3mg/dL, leading to initiation of hemodialysis. At this point, investigation revealed a IgA kappa MM with 48% bone marrow plasmacytosis. A second biopsy confirmed myeloma cast nephropathy in the transplanted kidney. He started treatment with bortezomib and cyclophosphamide and switched to high cut-off hemodialysis until disappearance of free light chains. He presented a surprisingly favorable evolution with progressive and sustained renal function recovery (RFR), being dialysis-free after 5 weeks of treatment and 21 dialysis sessions. Presently, 2 months after treatment initiation, he maintains a lowering sCr of 1.9mg/dL.

Discussion: The better survival of KTR results in older patients with associated longer immunosuppression times, which will possibly lead to previously infrequent types of malignant disease in this population. Our patient case is unique in reflecting both a rare case of MM cast nephropathy in KTR and the possibility of a good outcome regardless

of advanced disease/known negative predictive factors of RFR in the general population. Novel myeloma treatments should be promptly considered in KTR, as should the use of high cut-off membranes in dialysis-dependent patients. A high index of suspicion and early institution of curative treatment may potentially revert kidney injury and lead to complete RFR in the transplanted kidney.

PUB664

A Case of RPGN Due to Alport Post-Transplant Anti-GBM Nephritis

Sharon Reuben,[1] Ian Kaiser,[1] Thomas E. Rogers.[2] *[1]Nephrology, Emory University Hospital, Atlanta, GA; [2]Emory University, Atlanta, GA.*

Introduction: Studies show recurrent Anti-GBM disease in up to 50% of renal allografts after transplantation. De-novo occurrence of anti-GBM in transplanted Alport patients remains a rare phenomenon. We present a case of RPGN due to de novo anti-GBM disease post-transplantation in a patient with Alport syndrome.

Case Description: A 20-year-old African American male was diagnosed with Alport syndrome by renal biopsy at age 5, progressed to ESRD by age 13, and received a deceased donor renal transplant at age 14. Post-transplant, he developed 2A ACR after 1 year, AMR after 4 years, and acute and chronic AMR after 6 years. These biopsies had no evidence of glomerular disease. He presented to the hospital with AKI, hematuria, and hypervolemia 7 years post-transplant. Creatinine was 4.6mg/dl from baseline of 2.5mg/dl with 4.7g/g proteinuria on spot check. Renal allograft ultrasound was unremarkable. His clinical course rapidly deteriorated, requiring initiation of dialysis for electrolyte and volume management. Allograft biopsy immunofluorescence demonstrated 3+ IgG, kappa, and lambda linear staining with granular IgM staining in the mesangium and capillary walls. Serology was positive for anti-GBM antibodies. Diagnosis of anti-GBM disease was made. He received solumedrol, plasmapheresis, and was discharged on dialysis.

Discussion: COL4A5 gene mutations cause a defect in the alpha 3(IV)NC1 domain of the basement membrane component of type IV collagen. Anti-GBM alloantibodies bind only to this alpha 3(IV)NC1 domain. Anti-GBM antigen consists of the noncollagenous domain (NC1) of the α-3 chain of type IV collagen, indicating a connection in the pathogenesis between anti-GBM nephritis and Alport syndrome. This has implication towards allograft loss in transplanted patients with this underlying defect. Additionally, Anti-GBM pathology is consistent with linear IgG deposition along the GBM, which our patient demonstrated in addition to granular IgM staining on immunofluorescence. This may indicate an additional concommitant underlying process contributing to the de-novo appearance of anti-GBM disease in our Alport patient. Renal outcomes are reportedly poor in patients with anti-GBM in a renal allograft. Plasma-exchange and amplified immune suppression has been initiated to mitigate disease severity temporarily and improve pathologic findings, but evidence of anti-GBM has shown to inevitably result in graft loss.

PUB665

Out of Window: Late Disseminated Nocardiosis in Renal Transplant

Judith Gaite, Luis Eduardo del Rosario Gaite, Abel Gomez, Melina F. Cazzaniga. *Clínica de Nefrologia Urología y Enfermedades Cardiovasculares, Santa Fe, Argentina.*

Introduction: Opportunistic infections in solid organ transplantation cause high morbidity and mortality in our patients. When we talk about Nocardiosis we refer to an infectious, rare, localized or systemic affectation, produced by Nocardia spp, a genus of ubiquitous environmental saprophytes actinomyces. This group of Gram-positive bacteria, which in the microscope present an appearance of branched filamentous cells, are found in soil, There are more than 50 species generating infectious tables, the most important taxonomic groups being the complex N. asteroids complex producing mainly respiratory and disseminated infections, N. brasiliensis responsible for disease located in skin and soft parts. N. Nova and N. farcinica can produced Nocardiosis in patients transplanted from solid organ, with an approximate frequency that varies between 0.7 to 3.5%. The incidence of thes desease is high during firsts 6 moths post trasplant.

Case Description: Given this premise, we review our series of patients with kidney transplant from 2000 to 2007 with disseminated Norcardiosis; finding a total of 8 cases. All of them presened compromise of two or more organs; being the most frequent skin, lung and Central Nervous System. In all cases fever was dominant. The diagnosis was made by Staining Kynyoun (+). As a therapeutic scheme, doble and triple antibiotic therapy was started, including Ceftriaxone, Trimetroprim Sulfamethoxazole and Minocycline. All of the patients survival. The clinical resolution was equally frequent. The average time of the beging of the symphtoms in our population was 64 months after trasnsplant.

Discussion: Our conclution is that Nocardia may present in late period after kindey transplantation, and the early diagnosis and treatement contributed to a low mortality of this patology.

PUB666

How Low Can You Go? A Case Report of Disseminated Cryptococcus in a Kidney Transplant Recipient

Goni Katz Greenberg, Pooja Singh, Anju Yadav. *Thomas Jefferson University and Hospital, Philadelphia, PA.*

Introduction: In patients following solid organ transplantation, wider differential of infectious etiology is warranted as the presentation can be nonspecific.

Case Description: We present a 68 years old Caucasian male, with past medical history of hypertension and end stage renal disease due to polycystic kidney disease, status post deceased donor kidney transplant (DDKT) in Sept 2016, admitted following two weeks of malaise, fatigue and recurrent falls, with one fall leading to a wound on his right shin. His post-transplant period was also complicated by BK nephropathy in early post-transplant period, which was managed by reduction of his immunosuppression. He was maintained on tacrolimus and prednisone. On physical examination the patient was alert, with a mild cognitive deficit. An open wound of about 6 cm was seen on the anterior aspect of his right shin. The patient underwent irrigation and debridement of the wound. Patient was started on antibiotics for community acquired pneumonia for right side infiltration seen on chest X-ray. Wound pathology came back positive for Cryptococcus. Cerebrospinal fluid analysis which was done at this time, was consistent with Cryptococcus meningitis, and chest CT showed also showed right lower lobe cavitatary lesions and small calcification. Empirical treatment was initiated with IV liposomal amphotericin B and 5 flucytosine for disseminated Cryptococcus, later switched to IV fluconazole following results of cultures. Additionally, patient's remaining immunosuppression was further decreased, and is maintained on tacrolimus monotherapy at lower trough goal levels.

Discussion: Cryptococcosus neoformans is the third most common invasive fungal infection in organ transplant recipients after candidiasis and aspergillosis. Reports indicate that Cryptococcus usually presents as a symptomatic disease and despite therapy the mortality remains high. A common risk factor for Cryptococcal infection is the lifelong immunosuppression. We believe our case is unique as our patient's immunosuppression was reduced about 18 months prior to diagnosis of disseminated Cryptococcus following renal biopsy proven BK nephropathy. Furthermore, our patient's atypical presentation caused delay in the diagnosis.

PUB667

An Unusual Cause of Life-Threatening Bleeding in a Patient with Bladder Drained Kidney-Pancreas Transplant

Bhavnish Bucktowarsing, Priyamvada Singh, Uday S. Nori. *The Ohio State University Wexner Medical Center, Columbus, OH.*

Introduction: The optimal method of exocrine pancreatic transplant drainage has been highly debated. Enteric drainage was preferred from 1960s-1990s and regained popularity in the 2000s being more physiological. There was a transient shift during the 1990's when bladder drainage became popular as it allowed monitoring of graft rejection by detecting hypoamylasuria. However, pancreatic secretions can be inflammatory to the bladder wall and the duodenal stump anastomosed to the bladder. This can lead to ulceration or anastomotic dehiscence. Inflammatory erosion of artery leading to exsanguination is one of the most dreaded complications of bladder drainage. Since this technique is becoming rare, the experience to manage these catastrophic presentations might be meager. We report a case of successful management of arterial erosion in a bladder drained kidney-pancreas transplant.

Case Description: A 45-year-old female, status post combined bladder drained Kidney-Pancreas transplant in 2006 with repeat living unrelated renal transplant in 2012 presented with gross hematuria and acute blood loss anemia (Hemoglobulin 5.3 from baseline of 10.1). On presentation, she was hemodynamically stable but deteriorated into hemorrhagic shock requiring massive transfusion (5 units PRBC, 1 FFP, 1 Platelet) and transfer to ICU. Emergent exploratory laparotomy was performed showing grossly distended bladder containing one liter of blood. There was a 4mm ulcer on the duodenum eroding into a branch of the renal artery with active pulsatile bleed. Repair and transplant pancreatectomy was performed with resolution of hemorrhage. Post-procedure she was hemodynamically stable and was discharged on insulin.

Discussion: Inflammatory erosion into major arteries following KP transplant appears to be related to graft pancreatitis or leakage of pancreatic secretions in the region. This can result in pseudoaneurysms, fistulae formation (arterio-enteric or arterio-vesicular) and erosions. Fortunately, this is a rare complication but need to be considered in any patient with gross hematuria or blood clots. A high index of suspicion needs to be maintained by clinicians since it is treatable, at the expense of the pancreas allograft. Although our patient had pancreas anastomosed to the urinary bladder wall, this complication has been reported even in enteric-drained pancreas transplants.

PUB668

A Rare Case of Pneumonia in a Combined Kidney and Pancreas Transplant Recipient

Massini Merzkani, Momina M. Ahmed, Aleksandra Kukla. *Mayo Clinic, Rochester, MN.*

Introduction: Rhodococcus equi is an unusual cause of infection in humans. Patients on immunosuppressive medications that affect the cell-mediated immunity are susceptible for acquiring this infection. We present an unusual case of pneumonia in a combined kidney and pancreas transplant recipient.

Case Description: 72 year old male with a history of diabetes mellitus type 1 complicated by end stage renal disease. Patient received a living donor kidney transplant in 2002, followed by pancreas after kidney transplant six months later with Thymoglobulin (ATG) induction. He was maintained on Cellcept, Tacrolimus and prednisone. Post transplant course was complicated by two acute cellular rejections of the pancreas in 2012 and 2015 treated with ATG. He present to outside hospital with productive cough, fever and diaphoresis of 3 weeks duration. He traveled to Arizona 2 months prior. He denied contact with animals or desert activities. Three weeks prior symptoms his neighbor started to use horse manure for farming. Chest CT showed a 5 cm consolidation in the left upper lobe. Bacterial, fungal and mycobacterial sputum cultures were negative. Biopsy done by bronchoscopy showed noncaseating granulomatous inflammation. Mycobacterial culture of the biopsy showed Rhodococcus equi infection and was started on azithromycin and rifampin. He came to our institution after 4 weeks without improvement. Vital signs and oxygen saturation were unremarkable. Lungs were clear to auscultation. Serum Cr was

stable at 0.7 mg/dL, lipase and amylase were elevated (157 U/L, 105 U/L). Chest CT had an increase in size of the consolidation 10.7cmx 9.1cm. He was started IV vancomycin, meropenem and PO azithromycin. The Tacrolimus level was undetectable due to use of rifampin. Tacrolimus was adjusted to a through level 7-9 and pancreatic enzymes improved. He completed 5 months of IV antibiotics with improvement of the infection.

Discussion: Rhodococcus equi is a gram-positive coccobacillus can cause pulmonary and extrapulmonary infection. Inhalation of soil contaminated herbivore manure is the most common route infection. Combination of 2–3 antibiotics is recommended for immunocompromised patient. Antibiotics interact with transplant medications; therefore levels need to be carefully monitored to avoid rejection. This case reminds us the importance educate our transplant patients the risk of exposure to manure

PUB669

Ganciclovir-Resistant Cytomegalovirus Treated with Foscarnet in a Pediatric Renal Transplant Recipient

Nadia T. Mclean,[1] Lisa Robinson,[2] Chia Wei Teoh,[2] Yvonne C. Yau,[4] Angela Williams,[3] Diane Hebert.[2] *[1]hospital for sick children, Toronto, ON, Canada; [2]The Hospital for Sick Children, Toronto, ON, Canada; [3]Hospital For Sick Children, Toronto, ON, Canada; [4]Hospital for Sick Children, Toronto, ON, Canada*.

Introduction: Human Cytomegalovirus HCMV poses significant morbidity in CMV-negative recipients (R) who receive a kidney transplant from a CMV-positive donor (D), (mismatch D+/R-). The usual treatment for CMV infection/disease is ganciclovir/valganciclovir. With molecular testing of resistance markers, we have been able to identify strains of HCMV resistant to ganciclovir and tailor treatment to prevent morbidity. In this report, we describe a case of a patient with CMV infection with a ganciclovir-resistant strain of CMV treated with foscarnet.

Case Description: We describe the case of a 6-year-old-girl with ESRD secondary to congenital nephrotic syndrome post deceased donor kidney transplant at age 3 years. Her serostatus at the time of transplant was CMV D-/R-, and she was maintained on prednisone, tacrolimus and Mycophenolate mofetil. CMV infection was first diagnosed 35 months post-transplant when quantitative CMV PCR was at detected 3.7 x 10^ 4 genome copies per ml. Treatment with ganciclovir 5 mg/kg/dose bid, titrated to 10mg/kg/dose bid failed with increasing CMV PCR load to 8.2 x 10^4 genome copies per ml. Initial resistance testing at 3 months was negative. Cytomegalovirus Immune Globulin infusions (twice/week) was commenced and continued for 2 months with no improvement in viral load. Repeat resistance testing showed CMV UL97 mutation (L595S) and no UL54 mutation confirming ganciclovir resistance and possible foscarnet susceptibility. Treatment was thus changed to foscarnet at 90mg/kg daily induction dose. After 1 month of foscarnet, CMV was undetectable but reappeared after a reduction in the dose of foscarnet to 60mg/kg daily. Foscarnet dose was re-increased to 90mg/kg daily and CMV was undetectable after 3 weeks of at this dose. She completed a further 2 months of treatment at this dose. The most notable side effect of foscarnet was a transient rise in her serum creatinine that improved with pre- and post-medication hydration with 0.9%NaCl.

Discussion: The effects of CMV disease can lead to significant allograft-related and systemic effects to the transplant recipient. We highlight the utility of resistance testing to detect de-novo ganciclovir resistance in newly acquired drug-resistant HCMV in the seronegative renal transplant patient, and the use of foscarnet in the successful eradication of CMV infection.

PUB670

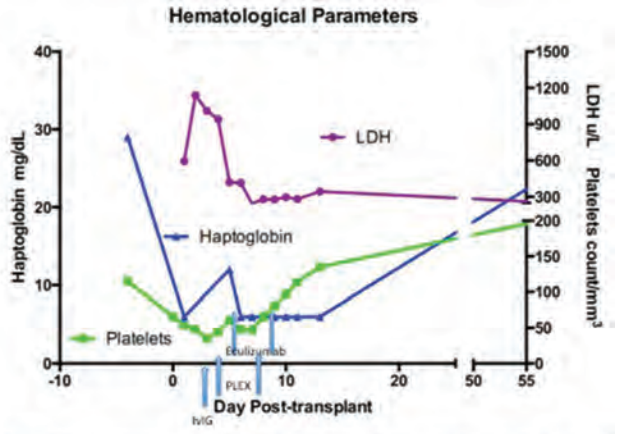
Eculizumab as Salvage Therapy in a Patient with APLS Undergoing Renal Transplantation

Mohit Gupta,[1] Michelle L. Lubetzky,[2] Jun B. Lee,[4] Choli Hartono,[4] Darshana Dadhania.[3] *[1]New York Presbyterian - Weill Cornell, New York, NY; [2]Division of Nephrology and Hypertension, New York, NY; [3]Weill Cornell Medical College, New York, NY; [4]Rogostin Institute, New York, NY*.

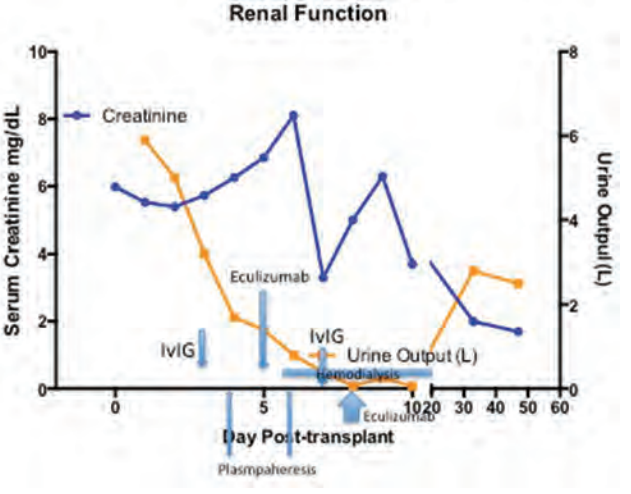
Introduction: APLS is associated with an increased risk of kidney allograft loss. We describe a patient with high titer APLS who developed oliguric renal failure post living donor transplant and was treated with Eculizumab.

Case Description: A 63 y/o sensitized F with triple positive antibody APLS underwent a living donor transplant with no donor specific antibodies (DSA). She received Hydroxychloroquine, Mycophenolate Mofetil and Rituximab as immunomodulatory therapy pre-transplant and steroid /ATG induction with anticoagulation with unfractionated heparin. On POD 6, she developed oliguric AKI necessitating hemodialysis. Labs were notable for a rise in LDH, decrease in platelets, and low haptoglobin (Figure 1). Thrombocytopenia precluded the possibility of biopsy. She received IvIg 200 mg/kg, 2 sessions of plasmapheresis followed by Eculizumab. Approximately 1 month after starting Eculizumab, she recovered her renal function and continues to have excellent graft function (Table 1, Figure 1).

Discussion: Although patients with APLS are at increased risk for acute kidney injury and allograft loss, anticoagulation remains the mainstay of management. The role of preemptive immunosuppression remains unclear. In our patient, despite pre-transplant immunosuppressive therapy, she developed an acute hemolytic syndrome with AKI that resolved with a combination of plasmapheresis and Eculizimab therapy. Our data suggests that the use of Eculizumab modulated the development of APLS associated TMA despite significantly high antibody titers.



APLS antibody	Pre-transplant	Day 10	Day 60
B_2 Glycoprotein IgG	149.6	125.8	135.3
Phosphatidylserine IgG	100	>100	>100
Phosphatidylserine IgA	4	1	3
Phosphatidylserine IgM	61	18	34
Cardiolipin IgG	132.1	79.4	91.8
Cardiolipin IgA	4.4	0.7	1.6
Cardiolipin IgM	36.2	14.4	26.9



PUB671

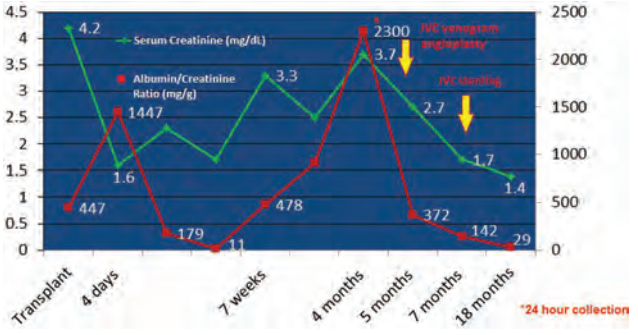
Recurrent FSGS? Maybe the Problem Is in the Plumbing

Massini Merzkani, Matthew R. D'Costa, Momina M. Ahmed, Mary E. Fidler, Hatem Amer. *Mayo Clinic, Rochester, MN, Rochester, MN*.

Introduction: Primary Focal Segmental Glomerulosclerosis (FSGS) in adults can recur in up to 40% of first transplants and >90% with a repeat transplant. Here we present a patient who had a third kidney transplant with worsening proteinuria that was not due to recurrence.

Case Description: A 40-year-old male with ESRD disease received his third living donor transplant from his father. His two prior renal allografts had developed recurrent FSGS. The first lasted for 12 years, and the second for 8 years. During his second transplant he developed an iliofemoral thrombosis in the setting of heavy proteinuria. During his evaluation for the third transplant, he was noted to have an occluded inferior vena cava but with extensive collaterals and underwent the third renal transplant by removing the second renal allograft and attaching the new kidney to site of the second allograft. He underwent conditioning with pre-transplant plasma exchange and received two doses of Rituximab. His post-transplant course was characterized slow graft function and fluctuating proteinuria, punctuated by repeated episodes of acute kidney injury (See fig 1). Several biopsies performed showed acute tubular injury with only mild focal foot process effacement. Ultrasound revealed no hydronephrosis and renal vein was patent. He was transitioned to Belatacept with no change in his course. Noting the thrombosed IVC and dependence on collaterals we proceeded to venography and pressure measurements. The IVC was canalized and stented with an improvement in venous pressures of the renal allograft vein. Subsequent to this there was a marked improvement in renal function with resolution of proteinuria.

Discussion: This is a case shows that although recurrent FSGS the most likely cause for the increasing proteinuria, it was important to rule out other pathologies. An important sign in this case was the focal foot process effacement arguing against as systemic permeability factor affecting all the podocytes diffusely.



PUB672

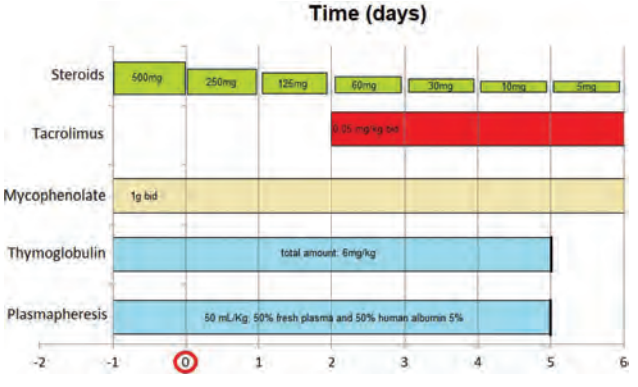
Deceased Donor Kidney Transplantation in Atypical Hemolytic Uremic Syndrome Without Preemptive Eculizumab Use

Àlex Favà,[1] Paula E. Mejia,[4] Rafael Alvarez,[5] Nuria Montero,[3] Ana Coloma,[2] Anna Manonelles,[3] Edoardo Melilli,[6] Oriol Bestard,[5] Josep M. Cruzado.[3] *[1]Hospital de Bellvitge, Barcelona, Spain; [2]Hospital San Pedro, Logro?o, Spain; [3]Hospital Universitari de Bellvitge, Barcelona, Spain; [4]Hospital Joan XXIII Tarragona, BARCELONA, Spain; [5]Bellvitge Hospital, Barcelona, Spain; [6]Hospital Universitari de BellVitge - Barcelona, BARCELONA, Spain.*

Introduction: Atypical hemolytic uremic syndrome(aHUS) has been associated with high risk for recurrence after kidney transplantation. In 2017, a consensus report on aHUS was published by KDIGO working group whereby eculizumab prophylaxis should be recommended in renal transplantation. However, it has recently been described the potential benefits from living kidney donors and low tacrolimus use to minimize recurrence rates in aSHU, thereby averting endothelial injury. Here we report two cases of successful deceased donor kidney transplantation in atypical hemolytic uremic syndrome without preemptive eculizumab treatment.

Case Description: They are a 58 and 46-yr old women with a history of CKD stage V in hemodialysis due to aHUS diagnosed in 1991 and 1993 respectively. The first one showed a total complement factor I(CFI)deficiency of 100% (mutation c.-173C>T), whereas in the second case, a complement factor B mutation (c.858C>G) was identified. Both underwent renal transplantation from cadaveric donor, sharing two HLA identities(class I and II) in each case. Cold ischemia time (CIT) were of 19h18' and 23h30', respectively. Our immunosuppressive strategy, based on preemptive plasmapheresis, is depicted in the attached image. The clinical course was uneventful, without hemodialysis requirements nor biochemical microangiopathic anemia signs. Actually, they show a normal renal function under tacrolimus (5-6pg/L), mycophenolate and steroid treatment, one month and four years after transplantation, respectively.

Discussion: According to our experience, preemptive plasma therapy could be effective in the prevention of disease recurrence in patients with high risk mutations with deceased kidney donors and long CIT. We need more evidence to define risk groups and tailor current treatments to each case to make better cost-effective decisions.



PUB673

Study of Factors Related to Survival of the Renal Graft in Rejection, by Means of Plasma Exchange Treatment: Experience in the Hemodialysis Unit of the National Medical Center November 20 ISSSTE

Monica Lopez Mendoza, Diana Maldonado Tapia, Ana Karen Garro Almendaro. *ISSSTE, Ciudad de Mexico, Mexico.*

Introduction: The therapeutic plasma exchange (TPE) is an extracorporeal blood purification, which consists of extracting plasma, to eliminate particles of great molecular weight, from a replacement with colloids or crystalloids. The use in the renal patient is indicated to desensitize or reject a renal transplant compatible with ABO and not compatible with terms of evidence levels. Currently there is no information in Mexican population under this treatment compared to the universal literature.

Case Description: A retrospective analysis during the period from 2016 to 2018 at the CMN November 20 ISSSTE, 9 patients, with TPE, under treatment with plasma exchange, Collection of demographic characteristics, filters, volume and fluid replacement, number of sessions and HD sessions performed. 9 patients being 44.4% female and 55.5% male, the mean age was 34 ± 12.1, the predominant type of donor was alive in 66.7% and cadaveric in 33.3%, most of the patients, 66.7%, did not have a reported immunological risk of the reference hospital and 3 ones were classified as low (11.1%), and intermediate (22.2%), the creatinine value previously recorded at the event of transplant rejection was 1.9 ± 2.3, with BUN at 22.4 ± 25.2. In the CMN, the mean in the reference time was 35.7 ± 26.1, the creatinine value was 8.4 ± 5.9, with BUN 61.2 ± 32.8, registering anuria in 33.3% and uresis preserved in 66.7 %, performing plasma exchange treatment in Hemodialysis Unit with a mean of sessions of 3.3 ± 1.6, during their stay required conventional hemodialysis sessions in 55.6% and recovery of kidney function after treatment was 44.4%, a creatinine of 4.5 ± 4 and BUN 31.5 ± 19.4 was reported. Analysis of categorical variables, chi square was occupied, finding a significant difference between the recovery of the renal function of the patient with the type of living or cadaveric donor, with a value of p 0.048.

Discussion: Within 3 years of experience of the Hemodialysis Unit, CMN November 20, the use of theTPE technique is a useful and effective treatment for transplant rejection, however the survival is influenced to risk factors, type of donor, the reference time and creatinine at the beginning of treatment. Currently patients are being collected for their subsequent analysis.

PUB674

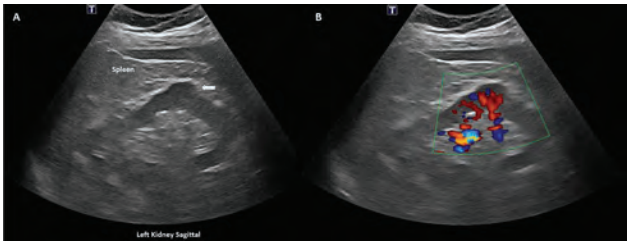
Dromedary Hump

Justin Lee Loy,[2] Gajapathiraju Chamarthi,[1] Abhilash Koratala.[1] *[1]University of Flroida, Gainesville, FL; [2]University of Florida Gainesville, Gainesville, FL.*

Introduction: Point-of-care renal ultrasonography, performed by clinicians at bedside assists in the management of kidney disease by allowing rapid evaluation of hydronephrosis, nephrolithiasis and other major structural abnormalities. It is being increasingly performed by internal medicine physicians as well as nephrologists, who typically do not have a formal training in radiology. As such, it is important for these physicians to have a thorough understanding of renal anatomy and the sonographic appearance of normal kidneys and various pathologies that can mimic one another. Herein, we describe a case of dromedary hump, a benign anatomic variant.

Case Description: A 58-year-old man with a history of hypertension, obstructive sleep apnea and mildly elevated serum creatinine underwent renal ultrasonography for evaluation of kidney size and structure. The scan reported no structural abnormalities except for a 'protuberance' in the left kidney [Figure 1A], for which Nephrology input was sought. The patient was reassured that this was a benign finding called 'dromedary hump' and no follow up imaging was indicated.

Discussion: Dromedary hump appears as a focal bulge on the lateral border of the left kidney, caused by molding of the normal renal parenchyma by the adjacent spleen. It is similar in appearance to the hump of a dromedary camel and thus the name. The incidence of this normal anatomic variant is estimated to be about 0.5%. It can sometimes mimic a kidney neoplasm and therefore considered a 'renal pseudotumor'. The hump demonstrates the same echogenicity as adjacent normal renal parenchyma on the sonogram unlike renal cell carcinoma, which typically appears as a heterogeneous mass with areas of necrosis, cystic changes, and hemorrhage. In addition, colour doppler ultrasonography demonstrates a normal blood flow within the hump [Figure 1B]. Failure to recognize this benign entity may result in unnecessary consultations and investigations.



PUB675

Spontaneous Bleeding in a Patient on Enoxaparin with Overestimated GFR

Jenny Shih,[1] Andrew Z. Fenves.[2] *[1]Harvard Medical School, Boston, MA; [2]Massachusetts General Hospital, Boston, MA.*

Introduction: Creatinine-based equations are commonly used to estimate glomerular filtration rate (GFR). Unfortunately, creatinine varies depending on factors such as age, gender, and muscle mass. Overestimation of renal function by creatinine-based equations can be dangerous for renally-dosed medications. We present a patient who developed spontaneous bleeding on enoxaparin with kidney function overestimated by creatinine-based equations.

Case Description: A 73-year-old woman with chronic obstructive pulmonary disease on home oxygen was admitted with sudden swelling, pain, and discoloration in her right hand. She was completing an enoxaparin bridge to warfarin for history of recurrent pulmonary embolism. Examination showed a hematoma on the dorsum of her right hand. Labs revealed hemoglobin 10.8 g/dL, creatinine 0.98 mg/dL, INR 1.2, and cystatin C 1.80 mg/L. She underwent two hematoma evacuations and required 2 units of packed red blood cells. Therapeutic enoxaparin was stopped, and she was resumed on warfarin at discharge.

Discussion: Creatinine-based formulas overestimated our patient's kidney function. Creatinine-based equations, such as Cockcroft-Gault, Modification of Diet in Renal Disease (MDRD) study, and CKD-EPI, placed her at Stage 2 or 3a CKD. Cystatin C, a low-molecular weight protein, can better predict kidney function independently of creatinine. Using the cystatin C equation, our patient had more severe renal dysfunction of Stage 3b CKD. The discrepancy between the equations can be due to creatinine variability from her older age, female gender, and decreased muscle mass with poor functional status. The dosing of enoxaparin sodium was likely too high for her renal function, placing her at increased risk of bleeding. Clinicians should be aware of the variability in using creatinine-based equations to estimate GFR, including patients with low functional status, and should consider using cystatin C to guide clinical decision-making.

	Range	
Serum Creatinine	0.86-0.98 mg/dL	
Serum Cystatin C	1.68-1.83 mg/L	
Equation		
Cockcroft-Gault	67-76 mL/min	Stage II
MDRD	59-69 mL/min/1.73m2	Stage II/IIIA
CKD-EPI	57-67 mL/min/1.73m2	Stage II/IIIA
CKD-EPI Cystatin C	31-35 mL/min/1.73m2	Stage IIIB

PUB676

Calciphylaxis in CKD: The Need for Vigilance in Nondialysis Patients

Mariam Zakher, Rafia I. Chaudhry, Loay H. Salman, Swati Mehta. *Albany Medical College, Albany, NY.*

Introduction: Calcific uremic arteriolopathy (CUA) or calciphylaxis is a small-vessel vasculopathy, primarily seen in end-stage renal disease, and although rare, it can also occur in patients with early stages of CKD. Calciphylaxis results in skin ulcerations and ischemia due to thrombosis of small arteries and arterioles triggered by intimal hypertrophy, medial calcification and endovascular fibrosis. We present a case of extensive calciphylaxis in CKD stage 3.

Case Description: A 48-year-old female with PMHx of CKD 3, DM, PVD, HLD, MI, DVT (on anticoagulation with warfarin), and PSHx of multiple vascular procedures including femoral-popliteal bypass and CABG presented with multiple painful ulcerations. Then ulcerations initially starting on the right inner thigh, and left breast, and later involved the left thigh and gluteal area. Serum creatinine was 0.86 mg/dL at the time of presentation, and calcium, phosphorus and PTH were 8.8 mg/dL, 3.5 mg/dL, and 137 pg/ml, respectively. Skin biopsy revealed sclerosing dermatitis and angioendotheliomatosis, concerning for calciphylaxis. The focal findings of arteriole wall calcium deposition supported the diagnosis of calciphylaxis, however ischemic changes and calcification of small arterioles were not seen. Warfarin was discontinued and the patient was started on intravenous sodium thiosulfate 25 gm three times a week, with subsequent dose titration to 50 gm three times a week. Therapy, including sodium thiosulfate and hyperbaric oxygen, were limited by patient compliance on discharge, with continued progression of lesions and untimely death at 6 months after initial diagnosis.

Discussion: Calciphylaxis should be suspected in patients with early to moderate CKD presenting with suspicious skin findings including non-healing ulcerations with surrounding areas of induration circumferentially, or painful subcutaneous nodules, especially in areas of increased adiposity (thighs, abdomen). Risk factors that have been associated with calciphylaxis include warfarin, obesity, and vitamin D analogues. Skin biopsy can help confirm the diagnosis of calciphylaxis[4], but carries risks of superimposed infections, and should not be performed with actively infected lesions. Timely diagnosis and identification of risk factors, along with therapeutic interventions i.e. sodium thiosulfate is key to slow progression.

PUB677

The Case: CKD Unmasked

Benjamin Gollasch,[1,2] Oskar Wischnewski,[1] Yoland marie Anistan,[1] Friedrich C. Luft,[1] Maik Gollasch.[1] *[1]Charité University Medicine, Berlin, Germany; [2]Cardiology/Nephrology/Pulmonology, HELIOS Klinikum Berlin, Berlin, Germany.*

Introduction: We present a 42-year-old Caucasian man with a body mass index (BMI) of 32 kg/m^2, who was referred because of heavy proteinuria and decreased renal function. We were impressed by his markedly muscular physique.

Case Description: A renal biopsy was performed, which showed advanced focal segmental glomerular sclerosis (FSGS). The patient is a professional bodybuilder who was not fat despite BMI criteria that classified him an obese (Obesity Class 2) person. He used progressive resistance exercise to develop his musculature from age 18 to 39 years. As part of his bodybuilding regimen, he consumed anabolic steroids, muscle-growth stimulating substances, and high-protein, low-fat diets. For more than six months until admission to our hospital, he resumed progressive resistance exercise and also regularly used anabolic androgenic steroids. We performed laboratory examinations and anthropometric data (BodPod) monitoring over time. Laboratory tests revealed a serum creatinine of 6.37 mg/dL (CKD-EPI, eGFR <15 mL/min) and a serum urea of 185 mg/dL. Endogenous creatinine clearance (CrCl) was 33 mL/min. Intact parathyroid hormone was 580.3 ng/L. There was an albuminuria of 3.01 g albumin/creatinine 1 g. The total proteinuria was 3.98 g protein/creatinine 1 g. Serum creatine kinase (CK, 5995 U/l, normal <190 U/l) (with CK-MB activity 66.4 U/l) and myoglobin (1554 μg/L) were elevated. Serum albumin (36 g/l) and protein (64 g/l) levels were in the low-normal range. Over a six-month period, our patient's renal function failed to improve despite reduction in lean body mass, discontinuation of anabolic steroid drugs, and muscle growth-stimulating substances. We developed and validated a new custom-targeted NGS gene panel (Ion Ampliseq FSGS panel) in two patient cohorts with FSGS, and detected several common DNA variants in FSGS genes, which could represent candidates for renal risk variants in our patient.

Discussion: We conclude that increased BMI due to increase muscle mass and/or body fat in combination with long-term anabolic steroid use and growth promoting substances should be included as risk factors in the differential diagnosis of secondary FSGS. Bodybuilders are a unique patient population that are fixated upon their behavior. Simple counseling is well meaning; however, nephrologists may have to recruit other health-care professionals when dealing with these patients.

PUB678

Homocysteine-Induced Renal Microvascular Injury in a Case with Vitamin B12 Deficiency Following Gastrectomy

Naoki Yamamoto,[1] Yasutaka Kamikawa,[1] Masahiko Kawabata,[1] Takashi Wada.[2] *[1]Internal Medicine, Toyama Prefectural Central Hospital, Toyama, Japan; [2]Division of Nephrology, Kanazawa University Hospital, Kanazawa, Japan.*

Introduction: High Homocysteine levels are established as an independent risk factor for atherosclerotic vascular diseases because of its atherogenic and prothrombotic properties. Although in ESRD patients the level is known to elevate, it has not fully been elucidated the mechanism how high concentration of plasma homocysteine affects the function of the kidney in human. We report a case with edema, proteinuria and renal function impairment, whose renal histopathology showed thrombotic microangiopathy (TMA) like lesions. Furthermore he was associated with marked hyperhomocysteinemia and vitamin B12 deficiency related to total gastrectomy.

Case Description: A 56 year-old man presented progressive systemic edema and weight gain by 7.2 kg over one month. Hypertension, diabetes mellitus or kidney disease including proteinuria had never been pointed out, except for the history of total gastrectomy. Laboratory data showed proteinuria of 3.2 g/day, u-occult blood 3+ and RBC casts in the sediment. Renal function was impaired as serum Cr 1.35 mg/dL, eGFR 44 mL/min/1.73 m^2, and were serum albumin 3.4 g/dL and LDH 246 IU/L. Blood cell count indicated mild anemia, RBC 3.46×10^6 /μL, Hb 9.3 g/dL and Ht 29.1%, and normal Plts count (266×10^3/μL). Both serum ferritin and vitamin B12 were low, 4.3 ng/mL and 95 pg/mL (normal: 180-914), respectively. In further tests, IgG, IgM, IgA, C3 and C4 were within normal limits, and ANA, ANCA and anti-GBM were all negative. Renal biopsy revealed endothelial cell swelling and mesangiolysis in glomeruli. Later his homocysteine level in plasma was reported to be very high, 55.8 nmol/mL (normal: 5-15). Treatment with cyanocobalamin injection was started.

Discussion: Vitamin B12 plays a crucial role as a cofactor in the metabolism of homocysteine. Its deficiency, thus, leads to very high homocysteine concentration of the amino acid in plasma. The level is also related to serum Cr in patients with renal diseases, partially because the elimination is dependent on the clearance in the kidney. Our case indicates the relationship between hyperhomocysteinemia and the pathological findings of glomerular endothelial cell damage similar to TMA, suggesting homocysteine-induced renal microvascular injury. We propose hyperhomocysteinemia is one of important causes in unexplained renal TMA, especially in vitamin B12-deficient adults.

PUB679

"It's Not Always Lupus": A Case Report

Jaime A. Baynes-Fields,[1] Christina Payne,[1] Abbas Raza,[1] Amanda A. Karasinski,[2] Hasan Arif.[1] *[1]Drexel University, Philadelphia, PA; [2]Drexel University/ Hahnemann Hospital, Larksville, PA.*

Introduction: Autoimmune hemolytic anemia (AIHA) can be a clinical manifestation as well as a sequel to lupus flares. Mechanical valves can cause hemolytic anemia due to shearing of red blood cells (RBCs). Here we are presenting a case of a patient with active lupus and mechanical mitral (MVR) and aortic valves (AVR) presenting with jaundice.

Case Description: 37-year-old female with prior history subacute bacterial endocarditis with mechanical MVR and AVR on anticoagulation, systemic lupus erythematosus (SLE) complicated by non-biopsy proven lupus nephritis, transaminitis, hemolysis. In August 2017 she was hospitalized with severe anemia requiring multiple blood transfusions, worsening fatigue, 1+ blood on urine dipstick associated with hypocomplementemia while on MMF. She developed frank hematuria and high dose steroids were initiated. UA illustrated RBC casts and Cytoxan was initiated given presumed class IV lupus nephritis. Due to her being anticoagulated a biopsy could not be performed. In January she was found to have scleral icterus, jaundice, transaminitis, anemia and gross hematuria. At this time our differentials were lupus induced hemolysis vs mechanical shearing. Her LDH was high and her haptoglobin was low indicating hemolytic anemia. Her ESR/ANA/C3/C4/dsDNA were at normal. Her anti-cardiolipin, Parvovirus, direct and indirect Coombs were negative. Her Glucose 6 Phosphate Dehydrogenase (G6PD) levels were normal. On physical exam no murmurs detected. Her first echo showed a well-seated MVR, AVR was with a normal gradient across the valve, no pericardial effusion, and EF 60-65%. Repeat cardiac echo less than 2 weeks later which illustrated moderate medial paravalvular leak and severe anterio/lateral paravalvular leak of the MV, in addition, her AVR illustrated elevated AVR gradients likely of obstructive physiology. She was taken to the operating theater with a diagnosis of aortic and mitral paravalvular leak, pseudoaneurysm between the aortic and mitral valve where she underwent a third sternotomy with redo mechanical MVR and redo AVR with repair of pseudoaneurysm at the base of the heart. She is post-op from her open heart surgery.

Discussion: Here we would like to emphasize that in the setting of existing and recently active Lupus nephritis, all etiologies must be considered and ruled out. Hemolytic anemia is a known complication of SLE however not all are due to an autoimmune etiology.

PUB680

A Mysterious Case of Hypercalcemia

Shannon H. Harrington, Anshul Kumar. *Inspira Health Network, Cherry Hill, NJ.*

Introduction: Hypercalcemia is often associated with endocrine dysfunctions, sarcoidosis, and malignancies. Among malignancies, the physiologic processes resulting in hypercalcemia differ. Bony metastases cause lysis of bone calcium deposits, or tumors can release parathyroid hormone (PTH) or parathyroid hormone-related protein (PTHrP), altering hormonal axes. Rarely, malignancies secrete Vitamin D_3 (Calcitriol), causing increased intestinal absorption of calcium and increased osteoclastic bone activity.

Case Description: A 47-year-old female with no significant past medical history presented with palpitations and dyspnea on exertion. On physical exam, she was tachycardic at 144 bpm, hypertensive at 195/129 mmHg, and had palpable splenomegaly. Lab values showed a calcium level of 17.7mg/dL. Blood smear showed normal erythrocyte morphology with normocytic anemia and some tear-drop cells. White blood cells were without inclusion bodies. Platelets were unremarkable. Calcium was stabilized with IV fluids and pamidronate. A CT revealed 25cm heterogeneous splenomegaly. A bone marrow biopsy demonstrated normocellular marrow with lymphoid aggregate and no evidence of an infiltrative process. Microscopic examination showed normocellular marrow with moderately decreased iron and no evidence of acute leukemia or lymphoproliferative disorder. PTH was depressed at 5.2 pg/mL (reference range 14-64 pg/mL), and PTHrP was 19 pg/mL (reference range 14-27 pg/mL). An acetylcholinesterase (ACE) level was negative. A 24-hour urine calcium was elevated. No monoclonal spikes were identified on SPEP and there was no abnormal distribution of immunoglobulins on immunofixation. Abnormally high calcitriol levels at 118 pg/mL were noted. Subsuqently, a total splenectomy was performed. Post-operative calcium corrected to 8.5 mg/dL. Surgical pathology of the spleen revealed a high grade diffuse large B cell lymphoma. She received systemic chemotherapy. Follow-up PET-CT was without residual or recurrence of tumor burden.

Discussion: Primary Splenic Lymphomas are uncommon and presenting symptoms are often non-specific. This case is an example of Splenic B Cell Lymphoma presenting with hypercalcemia secondary to ectopic calcitriol production. With splenectomy the ectopic calcitriol was eliminated and calcium levels abruptly corrected. This case demonstrates that with application of basic physiologic principles even a mysterous cause of hypercalcemia can be unveiled.

PUB681

Mesenteric Ischemia in Post-Kidney Transplant Patient Associated with the Use of Sevelamer

Paloma Noda,[1] Nathally Baston,[1] Laura Claro,[1] Marcela Carvalho,[1] Dino Martini,[1] José F. Souza,[1] Patricia Malafronte,[2] Andréa O. Magalhães,[1] Luiz A. Miorin.[3] *[1]Irmandade Santa Casa de Misericórdia de São Paulo, Sao Paulo, Brazil; [2]Santa Casa de Misericórdia de São Paulo - SP, São Paulo, Brazil; [3]Faculdade ciencias medicas Santa Casa sao paulo, São Paulo, Brazil.*

Introduction: It is well known that hyperphosphatemia leads to vascular calcification, increasing mortality in chronic kidney disease(CKD)patients. Sevelamer is a phosphate binder, widely used to control hyperphosphatemia. One of the barriers to the use of Sevelamer are the gastrointestinal(GI)symptoms. As other resin-based binders, it can crystallize, deposit and injure the GI mucosa through mechanisms not yet well established. In this paper, we will report a case of a post kidney transplant patient that presented intestinal perforation with the presence of sevelamer crystals(SC)on the GI mucosa.

Case Description: AMSR,41 years old, female, with a history of Systemic Lupus Erythematosus, with prolonged use of corticosteroids, Hypertension, CKD due to Lupus Nephritis, in haemodialysis(HD)since 2010, and Secondary Hyperparathyroidism. To treat bone mineral disease the patient used Sevelamer, CaCO3 and Cinacalcet. The patient underwent kidney transplant(deceased donor), progressing to delayed graft function, requiring HD for 2 weeks. During that period, she presented with severe abdominal pain. The pain ceased with interruption of HD, leading to the suspicion of mesenteric ischemia. Contrast tomography was performed, showing perforation of the colon and ileum, and she underwent exploratory laparotomy. When analysed by optic microscopy, the lesions showed multiple ulcers, micro thrombi and foci of fibrinoid necrosis in the small vessel walls, and yellow-brownish intramural deposits, suggestive of drug resin, with eosinophilic background and presence of a fish scale curvilinear pattern in the haematoxylin-eosin and Ziehl-Neelsen stains. Calcium deposit were not characterized on vessel walls submitted to Von Kossa's stain.

Discussion: Comparing Sevelamer with the resin found in the patient's mucosa and current data, we conclude the lesion in question is a SC deposit, since the patient had used this medication. These lesions should be considered in patients with CKD and GI symptoms, once other causes have been ruled out. Although rare or underdiagnosed, the complications of resin deposition in GI tract are severe and increase patient mortality. Further studies should be performed so that these complications can be detected and prevented.

An Infectious Case of Calciphylaxis Prior to Renal Replacement Therapy

Zach Lauer,[2] Ahmad M. Tuffaha.[1] *[1]Nephrology and Hypertension, Kansas University Medical Center, Kansas City, KS; [2]Kansas University Medical Center, Kansas City, KS.*

Introduction: Calciphylaxis is a rare disorder characterized by slowly progressive necrosis of skin and subcutaneous tissue. It is rarely reported in patients with chronic kidney disease (CKD) before the initiation of renal replacement therapy.

Case Description: A 62 year old male presented with multiple rapidly spreading skin lesions. His past history is significant for hypertension, diabetes mellitus type 2 and CKD stage 4 with baseline creatinine 2.8 with eGFR 25 ml/min/1.73m^2. Physical examination was notable for multiple lesions manifesting as hard black eschars with violaceous and purpuric borders on both legs. The glans penis was indurated and necrotic. Laboratory data revealed creatinine 5.9 mg/dl, BUN 85 mg/dl, Ca 6.8 mg/dl, phosphorus 4.5 mg/dl and albumin of 2.6 g/dl. Blood cultures grew Methicillin Sensitive Staph Aureus. Biopsies of the lesions demonstrated degeneration of adipose tissue with necrotic leukocytic infiltrate and thrombosis of the subcutaneous small vessels. Von Kossa staining highlighted vascular and adipocytic calcification. Biopsy findings were compatible with calciphylaxis with superimposed staphylococcal scalded skin infection. He was started on intrravenous antibiotics. Aggressive daily hemodialysis was initiated with administration of Sodium Thiosulfate three times a week. Repeat cultures were negative but the lesions continued to worsen. The patient passed away two months later.

Discussion: Calciphylaxis should be included in the differential diagnosis of skin lesions in patients with CKD. Dialysis vintage is one of the main risk factors reported in literature but the absence of this risk factor doesnn't rule it out. The patient didn't have any uremic signs or symptoms but the presence of biopsy proven calciphylasxis necessitated dialysis initiation. The rapid progression of CKD along with the superimposed staphylococcus infection are potential culprits. High morbidity and mortality are observed in both uremic and non-uremic cases of calciphylaxis.

Calciphylaxis lesions involving lower extremities

PUB683

A Case of Tumoral Calcinosis After Renal Allograft Failure

Bianca Madrid. *University of Miami, Miami, FL.*

Introduction: Tumoral calcinosis is a rare manifestation in chronic renal failure patients. This report describes a case of patient who had a living unrelated kidney transplant, but developed allograft failure within a year and developed tumoral calcinosis of the left thigh.

Case Description: A 45-year-old male was admitted to the hospital due to a five-day history of progressive left thigh swelling and pain, with no recent trauma. His medical history was notable for coronary artery disease, end-stage renal disease from membranous nephropathy, and a living unrelated kidney transplant in 2013, but developed allograft failure in 2014 and resumed home hemodialysis. Physical examination revealed normal vital signs. The left upper leg revealed swelling and tenderness over the anterior and lateral thigh, with an ill- defined palpable mass; however, no erythema, ecchymosis or wounds were noted. Sensation and reflexes were intact. Initial laboratory assessment revealed serum calcium 8.5 mg/dL (ref: 8.6-10.3 mg/dL), serum phosphorus 7.9 mg/dL (ref: 2.5-4.5 mg/dL), serum creatinine 7.20 mg/dL and intact serum PTH 636.5 pg/mL (ref: 15-65 pg/mL). MRI revealed large multi-locular cystic calcified masses occupying the anterolateral, medial and posterior compartments of the left thigh, and extending into the left gluteal region with fluid-fluid levels. The multifocal areas on MRI with hypointense T1 and T2 signal suggested osteoid matrix/calcification.

Discussion: Calcinosis develops in the soft tissues, and is usually distributed along the extensor surfaces of the large joints such as the hip, elbow, shoulder or foot. It can be differentiated from other soft tissue masses by evidence of hemorrhage and/or septations on imaging, as well as the T1/T2 high intensity signal seen on MRI with synovial sarcomas. Evidence of bone involvement is characteristic of osteosarcomas, and is not seen with calcinosis. The greater trochanteric bursa has been cited as the most common area affected for calcinosis; however, the extensive involvement of soft tissue on this patient was unlike others reported in literature, especially since the masses extended beyond the previously described periarticular distribution. Management of tumoral calcinosis from renal failure includes phosphate lowering therapy and intensification of hemodialysis treatments.

PUB684

Calciphylaxis in Non-Dialysis Patient

Edgar Guzman-Suarez. *Jefferson Hospital, Philadelphia, PA.*

Introduction: The patient is a 57 y.o. male with PMHx of alcoholic liver cirrhosis, HFpEF, CKD stage 4, recent admission due to hepatic encephalopathy, VDRF and dialysis

dependent AKI with recovery of renal function who presented from rehab in the setting of AMS and AKI.

Case Description: Patient initially presented on 2/18/18 for hepatic encephalopathy and respiratory failure due to pneumonia and hepatic hydrothorax requiring intubation. Per outside hospital records patient had baseline CKD stage 4. He developed anuric AKI thought to be secondary to ATN. He was dialysis dependent from 2/20-3/14. He was discharged to sub acute rehab off dialysis on 3/18/18 with a creatine of 1.9. On follow up visit on the outpatient clinic creatinine was 2.4. It appears that he was advised to hold diuretics for a couple of days and then resume. He had a second hospitalization on 4/16/18 due to AMS and he was found to have a creatinine of 4.6. Pt was being treated for hepatic encephatlopathy again. He was noted to have necrotic lesions on lower extremities. Necrotic lesions on the thighs and calf have been present for 2-3 weeks per wife. Biopsy confirmed calciphylaxis.

Discussion: Unique presentation of calciphylaxis in non dialysis patient with rapid progression of lesions over weeks.

PUB685

Overlap of Type 1 Diabetes (DM) and Systemic Lupus Erythematosus (SLE) – A Perilous Combination in Pregnancy and Postpartum

Monica L. Reynolds, Akhil Hegde. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Introduction: Patients with type 1 DM are at increased risk for developing other autoimmune diseases and renal biopsy remains the gold standard for diagnosing diabetic nephropathy (DN). SLE can present at any time during pregnancy and should be suspected with atypical presentations of underlying disease.

Case Description: A 24-year-old African American female with type 1 DM, hypertension (HTN), and proteinuria presented to clinic at 24 weeks gestation for new edema. Her DM was complicated by poor glycemic control (A1c 11%), retinopathy and neuropathy. Nephrotic proteinuria in her first trimester was attributed to DN. Urine sediment was unremarkable. Labs revealed creatinine (Cr) 0.85mg/dL, albumin 3.0mg/dL, hemoglobin (Hgb) 7.6g/dL, ferritin 107, iron sat 18%, normal B12 and folate. ANA was >1:640 with normal C3 and C4. She was started on oral iron. Two weeks later, Hgb was 7.6g/dL and she was admitted. Hgb electrophoresis, bilirubin and LDH were normal. Direct coombs test was negative and peripheral smear showed rare schistocytes. Double stranded DNA antibody (dsDNA) was pending at discharge but returned positive. She was re-admitted a week later with headaches and HTN. Cr was 1.11mg/dL and UP/C was 8.5g. She delivered via c-section at 29 weeks and 6 days due to superimposed preeclampsia. Five days post-discharge, she presented with fatigue. Blood pressure was 150/89, Hgb 8.1g/dL, glucose 336mg/dL, Cr 1.73mg/dL and UP/C 11.7g. CXR showed cardiomegaly and echocardiogram (TTE) revealed a large circumferential pericardial effusion. Rheumatology felt she met criteria for SLE and began pulse corticosteroids. Following therapy, glucose rose to 970mg/dL requiring the ICU. Renal biopsy was performed and revealed DN with nodular glomerulosclerosis with segmental tuft sclerosis and moderate to severe interstitial fibrosis and tubular atrophy. She was treated with a steroid taper and hydroxychloroquine. One month later, TTE showed decreased effusion and dsDNA was negative.

Discussion: This case highlights the diagnostic conundrum of coexisting autoimmune diseases and the cumulative adverse maternal outcomes that can arise from both diseases and their treatments. Failure to respond to iron therapy in pregnancy should prompt further investigation and may suggest a misdiagnosis. Earlier renal biopsy may have allowed for lower steroid dose and avoided ICU transfer.

PUB686

Prolonged Hemodialysis for Refractory Lactic Acidosis Secondary to Metformin Overdose

Arushi Goel,[1] Raghu Juvvadi,[2] Monicka Felix.[1] *[1]Department of Internal Medicine, Oak Hill Hospital, Spring Hill, FL; [2]Department of Nephrology, Oak Hill Hospital, Spring Hill, FL.*

Introduction: Metformin is a biguanide oral antihyperglycemic agent that has been used in the United States since 1995 for treatment of type 2 diabetes mellitus. According to the American Diabetic association, recommended as the first drug of choice. Except in overdose situations, the association of metformin with lactic acidosis is quite rare with an estimated incidence of 3 per 100,000 patient-years. When it does occur, metformin-associated lactic acidosis is most often associated with an intercurrent disease and renal insufficiency. A 2009 review article could identify only 22 cases of metformin overdose. We describe a patient with metformin overdose who was successfully treated with hemodialysis.

Case Description: A 57 year old male with past medical history of type 2 diabetes mellitus and hypertension was brought to the emergency department with altered mental status. His wife reported that he has become increasingly lethargic and fatigued over the course of a week. In the emergency department, due to low Glasgow Coma scale, he was intubated. The laboratory test revealed severe metabolic acidosis secondary to lactic acidosis and acute renal failure. His values were: BUN 103 mg/dL, serum creatinine 11.2 mg/dL, carbon dioxide 7 mEq/L, anion gap 40, pH 6.78 with a lactic acid level greater than 12.7 mmol/L. He was evaluated by Nephrology and underwent emergent hemodialysis, which he underwent twice without improvement in his lactic acid. Upon re-evaluation, his wife revealed that he was taking metformin 2000 mg daily. A third hemodialysis decreased the value for lactic acidosis. After 7 days of inpatient treatment with antibiotics and hemodialysis, he was finally extubated. His renal function improved with creatinine of 1.7 mg/dl on the day of discharge.

Discussion: Metformin is cleared by the kidney with about 90% of drug eliminated by glomerular filtration and tubular secretion in 12 hours. Thus, renal insufficiency is a risk factor for drug accumulation. Treatment includes use of NaHCO3. Dialysis therapy has benefit of correcting the acidosis while removing the toxin. Prolonged hemodialysis is indicated in patients with severe overdose.

Achieving Equilibrium Is Not That Easy: A Case of Dialysis Disequilibrium Syndrome

Lauren Lamie,[1] Mohamed Mortagy.[2] *[1]WMU Homer Stryker MD School of Medicine, Kalamazoo, MI; [2]Western Michigan University School of Medicine, Kalamazoo, MI.*

Introduction: Dialysis disequilibrium syndrome (DDS) is an increasingly rare neurological syndrome attributed to cerebral edema and osmotic shifting following dialysis. Symptoms vary in severity from restlessness and headache to less commonly seizure, coma, or death. Risk factors include first dialysis session, markedly elevated BUN, and severe acidosis. As there is no specific treatment, prevention is essential.

Case Description: A 27-year-old female with end stage renal disease (ESRD) on hemodialysis (HD) and antiphospholipid syndrome on warfarin presents with generalized weakness, anasarca, fatigue, and gingival bleeding in the context of noncompliance with HD for four weeks. She was afebrile and hypertensive with blood pressure of 188/120. Labs significant for BUN/creatinine 231/22.6 mg/dL, sodium 141 mEq/L, potassium 7.2 mEq/L, bicarbonate 7 mEq/L, hemoglobin 5.2 g/dL, platelets 119,000/mm^3, and INR 1.8. DIC screen was negative. She was transfused and emergent HD initiated. Shortly after her 3-hour HD session, the patient had a seizure complicated with hypoxia and subsequent cardiac arrest. She was resuscitated for two minutes with return of spontaneous circulation and was intubated. Once she was stabilized, CT head was negative for hemorrhage or stroke, BUN 83 mg/dL, bicarbonate 15 mEq/L, glucose 122 mg/dL, sodium 141 mEq/L, potassium 3.3 mEq/L, calcium 8.3 mg/dL, magnesium 1.9 mg/dL. The patient was diagnosed with DDS and she was initiated on continuous renal replacement therapy (CRRT) without ultrafiltration. She ultimately achieved neurological recovery, was extubated and transitioned back to intermittent hemodialysis successfully after two days.

Discussion: Prevention of DDS involves initiating HD cautiously with low flow rates, short duration, and increased frequency. Care must be taken on initiation of HD not only in new dialysis patients, but also in noncompliant ESRD patients with marked metabolic disturbances as presentd in this case. Treatment is largely supportive as no benefit has been proven with agents aimed to decrease intracranial pressure such as mannitol or hypertonic saline.

PUB688

Calcium - To Drip or Not to Drip: The Curious Case of Masked Hypercalcemia on Regional Citrate

Gurleen Kaur,[1] Ali Kashkouli.[2] *[1]Emory, Decatur, GA; [2]Emory University, Atlanta, GA.*

Introduction: Continuous renal replacement therapies (CRRT) has several short-term advantages. However, there is a paucity of data on the long-term effects when used in End Stage Renal Disease (ESRD). Anticoagulation is frequently required to maintain filter patency. Regional citrate is the recommended form and functions most effectively when the post-filter ionized calcium (iCa) is kept ~ 0.2-0.4 mmol/L while a calcium drip maintains the systemic iCa ~ 1.0-1.3 mmol/L. We describe a case of a patient on regional citrate with hypercalcemia secondary to prolonged immobilization and history of tertiary hyperparathyroidism(THP) which was masked by the use of the regional citrate protocol.

Case Description: A 67-year-old male with ESRD and THP presented for shortness of breath. His hospital stay was prolonged due to development of small bowel obstruction associated with perforation and hemodynamic compromise, hence was initiated on CRRT. Due to frequent filter clotting, a regional citrate protocol with prefilter Anticoagulant Citrate Dextrose Solution A (ACD-A) was initiated and a 2% calcium gluconate drip was used systemically. While on CRRT with regional citrate, he was requiring only minimal calcium gluconate at 20ml/hr. In subsequent days, this drip was stopped due to elevated systemic iCa. We continued his pre-filter citrate drip and were able to maintain his post-filter iCa between 0.2-0.4 mmol/L per protocol. In evaluating his hypercalcemia, he was found to have 25-OH vitamin D level of <7.0 ng/mL, 1,25-OH Vitamin D was <8pg/mL, PTH was 260.9 pg/mL (off cinacalcet) with a level of 777.8 pg/mL on admission. Alkaline phosphate was 242 IU/L, Bone-specific alkaline phosphate was 53.7 mcg/L, iCa while off the calcium drip was 1.33-1.24 mmol/L with a total calcium of 9.7-9.4 mg/dL and a citrate requirement of 280cc/hr.

Discussion: Regional citrate is the recommended form of anticoagulation on CRRT. Prolonged immobilization in patients with ESRD and THP can liberate calcium from bone which can be further exacerbated by the effect of chronically elevated PTH. This hypercalcemia may be masked if citrate is used for CRRT. If left up to the protocol, patients can come off calcium drips with their bone calcium stores acting effectively as a calcium drip. Given this increased bone mineral loss alternate therapy must be instituted as soon as the subject becomes hemodynamically stable.

PUB689

Cardiac Arrest from Baclofen Overdose: Dialysis to the Rescue

Agustin G. Velazquez perez. *LSU health shreveport, Shreveport, LA.*

Introduction: Baclofen overdose often presents with CNS and respiratory depression, leading to coma requiring mechanical ventilation. Seizures, hypothermia and cardiac instability have also been reported. Treatment is primarily supportive in those with normal kidney function. We report a case of baclofen overdose complicated by bradycardia, sinus pause, and cardiac arrest treated with hemodialysis.

Case Description: A 54 year old African American female with history of bipolar and schizoaffective disorder was found unresponsive and brought to the emergency department. The patient had allegedly overdosed on 40 tablets of baclofen (10 mg) 2 hours prior. On arrival, her GSC was 3/15, pupils dilated, with agonal breathing. Patient was intubated promptly and placed on mechanical ventilation. Laboratory data were normal; including creatinine of 0.76 mg/dl and negative urine drug screen. Poison control recommended supportive care. 9 hours after admission, patient became hypotensive, bradycardic and was noted to have frequent sinus pauses lasting 20-30 seconds leading to asystole. Following successful resuscitation she was emergently dialyzed which resulted in marked improvement of her clinical status and extubation the next day.

Discussion: Baclofen acts as an inhibitory neurotransmitter and is commonly used to treat spasticity. The kidney primarily excretes Baclofen. However there have been reports where hemodialysis has been used for Baclofen overdose even in patients with normal renal function. Properties that enhance dialytic clearance include its low molecular weight, low volume of distribution and relatively low protein binding. 79% of the drug is cleared with a 4 hour dialysis session leading to a reduction in half life from 7 to 3 hours. This shortens recovery time. This case teaches us that dialysis should be considered early in those with life threating manifestations.

PUB690

Acute Hepatic Encephalopathy: An Underexplored Indication for Renal Replacement Therapy

Mayanka Kamboj,[1] Martin Runnstrom,[3] Amir Kazory.[2] *[1]University of florida, Gainesville, FL; [2]University of Florida, Gainesville, FL; [3]University of Florida, Department of Medicine, Gainesville, FL.*

Introduction: Hepatic encephalopathy (HE) is associated with high mortality. While the key role of serum ammonia level (SAL) in development of HE has long been recognized, emerging evidence points to distinct mechanisms underlying chronic alterations in neural metabolic functions and acute changes in cerebral perfusion. In acute HE, formation of glutamine, a strong osmolyte, leads to cerebral edema as ammonia crosses the blood–brain barrier at high levels.

Case Description: A 52-year-old man with liver cirrhosis and esophageal varices presented with hematemesis and decline in mental status. He was afebrile, normotensive, and confused. Laboratory studies showed hemoglobin level 6.8 g/dL, platelets 9000/mm^3, serum creatinine 0.5 mg/dL and SAL 176 μmol/L (normal <35). He received intravenous fluids, blood transfusion, and antibiotics. However, his mental status deteriorated further with development of decerebrate posturing; he was intubated. Head CT was unremarkable. Bleeding varices precluded nasogastric tube placement while administration of lactulose per rectum was high risk due to thrombocytopenia. Hence, the decision was made for renal replacement therapy (RRT), starting with hemodialysis (HD) followed by continuous venovenous hemofiltration (CVVH). Despite 4 hours of HD with a high flux filter, the post-HD SAL was as high as 262 μmol/L making it unlikely for the patient to survive had the RRT started with delay. SAL progressively declined to 71 μmol/L, 19 hours post-RRT. Improvement in his mental status closely mirrored the reduction in SAL. Endoscopy could be performed to stop the bleeding, RRT was stopped, and he was extubated.

Discussion: Rapid lowering of SAL remains the primary goal of therapy in HE. Ammonia is readily dialyzable as it is a non-protein-bound small molecule. While HD is a plausible option when less invasive medical options are not feasible, post-HD rebound could represent a major drawback. To minimize this effect, we used CVVH in conjunction with HD, which could also portend a salutary impact through temperature control. Using a combined RRT strategy helped stabilize the patient so the underlying cause of HE (i.e. bleeding varices) could be treated. This case coupled with previous reports represents an underexplored indication for RRT and highlights the significance of an interdisciplinary approach for efficient treatment of these patients.

PUB691

Liver Dysfunction from Immune Reconstitution Syndrome After Treatment of Hepatitis C Virus Infection in ESRD Patient

Junaid Nasir,[2] Elvira Gosmanova,[1] Odirichukwu O. Duru.[3] *[1]Stratton VA Medical Center and Albany Medical College, Albany, NY; [2]Nephrology, Albany Medical Center, Albany, NY; [3]Albany College of Pharmacy and Health Sciences, Albany, NY.*

Introduction: Hepatitis C virus (HCV) infection is associated with worse outcomes in ESRD patients. Elbasvir/grazoprevir-a combination direct antiviral agent (DAA) demonstrated safety and effectivines in treating ESRD individuals with genotype(GT)-1 HCV infection. We report a case of autoimmune liver injury in a hemodialysis(HD) patient after successful HCV eradication.

Case Description: A 57-year old female with ESRD was noted to have yellow discoloration of the dialyzer filter at the end of HD session 2 days prior to completion of a 12-week elbasvir/grazoprevir course for chronic HCV GT-1A infection resulting in a sustained virologic response. She reported insidious onset of pruritus, vague abdominal pain, nausea and reduced appetite. On exam she had scleral icterus and diffuse abdominal tenderness. Laboratory investigations showed hypercholesterolemia, alkaline phosphatase rise from baseline of 184U/L to 548U/L with liver-specific fraction of 64%. Total and direct bilirubin were 4.6mg/dL and 3.9mg/dL. Computed tomogrpahy scan revealed new hepatomegaly. Cholestasis symptoms persisted 8 months after completion of DAA. In addition, the patient had new elevated antimitochondiral antibodies (AMA 68U, normal <20U). A liver biopsy was performed as a part of kidney transplant evalution. Unexpectadly, it showed the biliary pattern of liver injury consistent with primary biliary cholangitis (PBC). Ursodeoxycholic acid was initiated but stopped due to intolerable gastrointestinal side effects. Despite no additional therapy, pruritus and hyperbilirubinemia gradually resolved 18 months after completion of DAA; however, AMA levels remained elevated.

Discussion: HCV infection is associated with chronic state of antigenemia and resultant immune activation and impaired function of several immune cell populations. It was shown that HCV eradication can lead to reactivation of chronic hepatitis B and recurrent hepatocellular carcinoma. We hypothesize that PBC-like liver injury in the present case was due to immune reconstitution inflammatory syndrome and imbalance of immune-regulatory mechanisms associated with eradication of HCV infection rather than *de novo* PBC. Potential benefits of HCV treatment in ESRD patients should be balanced with possible complications, reduced ability to receive HCV positive organ for kidney transplantation and increased cost of care.

PUB692

Unexpected Allergic Reaction in a Patient Receiving Chronic Hemodialysis

Srikar Kumar,[1] Abhijit V. Kshirsagar,[2] Raven A. Voora.[2] *[1]University of North Carolina, Chapel Hill, NC; [2]University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Introduction: Anaphylactic reactions usually occur during the initial dialysis session. We present a patient on chronic hemodialysis who suddenly develops an anaphylactic reaction to a part of the dialysis apparatus.

Case Description: 34-year-old man with ESRD presented to the emergency department with hyperkalemia and dyspea secondary to volume overload after missing outpatient dialysis. Hemodialysis was started using his outpatient prescription (1). Two minutes after initiating dialysis, the patient became hypoxic and hypotensive, requiring emergent intubation and vasopressors. He was started on CRRT (2) and had no adverse reactions. The next day, he was weaned from pressors and extubated. Hemodialysis was again attempted (3), but he developed hypotension and hypoxia. At this point, there was suspicion for a dialysis-related issue. Hemodialysis was attempted using a different dialyzer (4), double priming of the extracorporeal circuit, and pre-medication with antihistamines, but he again developed anaphylactic symptoms. Since he tolerated CRRT with NxStage, hemodialysis using the NxStage machine was ultimately performed with no issues (5). He is currently dialyzing at his outpatient unit with this set up without incident.

Discussion: This chronic dialysis patient likely had a severe allergic reaction to ethylene oxide sterilant used for dialyzer components. Type A reactions (anaphylactoid) occur within the first five minutes, and are an IgE medicated process, causing hypotension and possibly shock. Patients with prior history of allergic reactions during dialysis are at higher risk of type A reactions, so it is unexpected that this patient developed a reaction after receiving outpatient dialysis treatments for several years without incident. Because this patient tolerated CRRT with the Purema cartridge, the reaction was thought to be due to the sterilization method, specifically to the tubing. It is unclear why he suddenly developed these symptoms. One should always consider Type A reactions in patients on chronic dialysis who develop instability while receiving dialysis.

Effect of Intermittent Hemodialysis (iHD) on Patient and Left Ventricular Assist Device (LVAD) Hemodynamics: A Case Report

Muhammad O. Hanif, Abbas Raza, Karthik M. Ranganna, Sandeep Aggarwal, Ellie Kelepouris, Ziauddin Ahmed. *Drexel University College of Medicine, Philadelphia, PA.*

Introduction: IHD in patients with a LVAD is challenging due to non-physiological and complex circulatory hemodynamics, especially in modern LVAD which have continuous instead of a pulsatile blood flow. There is a general lack of literature in this field. We present a case of an ESRD patient with LVAD in whom we studied the hemodynamics effect of iHD.

Case Description: 42-year-old male with past medical history of Non ischemic cardiomyopathy with Ejection Fraction of 10-15% on Destination LVAD (Heart ware continuous flow, centrifugal), ESRD on IHD for 1.5 years due to cardiorenal syndrome. We prospectively collected pre and post dialysis Mean Doppler Pressure (MDP, mmHg), Cardiac Output (CO, Liters/min), Heart rate (HR, beats per min BPM) Dialysis time, and Ultrafiltration volume; from 35 consecutive treatments. MDP mmHg was measured as first brachial artery doppler signal after manual cuff deflation (Lanier et al), CO were recorded from LVAD device monitor and HR was collected using continuous chest lead telemetry. Paired 2 tailed T-test was used for within group difference, Pearson's r was used for correlation analysis. There was a statistically significant improvement in CO, reduction in MDP and

increase in HR(table 1). The average Ultrafiltration volume was 3.4±0.7 Litres and average dialysis time was 3.7±0.6 hours. There were 3/35 post ultrafiltration hypotensive episodes (MDP < 55mmHg), all were asymptomatic and resolved spontaneously. Midodrine was not required in any instances. Interestingly there was no correlation between ultrafiltration volume and change in cardiac output (r2 = 0.013) or change in MDP (r2 = 0.002).

Discussion: Hemodialysis in LVAD patients remains challenging. Our case showed that iHD is tolerated well and significant increased in CO occurred after UF despite decrease in the MDP. We recommend further larger scale studies in this regard.

Dialyzing Massive Metformin Overdose

Syed H. Bukhari,[1] Itunu O. Owoyemi,[3] Joshua D. King,[3] Brendan T. Bowman.[2] *[1]University of Virginia Div. of Nephrology, Charlottesville, VA; [2]University of Virginia Health System, Charlottesville, VA; [3]University of Virginia, Charlottesville, VA.*

Introduction: Metformin is a biguanide oral antihyperglycemic, prescribed to over 120 million people globally. Metformin associated lactic acidosis (MALA) is a serious complication of metformin overdose. We present a case of massive metformin overdose and MALA successfully managed with sequential rounds of hemodialysis (HD) and continuous venovenous hemodialysis (CVVHD).

Case Description: A 19-year-old male was admitted after taking approximately 360 pills of 500 mg metformin in a suicide attempt. Initial serum lactic acid (LA) level was 5.0 mmol/L and metformin level was 350 mcg/mL (therapeutic 0-2 mcg/mL). He was started on a bicarbonate drip and underwent emergent HD for 4 hours; however, LA worsened to 27 mmol/L and developed acute respiratory failure and hemodynamic compromise requiring mechanical ventilation and vasopressor support. LA had worsened to 39 mmol/L with an anion gap (AG) of 40. Patient also developed acute kidney injury (AKI) with a peak creatinine of 4.4 mg/dL. Blood gas analysis showed pH 7.02, pCO2 23 mm Hg and bicarbonate 6.0 mmol/L. Patient underwent successive rounds of HD for 6 hours with a high flux dialyzer and then switched to CVVHD with a dialysate flow rate of 112 ml/kg/hr. The total duration of renal replacement therapy (RRT) was 60 hrs after which AKI resolved and serum bicarbonate, LA and AG normalized.

Discussion: Metformin has a relatively high volume of distribution (1-5L/kg) and its toxicity is associated with a mortality of >38% with levels above 50 mcg/mL. MALA poses a multifaceted challenge including drug removal, correction of acidosis and prevention of rebound. Our case was unique for various reasons. The magnitude of toxicity was massive and patient was dialyzed three times in 24 hrs using a high flux, high surface area dialyzer and metformin level decreased from 350 mcg/mL to 8.7 mcg/mL. To prevent rebound, patient was continued on high volume dialysate at 112 ml/kg/hr with CVVHD achieving clearance rates of approximately 130 mL/min. The total duration of RRT of 60 hours was much shorter compared to previously reported cases involving low flux, low-efficiency dialyzers that required RRT for days to weeks. This resulted in earlier resolution of MALA and may have influenced renal recovery. Sequential use of high flux, high surface area dialyzer and high volume CVVHD can decrease metformin levels precipitously, prevent rebound MALA and promote early renal recovery.

PUB695

Baclofen Neurotoxicity: A Case for More Stringent Guidelines

Hong loan T. Nguyen, Muhammad S. Shamim, Samaya J. Anumudu, Ahmed A. Awan, Jose J. Perez. *Baylor College of Medicine, Houston, TX.*

Introduction: Baclofen is a Y-aminobutyric acid (GABA) derivative whose inhibitory effect at the motor neuron synaptic reflexes is utilized in muscle spasticity reduction. Baclofen elimination occurs primarily through the kidneys (69% +/- 14%) and therefore is severely reduced in patients with renal insufficiency; hemodialysis (HD) clearance of Baclofen is 128mL/min. Baclofen neurotoxicity in end stage kidney disease (ESKD) is a major concern.

Case Description: A 44 year-old male with ESKD on scheduled HD, diabetes mellitus II, hypertension, and diastolic heart failure was admitted for acute encephalopathy. One day prior to presentation, the patient visited a local clinic for leg pain for which he was prescribed Baclofen 10mg two times daily. After taking two tablets as instructed, he had progressive encephalopathy leading to hospital admission. At presentation, he had notable dyskinesia and encephalopathy and was emergently intubated for airway protection. Head and chest imaging was unremarkable and infectious workup was negative. Nephrology was consulted for emergent HD for metabolic clearance. EEG was consistent with metabolic-toxic etiology. He received three consecutive daily HD sessions, was successfully extubated, returned to baseline mental status, and was discharged on day five of hospital admission.

Discussion: Our case highlights potentially lethal Baclofen neurotoxicity in patients with ESKD. Avoidance of Baclofen in this population has been recommended. However, if necessary, prescribers are advised to start at a low dose with close monitoring for adverse effects. From our experience and detailed literature review, even a small/renal-adjusted dose of Baclofen in an ESKD patient may lead to rapid subsequent neurotoxicity. Despite recognition by nephrologists of this severe adverse effect, Baclofen is still being prescribed to ESKD patients. This may be due to the fact that there is no clear contraindication for its use in this population. Very often, nephrologists are not the providers first in line treating common complaints such as muscle spasms/pain for which Baclofen is often prescribed. Our case highlights the need for clearer Federal Drug Administration (FDA) guidelines for the cessation of Baclofen use in patients with ESKD and advises for greater education to primary care and emergency care providers of baclofen neurotoxicity in patients with ESKD.

PUB696

Methotrexate Toxicity Following Treatment of a Caesarean Scar Pregnancy

Sarah Gleeson,[1] Ian Kando,[2] Audrey A. Long,[3] David Semple.[1] *[1]Nephrology, Auckland hospital, Auckland, New Zealand; [2]Auckland District Health Board, Auckland, New Zealand; [3]Auckland City Hospital, New Zealand, Auckland, New Zealand.*

Introduction: Caesarean scar pregnancies(CSP) require treatment with methotrexate(MTX). Local MTX was not thought to be systemically absorbed. Our end stage renal failure(ESRF) patient developed severe MTX toxicity following local MTX therapy.

Case Description: A 30-year-old woman with ESRF maintained on haemodialysis(HD) presented with an unplanned pregnancy. She previously had a vaginal delivery followed by a caesarean section. An ultrasound scan at 8 weeks showed an ectopic CSP. This was managed with an intra-sac injection of 50mg MTX Post-procedure she deteriorated with fever, mucositis, rash, neutropenia and thrombocytopenia. On Day 5 MTX toxicity was considered and a MTX level was 0.30umol/L. Folinic acid and granulocyte colony stimulating factor were started. Despite this she developed severe neutropenia had a prolonged hospital admission with a protracted recovery.

Discussion: Management of pregnancy in dialysis patients is challenging. This case was further complicated by a CSP, a condition where ongoing pregnancy is ill-advised and complications of uterine rupture, severe haemorrhage and death can occur. Treatment options include systemic or local MTX, uterine artery embolization and surgery. MTX preferentially affects rapidly dividing cells, e.g. blastocysts and stem cells. In those with normal renal function MTX toxicity can be seen in patients receiving very high doses. Pre-emptive folinic acid and careful monitoring of MTX concentration may prevent toxicity. There are reports of MTX toxicity and death in patients on dialysis. There have been 2 cases of MTX toxicity in dialysis patients after systemic MTX administration for ectopic pregnancy, 1 fatal. There have been no reported cases of MTX toxicity following intra-sac MTX administration. Local administration of MTX for management of CSP has the theoretical advantage of less systemic exposure to MTX. However, a previous study in tubal ectopic pregnancies showed the mean peak serum level of MTX after local injection to the ectopic amniotic sac was not lower compared with systemic dosing. Caesarean scar ectopic incidence is increasing with the growing trend of operative deliveries. Improved outcomes and reduction of systemic toxicity in ESRF may be achieved with dose reduction, methotrexate concentrations, early folinic acid therapy, increased frequency of high flux dialysis and strong clinical index of suspicion for MTX toxicity.

PUB697

Excessive Elevation of Serum Phosphate During Tumor Lysis Syndrome: Lessons Learned from a Particularly Challenging Case

Prince Amaechi, Fredrik Jenssen, Zipporah Krishnasami, Anand Achanti, Tibor Fulop. *Medical University of South Carolina, Charleston, SC.*

Introduction: Tumor lysis syndrome in the modern era of allopurinol and recombinant uricase administration may present to Nephrologists with predominant abnormalities of phosphorus and calcium. Indications and choices of renal replacement therapy (RRT) may need to be customized to individual scenarios.

Case Description: An 18-year-old male received first cycle intensive chemotherapy for Burkitt lymphoma and developed massive tumor lysis syndrome. Lactate dehydrogenase peaked at 9,105 [130-250 U/L] with undetectable serum haptoglobin values. Initial medical therapy consisted of recombinant uricase enzyme, intravenous isotonic sodium-bicarbonate administration and oral phosphorus binders. Nonetheless, within 4 days he developed excessive hyperphosphatemia (up to 21.4 mg/dl) with acute kidney injury (serum creatinine 2.2 mg/dL), oliguria, hyperkalemia (6.2 mM), hypermagnesemia (3.1 and hypocalcemia (corrected calcium 7 mg/dL). The competing risk of dialysis disequilibrium syndrome vs. insufficient control of hyperphosphatemia prompted us to utilize an initial session of conventional dialysis session (HD) (4 hour session, with blood flow 200 mL/min, dialysate flow of 400 mL/min; electrolyte composition: sodium 150 mM/L; calcium 2.5 mEq/L), with simultaneous mannitol administration (12.5 gm) at two and four hours after start. Stability of serum osmolality was demonstrated (322 and 319 mOsm/kg before and after, respectively). Serum phosphate improved to 8.7 mg/dL; this improvement, however, may also partially represented test interference by mannitol. Thereafter, high-volume slow continuous hemofiltration started (initial hemofiltration rate 30 mL/kg/h, [2 L/h]); subsequently escalated to 3.5 L/h), where serum phosphate remained difficult to control and even rose transiently (13; 11 mg/dL) during the next 24 h. He had excellent tolerance of these therapies and recovered renal function uneventfully.

Discussion: The presented exceedingly high phosphorus remains the highest serum phosphorus witnessed in our institution. Early and aggressive RRT may involve upfront administration of both an initial conventional HD session to debulk phosphorus load and subsequent continuous modality, until full correction is achieved.

PUB698

Bullous Pemphigoid in Patients with ESRD: A Case Series

Karthik Kovvuru, Aldo E. Torres Ortiz, Jessica S. Everitt, Tia Hayes, Wisit Cheungpasitporn, Maria Lourdes Gonzalez Suarez. *Nephrology, University of Mississippi Medical Center, Jackson, MS.*

Introduction: Bullous Pemphigoid (BP) is an uncommon autoimmune subepithelial blistering disease. Very few single case reports of BP have been described in ESRD population. Prevalence and etiology of BP in hemodialysis (HD) patients (pts) is unknown. We describe a case series of 3 pts with ESRD from a single outpatient dialysis center diagnosed with BP.

Case Description: Case 1: 62 yo woman (W) developed BP during cessation of immunosuppression (IS) for her failed second kidney transplant (KTx). Native kidney failure was presumed secondary to HTN, first kidney allograft worked for 6 years and failed due to non compliance. She was on HD for 9 years before getting a second KTx which failed after 4 years due to rejection. She was restarted on HD and her IS decreased. She developed BP as her IS was decreased. She was restarted on high dose prednisone with prolonged taper. She is now on low dose prednisone and mycophelonate mofetil (MMF). Case 2: 44 yo W with type 1 DM and HTN, ESRD on HD who also developed BP immediately after cessation of IS for her 16 yr old failed KTx. She was treated with prednisone 60 mg with prolonged taper. She was unable to get MMF due to insurance issues and did not tolerate azathioprine. She could not be tapered off steroids and was kept on maintenance low dose prednisone with intermittent high doses for flares. Case 3: 52 yo W with DM, HTN, ESRD on HD who underwent bilateral below knee amputations due to recurrent infections and osteomyelitis. Her wound healing was slow and required prolonged wound care. She developed acute onset of blisters in both stumps about 2 years after surgery. Skin biopsy confirmed stump-related BP which resolved with short length of prednisone taper.

Discussion: Etiology of BP in HD pts remains to be determined. It has been speculated that unmasking of epitopes at the AV fistula/graft site could be playing a role. In KTx pts, cessation of IS could unmask de novo BP or allograft epitopes from a kidney undergoing rejection. BP should be considered high in the differential for blistering disease in HD pts (especially those with failed KTx) as early diagnosis would initiate appropriate therapy.

PUB699

Dialysis Disequilibrium Syndrome with Proper Precautions: A Case Series

Abbas Raza, Robert Fleyshman, Marc J. Kim, Sandeep Aggarwal. *Drexel University College of Medicine, Philadelphia, PA.*

Introduction: Dialysis disequilibrium syndrome (DDS) is an increasingly rare syndrome in modern dialysis practice. It can manifest as altered mentation, seizure, coma and even brain death. Pathogenesis is believed to be the result of rapid reduction in serum osmolality, and water movement into brain leading to cerebral edema. Among the risk factors is first dialysis session and significantly elevated blood urea nitrogen (BUN). To prevent DDS, small dialyzers and slower blood flow rates are employed whenever possible. We present two cases of DDS that developed following proper dialysis initiation precautions.

Case Description: Patient A: 70-year-old female with no significant history of renal disease presented with slurred speech and malaise. Laboratory workup revealed elevated BUN and creatinine (cr), hyperkalemia and severe metabolic acidosis (Table-1). After pretreatment with mannitol, dialysis was started with plan for 2 hours of slow hemodialysis (blood flow 200 ml/min). 90 minutes into the dialysis session the patient developed altered mentation. Dialysis was stopped and her symptoms resolved shortly after. Delivered hemodialysis dose: Kt/V of 0.61 (URR = 43%). **Patient B:** 56-year-old female with no significant history of renal disease presented with headaches and somnolence. Laboratory workup revealed elevated BUN and cr, hyperkalemia, and severe acidosis (Table-1). Dialysis was started with plan for 2 hours of slow haemodialysis (blood flow 250 ml/min) via small dialyzer (F16). 90 minutes into the dialysis session, she had a witnessed seizure. Dialysis was stopped and lorazepam was administered with subsequent resolution of seizure. Delivered hemodialysis dose: Kt/V of 0.71 (URR = 48%).

Discussion: DDS, although rare, is still a possible complication in new start dialysis patients. Dialysis initiation precautions that include small dialyzers and slower blood flow rates should be employed whenever possible. In spite of these precautions, DDS can occur with Kt/V and URR well below the target of 1.2 and 65% respectively. Larger studies are required looking into traditional and novel mechanisms and risk metrics of DDS in modern dialysis practice.

Table-1

Patient	Initial Laboratory Workup	BUN, cr after Dialysis
A	BUN: 249, cr: 23.6 K: 7.1, pH: 6.9	BUN: 142 cr: 13.6
B	BUN: 144, cr: 27.2 K: 6.1, pH: 7.093	Bun: 80 cr: 17.7

BUN & cr (mg/dL), K (mmol/L)

PUB700

A Tale of Two Cryptococcoses: Risks in HIV-Negative Hemodialysis Patients

Jefferson L. Triozzi, Lauren Nicholas S. Herrera. *Baylor College of Medicine, HOUSTON, TX.*

Introduction: Cryptococcosis is an opportunistic fungal infection typically associated with advanced HIV/AIDS. We report two cases in HIV-negative patients with end-stage renal disease (ESRD) on hemodialysis (HD).

Case Description: Patient 1 is a 47-year-old male with a history of ESRD secondary to type 2 diabetes mellitus and hypertension on maintenance HD with a tunneled dialysis catheter (TDC) who presented with two weeks of headache and fever. Lumbar puncture revealed an elevated opening pressure, and diagnosis of cryptococcal meningitis was made by cryptococcal antigen positivity in the cerebrospinal fluid. Peripheral and TDC blood cultures were negative. The patient improved with antifungal therapy and placement of a ventriculoperitoneal shunt due to persistent intracranial hypertension. Patient 2 is a 67-year-old male with a history of hepatitis C related cirrhosis and ESRD on maintenance HD with a TDC who presented with subacute abdominal pain, progressive ascites, and fever. Paracentesis was not consistent with spontaneous bacterial peritonitis; however, cultures of the peritoneal fluid grew *Cryptococcus neoformans*. Further workup revealed disseminated disease in the ascites, cerebrospinal fluid, and serum. His hospital course was complicated by sepsis and death four weeks after initiating antifungal therapy.

Discussion: Although ESRD is associated with immune dysfunction, the pathogenesis of cryptococcal infections in HIV-negative HD patients is not well described. Both patients presented here were HIV-negative Hispanic males from low socioeconomic backgrounds who had initiated HD within the last six months via TDC, and were found to have CD4 T-lymphocyte counts less than 400. ESRD is associated with both impaired T-lymphocyte function and lymphocytopenia, likely predisposing patients to fungal infections. Practice guideline recommendations for treatment in this population are limited. Catheter removal is associated with improved mortality in peritoneal dialysis patients, but this has not been studied in TDCs. Though challenging, early diagnosis improves morbidity and mortality. In conclusion, ESRD patients are at increased risk for cryptococcal infections, regardless of HIV-status. Further studies are needed to better understand the pathogenesis and treatment of cryptococcosis in ESRD patients.

PUB701

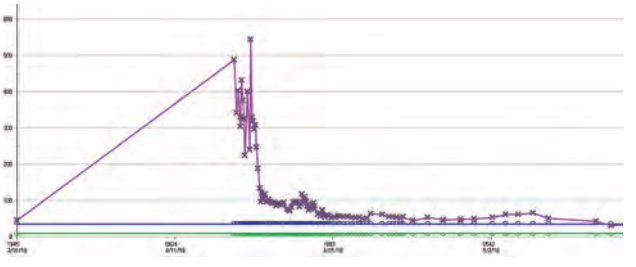
Treatment of Idiopathic Hyperammonemia Syndrome in a Post-Lung Transplant Patient

Meaghan S. Roche, Tiffany Wong. *Hospital of the University of Pennsylvania, Philadelphia, PA.*

Introduction: Idiopathic hyperammonemia syndrome (IHS) is a rare but well-described phenomenon occurring after solid organ transplantation. Here, we describe a case of IHS in a lung transplant recipient, which required renal replacement therapy as well as antibiotics and nitrogen-scavenging agents and was eventually attributed to donor-derived infection with a urea-splitting organism.

Case Description: A 62-year-old gentleman with a history of chronic obstructive pulmonary disease underwent bilateral orthotopic lung transplantation. He became acutely obtunded on post-operative day 13, and labs revealed an ammonia level of 489 umol/L (post-op day 0 ammonia level was 45). Renal replacement therapy was initiated with intermittent hemodialysis followed by continuous venovenous hemodialysis, with marked reduction in blood ammonia levels to less than 100 umol/L within 48 hours. He was empirically started on levofloxacin as well as Ammonul, and he was noted to have a large pericardial effusion. The pericardial fluid grew *Mycoplasma hominis*, which is a urea-splitting organism that has been associated with hyperammonemia. With the combination of prompt renal replacement therapy, nitrogen-scavenging agents, and antibiotics, the patient's ammonia levels returned to normal, and he was discharged home on post-operative day 59.

Discussion: (1) Review the metabolism of ammonia in normal and pathologic states (2) Recognize IHS due to urea-splitting organisms in the immediate post-operative period following lung transplant (3) Discuss renal replacement therapy options for lowering blood ammonia levels Ammonia is produced by amino acid metabolism and converted to urea by the liver. The brain and skeletal muscle also metabolize small amounts of ammonia by generating glutamine, which is then metabolized by the kidney to regenerate ammonia and subsequently excreted in the urine. Ureaplasma and Mycoplasma species produce urease and generate ammonia, and disseminated infection or transmission from a donor organ can cause IHS. There are no current guidelines to initiate dialysis in patients with hyperammonemia, though intermittent hemodialysis removes ammonia most efficiently.



PUB702

Renal Replacement Strategy in a Critically Ill Patient with Severe Azotemia and Hyponatremia

Muhammad O. Hanif, Abbas Raza, Marc J. Kim, Al J. Lee, Sandeep Aggarwal, Hasan Arif. *Drexel University, PHILADELPHIA, PA.*

Introduction: Severe Azotemia and hyponatremia in AKI with CKD is always difficult to manage in critically ill patients who end up requiring renal replacement therapy. Rapid correction of hyponatremia and reduction of BUN can lead to osmotic demyelination and dialysis disequilibrium syndrome. We are presenting a case of 66 year old female with multiple comorbids requiring Continuous Venovenous Hemodialysis(CVVHD) for severe uremia and hyponatremia.

Case Description: A 66 year old female with past medical history of CKD stage 3b with baseline creatinine(Cr) of 1.2 mg/dL, DM2, hypertension, depression, hepatitis C, CVA with residual aphasia, seizures, and dysphagia presented from nursing home with bradycardia, hypothermia and hypotension was found to have non-oliguric AKI over CKD with significantly raised BUN of 327 mg/dL, Cr of 4.17 mg/dL, hyperglycemia of 430 mg/dL with a serum sodium(Na) of 116 meq/L corrected for glucose to 121 meq/L, potassium of 5.5 meq/L, chloride of 80 meq/L, HCO3 of 15 meq/L with high anion gap metabolic acidosis secondary to lactic acidosis, respiratory acidosis and anemia with hemoglobin of 3.9 gm/dL due to upper GI bleed. She was initially resuscitated with IV fluids, IV bicarbonate, started on pressors, insulin infusion for hyperglycemia, IV Proton pump inhibitors for the GI bleed and later on intubated due to respiratory distress. She was started on CVVHD due to diffuse EKG changes. Her calculated dialysate dose was 2.5 L/hr (30ml/kg for a 88kg) but we started her at 1L/hr. We also calculated the urea reduction ratio(URR) via Kt/V= -ln(1-URR) which we estimated of 29%, but her URR came out to be 43% after the first day of treatment, after which we held the CVVHD for 8 hours and then restarted it again. Adequate sodium correction was monitored by obtaining ABGS with critical care panels every 2 hours, which showed a rise from 121 meq/L to 128 meq/L in first 24 hours and to 136 meq/L in the next 24 hours. Her BUN was gradually reduced from 327 mg/dL to 103 mg/dL over a period of 2 days and she was extubated with adequate urine output, EKG normalized and CVVHD discontinued.

Discussion: Our experience showed that frequent use of URR equation and low dialysate rate can be a useful tool in patients on CVVHD with severe azotemia and hyponatremia to avoid dialysis disequilibrium syndrome and osmotic demyelination.

PUB703

An Unusual Case of Hemodialysis-Associated Thrombocytopenia and Severe GI Bleeding

Gerard Martins,[1] Swati Lederer,[2,1] Jeffrey G. Penfield.[2] *[1]UTSouthwestern, Dallas, TX; [2]VA North Texas Health Care System, Dallas, TX.*

Introduction: Transient, mild, and asymptomatic thrombocytopenia (TCP) from hemodialysis (HD) has been reported. Clinically significant bleeding from HD-associated TCP has not been previously described.

Case Description: An 82-year-old Caucasian male with baseline TCP (120,000-150,000/μL) and no prior history of GI bleeding (GIB) was initiated on HD. Thereafter he was admitted 5 times for worsening TCP and severe GIB, requiring 40 units of PRBCs and 13 units of platelets. Workup revealed AV malformations. Patient complained of severe fatigue and chills during dialysis and associated each GIB event with HD treatment. A pre- and post-HD CBC revealed profound post-HD TCP, prompting concern for a dialyzer reaction. His polysulfone (PS) electron beam (EB)-sterilized dialyzer was switched to a polyarylethersulfone (PAES) and polyvinylpyrrolidone (PVP) steam-sterilized dialyzer with marked improvement in post-HD TCP and cessation of GIB (Figure 1).

Discussion: Severe and sustained TCP has been described in case reports. Most cases have been associated with PS EB-sterilized dialyzers. One prospective observation study revealed a significant improvement in post-HD TCP after switching to non-EB-sterilized dialyzers. EB-sterilization may alter the surface property of PS-dialyzers, thereby increasing platelet activation. Modified PS dialyzers appear to be associated with less TCP. We are describing the most severe case of HD-associated TCP that has been documented with use of an EB-sterilized PS dialyzer. Unexplained TCP with HD should prompt workup for a dialyzer reaction. Further research is needed to better characterize the mechanism of HD-related TCP and its risk factors.

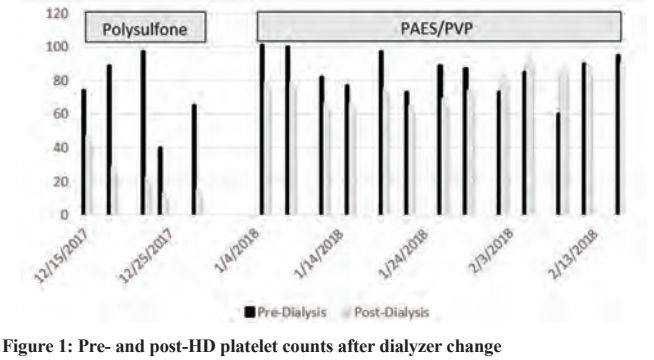


Figure 1: Pre- and post-HD platelet counts after dialyzer change

PUB704

Nocardia Peritonitis: A Rare Case of Peritoneal Dialysis Associated Peritonitis

Sunitha Kalyanam, Sarah A. Johnson. *Nephrology, Emory University School Of Medicine, Atlanta, GA.*

Introduction: Nocardia is a very rare cause of peritoneal dialysis (PD) associated peritonitis with only a few case reports reported. It is ubiquitous in soil, water and vegetable matter and known to cause infection in immunocompromised hosts. We report a rare case of PD associated peritonitis caused by Nocardia Asteroides.

Case Description: A 76 year old female with a history of ESRD on PD using a cycler for 4 years presented with symptoms concerning for peritonitis on day 1 received 2 doses of ceftazidime and 3 doses of vancomycin as an outpatient. She was admitted to the hospital on day 10 for a diffuse skin eruption thought to be a drug reaction to the cephalosporin. She was afebrile with stable vitals but a WBC count of 31, 000. Outpatient peritoneal cultures reported growing a gram positive organism, AFB positive. Repeat peritoneal fluid analysis showed no evidence of peritonitis with a cell count of 70/mcL and negative culture. However, she had an increasing WBC count with abdominal pain so cultures were repeated a third time. The culture was positive for Nocardia Asteroides sensitive to Sulfamethoxazole/Trimethoprim (TMP-SMX). CT scan of the abdomen-pelvis was concerning for a pancreatic mass. MRI with contrast showed 1cm intra-ductal pancreatic neoplasm, with benign appearance and recommended 1 year follow up. She was scheduled to follow up with Surgical -Oncology after discharge. She was treated with IV TMP-SMX for three weeks and her PD catheter was removed as she transitioned to hemodialysis at which time she began to improve clinically.

Discussion: Nocardiosis is an opportunistic infection and because of the slow growth, difficult to isolate. Partially acid fast, filamentous branching rods are pathognomonic of Nocardia. TMP-SMX is the drug of choice. The peritonitis has been treated successfully with both removal and retention of the PD catheter. Optimum duration of treatment for Nocardia Peritonitis is not known, usually 3 weeks is recommended and treatment is tailored to individual patients. Duration may need to be prolonged as it has the propensity to relapse on appropriate treatment. Our patient may also have an undiagnosed pancreatic malignancy causing her to be susceptible to this organism.

PUB705

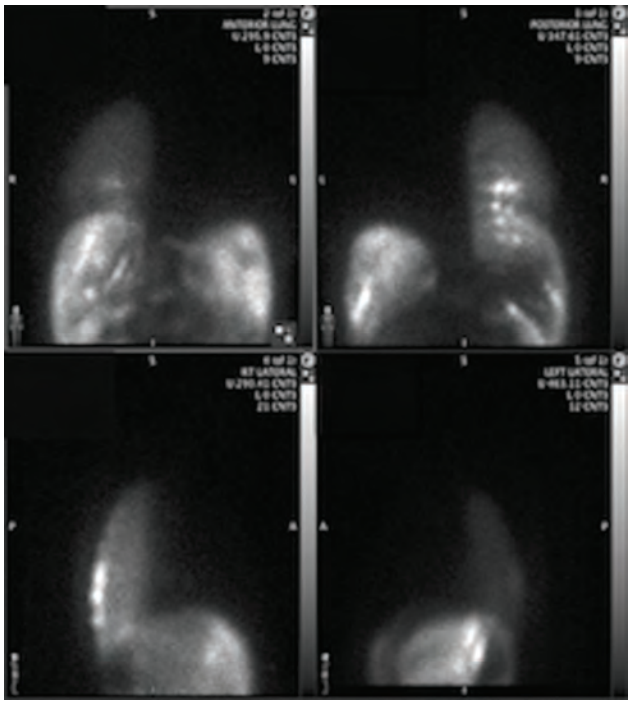
A Rare Cause of Outflow Tract Obstruction in Peritoneal Dialysis, Pleuroperitoneal Leakage

Natanong Thamcharoen,[1] Danwen Yang,[2] Sylvia E. Rosas.[3] *[1]Nephrology, Beth Israel Deaconess Medical Center, Boston, MA; [2]Bidmc, Boston, MA; [3]Joslin Diabetes Center, Boston, MA.*

Introduction: Pleuroperitoneal leakage is a complication in peritoneal dialysis(PD). Although it is rare, we should be familiar with this condition.

Case Description: A 54-year-old woman with ESRD on PD presented with inability to drain the dialysate. PD was started 10 months ago without issues and she was converted to automated cycler 2 months ago. She reports mild dyspnea, chest discomfort when lying flat and dry cough for 1 month. The physical exam showed decreased breath sound on right with dullness to percussion. Abdomen was soft, no tenderness. No redness, discharge at exit and tunneled site. Chest x-ray showed right sided pleural effusion. Right sided Thoracocentesis showed pleural fluid protein <0.2 g/dL LDH 15 IU/L Glucose 642mg/dL and pH 7.51. Cell differential and count did not suggest infectious process. High glucose level and alkaline pleural fluid gave the suspicion of dialysate pleuroperitoneal leakage. A radiotracer(Tc-99m DTPA) was injected via PD catheter in supine position. The images showed uptake above the diaphragm on right pleural space suggesting the leakage(figure). Video-assisted thoracic surgery (VATS) was performed, found 1.5 mm pore on the dome of diaphragm. The pore was sutured and doxycycline pleurodesis was done. PD was terminated and patient was converted to hemodialysis for 4 months, PD eventually was resumed again successfully.

Discussion: Pleural effusion with high glucose level and alkaline pleural fluid is suggesitve of this condition. It tends to occur early after initiating PD or change to cycler as this patient. Radionuclide scan, CT and MRI with tracer can be used to diagnose with moderate sensitivity(40-50%). Conservative treatment with PD interruption should be done for at least 4-6 weeks and if it has failed, invasive procedures such as pleurodesis or VATS can be applied.



PUB706

Candida albicans Peritonitis with Urgent Start Peritoneal Dialysis in a Patient with aHUS Treated with Eculizumab

Heedeok Han,[1] Sayee Sundar Alagusundaramoorthy,[1] Ali I. Gardezi,[1] Micah R. Chan.[2] *[1]University of Wisconsin, Madison, WI; [2]University of Wisconsin-Madison, Fitchburg, WI.*

Introduction: Fungal peritonitis occurs in about 2-13% of patients who undergo peritoneal dialysis (PD). Although rare, fungal peritonitis is a very serious complication with high rates of hospitalization, catheter removal, transfer to hemodialysis and death. The most commonly isolated species with fungal peritonitis is candida sp., with *Candida albicans* being the most frequently isolated organism. Common risk factors associated with the development of fungal peritonitis include episodes of bacterial peritonitis, recent antibiotic use, and immunosuppression. Atypical hemolytic uremic syndrome (aHUS) is a hereditary disease process that occurs due to dysregulation in the complement cascade. It typically presents with a triad of microangiopathic hemolytic anemia, thrombocytopenia and acute renal failure secondary to thrombotic microangiopathy. Eculizumab, a monoclonal antibody against C5, is the mainstay in the treatment of aHUS and its introduction has made prevention of ESRD a possibility. However, some patients do develop ESRD despite the treatment and require chronic renal replacement therapy (RRT). Although Eculizumab is known to increase susceptibility to meningococcal infections, case reports of intraabdominal fungal infection while being treated with eculizumab have been rare.

Case Description: We present a case of *Candida albicans* fungal peritonitis within 24 hours of a fluoroscopically placed peritoneal dialysis catheter in an ESRD patient maintained on Eculizumab for aHUS. The patient was given surgical prophylaxis for bacterial pathogens, but not for fungal pathogens prior to the PD catheter placement. Patient clinically improved after removal of PD catheter and was treated with IV then oral fluconazole.

Discussion: Perhaps surgical prophylaxis for bacterial and fungal pathogens is indicated in patients undergoing PD catheter placement who are treated with eculizumab.

PUB707

A Typical Peritoneal Dialysis Patient with an Atypical Cause of Hyperparathyroidism

Praveen K. Errabelli,[1] Manisha Singh.[2,1] *[1]University of Arkansas for medical Sciences, Little Rock, AR; [2]University of Arkansas For Medical Sciences, Little Rock, AR.*

Introduction: We present a patient on peritoneal dialysis with a combination of normal gland; hyperplasia, a gland replaced by fibrous tissue and an ectopic gland, emphasizing that there may be role of dual imaging prior to surgical intervention.

Case Description: A 58 y/o women on peritoneal dialysis developed severe Tertiary hyperparathyroidism. She was unable to tolerate cinacalcet. Surgical resection was done after Ultrasound showed enlarged glands. Upon resection, ¼ glands were normal, 2/4 glands had hyperplasia and 1/4 glands pathology revealed fibrous tissue. However post-resection PTH did not change significantly even one month after surgery. Contrast CT of neck showed 2 cm x 1 cm ectopic gland in right superior mediastinum located between vertebral and subclavian artery. Resection of ectopic gland through transcervical approach was planned. However patient refused surgery which was deemed high risk given the critical location of the gland.

Discussion: End Stage Renal Disease patients usually have hyperparathyroidism secondary to hyperplasia or adenomas or a combination. If unable to tolerate medical management they undergo subtotal or total parathyroidectomy (1). Ectopic adenomas are commonly in thymus, retroesophageal and intrathyroidal areas (3). Accurate localization is needed to improve outcomes [1]. Sestamibi (MIBI) has higher sensitivity (89%) than USG (59 %) for detecting ectopic glands. MIBI accurately locates ectopic glands in the thymus, mediastinum or retroesophageal space and USG accurately detects intrathyroidal glands [2].This suggests that combining preoperative USG and Sestamibi can help locate ectopic parathyroid glands effectively and prepare for focussed surgical intervention which is both time and cost effective.

Peritoneal Dialysis (PD) Cell Count May Not Always Diagnose Intra-Abdominal Catastrophe

Justin Lee Loy, Mayanka Kamboj, Ashutosh M. Shukla. *Division of Nephrology, Hypertension and Renal Transplantation, University of Florida, Gainesville, FL.*

Introduction: Abnormalities in PD fluid, e.g. high white or red cell counts, bilious or chylous peritoneum, and particulate matter etc. can assist in early diagnosis of intra-abdominal events. A benign PD fluid in a patient with otherwise stable abdominal examination makes the diagnosis of intra-abdominal catastrophe highly unlikely. We present an unusual case, where equivocal radiological findings and benign PD fluid cytology contributed to uncertain diagnosis and adverse patient outcome.

Case Description: A 60-year-old female with end-stage renal disease on PD was admitted with nausea and vomiting. She had benign abdominal examination, no exit site abnormality, peritoneal signs, or evidence for focal findings. CT scan revealed small bowel obstruction with free intraperitoneal air and a transition point in the right lower quadrant, concerning for internal hernia. Repeated PD fluid analysis revealed 62-73 WBC with 3-5% neutrophils. After 3 days of conservative management and unchanging clinical course, exploratory laparotomy was performed which showed matted bowel lumens in right lower quadrant requiring resection of ileum and right hemi-colon. Pathology examination showed the features of early Encapsulating Peritoneal Sclerosis (EPS). Post-operative course was complicated by recurrent intra-abdominal bleedings, multiple laparotomies, splenectomy, and death by day 14.

Discussion: Encapsulating Peritoneal Sclerosis (EPS) is an uncommon but well-reported complication of chronic peritoneal dialysis (PD). History of recurrent peritonitis, indolent onset, malnutrition, and radiological findings are typical presenting findings in these patients. However, acute abdomen presentation with non-inflammatory PD cytology with or without EPS is considered unlikely and has been rarely reported. We present a unique case where incongruent symptomatology, radiological findings and benign PD cell counts could not definitively rule out an internal herniation requiring a surgical approach and adverse outcome. Through this case, we conclude that a non-inflammatory PD fluid cytology could provide an important indication for EPS in PD patients who present with CT findings of possible acute abdomen but are clinically stable. Special considerations for an ongoing trial for conservative management may save lives in such situations.

PUB709

Low Dose Gabapentin Therapy Resulting in Bilateral Lower Extremity Edema in a Young Female Peritoneal Dialysis Patient

Alissa Ice, Farshid Yazdi, Mihran V. Naljayan. *Louisiana State University Health Sciences Center New Orleans, New Orleans, LA.*

Introduction: Peripheral edema is a known side effect of gabapentin with an incidence of roughly 6-8%. This adverse effect has mainly been noted in elderly patients at high (>1200 mg/d) doses of gabapentin. It is unclear whether renal dysfunction may contribute to this clinical finding. We report the first case of gabapentin induced lower extremity edema in a young female patient on peritoneal dialysis.

Case Description: A 36 year old female with end stage kidney disease secondary to lupus glomerulonephritis syndrome, WHO class IV and V, on peritoneal dialysis presented to clinic with bilateral lower extremity edema one month after initiating gabapentin therapy with symptomatic resolution upon discontinuation. The patient began experiencing progressive edema approximately two weeks after starting gabapentin 100-300 mg/d for her peripheral neuropathy. She presented to clinic with 2+ bilateral pitting lower extremity edema and an 8 kg increase in weight one month after beginning therapy. Prior to the onset of her lower extremity edema, there were no recent significant changes to her prescribed medications, continuous cyclic peritoneal dialysis (CCPD) regimen, or laboratory results (albumin remained between 3.3-3.7 g/dL). She had no history of lower extremity edema since beginning peritoneal dialysis in 2016. Upon discontinuing the drug, the patient's swelling resolved over the course of one week, and she returned to her target weight. The patient was then started on pregabalin 25 mg/d with no subsequent edema.

Discussion: The incidence of gabapentin related peripheral edema has been shown at higher doses and tends to increase with age. This unique case illustrates the necessity to consider this medication effect in younger populations and at lower doses, particularly with decreased renal clearance such as in patients on peritoneal dialysis. Gabapentin is frequently used in this patient population due to multiple comorbidities that increase the risk of developing peripheral neuropathy; therefore, we must remain cognizant of this particular side effect as these patients are prone to develop peripheral edema due to other various etiologies. Interestingly, despite some studies showing an increased prevalence of peripheral edema in patients using pregabalin compared to gabapentin, this patient did not develop edema after initiation of pregabalin.

PUB710

Sweet Hydrothorax: Comparing Pleural Effusions in Two Peritoneal Dialysis Patients

Naseem Khorram,[1] Ramzi B. Vareldzis,[4] Farshid Yazdi,[3] Mihran V. Naljayan.[2] *[1]LSU Health Sciences Center New Orleans, New Orleans, LA; [2]LSUHSC School of Medicine, New Orleans, LA; [3]Louisiana State University Health Sciences Center New Orleans, New Orleans, LA; [4]LSU, New Orleans, LA.*

Introduction: Pleural effusion in patients receiving peritoneal dialysis (PD) has a prevalence ranging from 1.2%-10%. When hypertonic dialysate enters the pleura it forms a 'sweet hydrothorax' (transudative effusion with elevated glucose compared to serum glucose). Underlying mechanisms include an increased intra-abdominal pressure with acquired weakening of the diaphragm and impaired lymphatic drainage. We report two cases of patients receiving PD with right-sided pleural effusions.

Case Description: Patient 1- A 59 year old female with ESRD on PD presented to the ED with shortness of breath and nonproductive cough. Four days prior to presentation she fell and sustained a left 10th rib fracture. Following her fall she noticed reduction in ultrafiltrate volume and increasing shortness of breath. She was found to have a significant right pleural effusion associated with hypercapnia (pCO2 62.7 mmHg) and hypoxia (pO2 59 mmHg). Thoracentesis removed 1700 mL of fluid in the ED followed by 1500 mL the following day. Pleural fluid was transudative with elevated glucose compared to serum glucose (502 mg/dL and 169 mg/dL, respectively). Patient 2- A 64 year old female with ESRD on PD for 2 months presented to the ED with shortness of breath and nonproductive cough worsening over several days. She was found to have a large right sided pleural effusion that was removed with thoracentesis (1200 mL). Pleural fluid was transudative with elevated glucose compared to serum glucose (148 mg/dL and 82 mg/dL, respectively). She resumed PD with lower volumes and returned to the ED the following day with shortness of breath and a re-accumulated right-sided pleural effusion for which she did not undergo thoracentesis.

Discussion: These cases highlight etiology of the PD effusion (trauma and congenital diaphragmatic abnormality) and the use of pleural fluid glucose levels in identification of the 'sweet hydrothorax'. Although the site of trauma in patient 1 was on the left, the PD effusion was present on the right indicative of the consistent laterality of such effusions. Furthermore, while patient 2 had a glucose level that was not notably elevated as in patient 1, it was sufficiently raised from her serum glucose. This suggests body fluid glucose content alone should not be so heavily relied upon for diagnosis of pleuroperitoneal leak.

PUB711

Using Indocyamine Green to Diagnose Hydrothorax in Peritoneal Dialysis

Jun Young Lee,[1] Jae seok Kim,[4] Seung-Ok Choi,[3] Jae Won Yang,[2] Byoung Geun Han.[1] *[1]Wonju Christian Severance Hospital, Wonju, Kangwon do, Republic of Korea; [2]Wonju Christian Hospital, Wonju, GANGWON-DO, Republic of Korea; [3]Yonsei University Wonju College of Medicine, Wonju, Kangwon, Republic of Korea; [4]Yonsei wonju college of medicine, Won-ju, Republic of Korea.*

Introduction: Massive hydrothorax is uncommon, but important complication of peritoneal dialysis. Several methods were used to diagnose hydrothorax in peritoneal dialysis patients. However, there was no single definite method to diagnose hydrothorax with peritoneal dialysis patients. Here we report two cases who were diagnosed hydrothorax by using indocyanine green mixing test.

Case Description: CASE 1 A 50-year-old female with PD secondary to diabetic nephropathy visited the emergency room because of abdominal pain and diarrhea. She was treated already for five months with CAPD. Her chest radiograph showed a right-sided pleural effusion. Thoracentesis was performed and her pleural fluid was transudate (Table 1). There was no evidence of heart failure and liver cirrhosis. CAPD peritonitis was improved by intraperitoneal antibiotics. Peritoneal scintigraphy showed no definite abnormality. To confirm the origin of pleural fluid, we mixed ICG on the peritoneal fluid in infused through Tenkhoff catheter. After injected ICG mixed (green color) peritoneal fluid, pleural fluid was drained with green color. **CASE 2** A 78-year-old female with ESRD on PD secondary to diabetic nephropathy visited the emergency room because of shortness of breath. She had been started CAPD for 33 months. On brief sonography demonstrated a massive right-sided pleural effusion and pleural fluid revealed transudate (Table 1). There was no evidence of heart failure and liver cirrhosis. ICG was mixed in peritoneal fluid and injected (2L) to peritoneum then green color pleural fluid was drained via the pleural fluid.

Discussion: ICG is non-toxic, water soluble dye that is used for cardiac output measurement, hepatic function estimation, and retinal microcirculation assessment. Toxicity of ICG is low incidence and mild allergic reactions. In conclusion, we recommend that ICG mixing test may be a reliable, simple, non-harmful, and non-expensive method in differentiating pleuroperitoneal communication from other causes of transudate hydrothorax in PD patients.

Table 1. Results of serum, pleural fluid in two cases of CAPD related hydrothorax.

PUB712

Conversion from Peritoneal Dialysis (PD) to Hemodialysis (HD) in Patients with Calciphylaxis

John Y. Choi,[1] Sagar U. Nigwekar.[2] *[1]BWH-MGH nephrology fellowship, Brookline, MA; [2]Massachusetts General Hospital, Cambridge, MA.*

Introduction: Calciphylaxis is a rare but devastating skin disease in the end-stage renal disease (ESRD) population. Treatment options are limited, and the utility of conversion from PD to HD in patients diagnosed with calciphylaxis remains unclear.

Case Description: A 46-year-old female with morbid obesity, paroxysmal atrial fibrillation on warfarin, poorly controlled diabetes mellitus (DM), ESRD on PD presented to a hospital with painful skin lesions over bilateral thighs. Her outpatient clinic reported gradual loss of renal reserve over the past year resulting in up-titration of her PD prescription. Her parathyroid hormone and phosphate level were refractory to medical therapy. Her skin examination revealed indurated plaques over both thighs. Skin biopsy was consistent with a new diagnosis of calciphylaxis. Her home medications containing calcium and vitamin D were discontinued. Warfarin was substituted with a direct anti-Xa inhibitor. After discussion of the risks and benfits, the patient agreed to convert from PD to HD with a plan to start intravenous sodium thiosulate.

Discussion: It remains unclear if patients on PD will benefit from converting to HD when calciphylaxis is diagnosed. Concerns have been raised with some studies suggesting a higher incidence of calciphylaxis reported in the PD population when compared to the HD population. Furthermore, experts at the first calciphylaxis consensus meeting supported intensifying dialysis treatment which included switching from PD to HD. However, outcome data surrounding dialysis intensification is mixed. While Baldwin et al. published a case series of successful treatment of calciphylaxis by utilizing intense HD, Santos et al. conducted a retrospective analysis of single center data showing increased risk of mortality associated with intense HD. In order to provide the best care for PD patients who develop calciphylaxis, further studies to compare outcomes between continuation of PD versus conversion to HD are needed.

PUB713

Sweet Hydrothorax

Ahmed Subahi, Sulaiman J. Barkho, Zeenat Y. Bhat. Wayne State University/ Detroit Medical Center *Wayne State University/Detroit Medical Center, Dearborn, MI.*

Introduction: Peritoneal dialysis (PD) Patients can develop various complications, one such rare complication is hydrothorax.

Case Description: A 35-year-old man with a history of hypertension, and end-stage renal disease secondary (ESRD) on peritoneal dialysis (started six-weeks earlier) presented due to right-sided pleuritic chest pain that started one day before admission. Over the preceding days, he had noticed an unexplained low drainage volume of dialysate. Vital signs were normal. Physical examination revealed decreased air entry on auscultation at the right side. Chest X-ray revealed a massive right-sided pleural effusion. Laboratory evaluation demonstrated renal dysfunction indicative of his ESRD status with unremarkable complete blood count and liver function test. Ultrasound-guided thoracentesis was performed, and 2300 ml of clear pleuritic fluid was removed without complications. The fluid analysis revealed a high glucose concentration of 447 mg/dl. The fluid was a transudate according to the Light's criteria (Table 1). PD dialysis was temporarily ceased, with very close monitoring of his labs and plan to re-introduce peritoneal dialysis with low-volume exchanges.

Discussion: PD related hydrothorax is rare and can be seen in 2% of the PD patients due to congenital or acquired diaphragmatic defects with a consequent peritoneo-pleural migration of the dialysate. Effusion can develop shortly or several weeks to months after commencing PD. The pleural-fluid analysis is usually diagnostic, revealing a clear fluid with a low protein and a high glucose concentration (sweet hydrothorax). Pleural-serum glucose gradient of more than 50 mg/dL has a 100% sensitivity and specificity to detect PD related pleural effusion. Temporary (2–6 weeks) interruption of CAPD is recommended as a first-line conservative option which can prevent effusion recurrence in approximately 50% of the cases. Other treatment options include chemical pleurodesis via chest drain, limited thoracotomy, and video-assisted thoracoscopy. **Teaching points** Hydrothorax can occur at any time after PD initiation. The pleural-fluid analysis is diagnostic. Interruption of PD is recommended as a first-line therapy.

Table 1. Chemical analysis of the simultaneously drawn serum and pleural fluid

Variable	Serum	Pleural Fluid
Glucose (mg/dl)	89	447
Total protein (g/dl)	6.4	< 3
Lactic dehydrogenase (U/L)	< 25	215

PUB714

Treatment of Mycobacterium Abscesses Exit Site Infection: Looks Can Be Deceptive

Gajapathiraju Chamarthi,[1] Mayanka Kamboj,[3] Judith E. Sallustio,[4] Lennox K. Archibald,[2] Ashutosh M. Shukla.[1] *[1]University of Flroida, Gainesville, FL; [2]University of Florida, Gainesville, FL; [3]University of florida, Gainesville, FL; [4]VAMC Gainesville, FL, Gainesville, FL.*

Introduction: Exit site infections (ESI) caused by *Mycobacterium abscessus* (a rapidly growing nontuberculous mycobacterium) in patients on peritoneal dialysis (PD) are uncommon and difficult to treat. Successful intraperitoneal (IP) antimicrobials regimen for *M. abscessus* ESI has not been established and most patients require systemic therapy with switch to hemodialysis. We report a case of *M. abscessus* ESI that resolved clinically following 9-month therapy with IP agents, only to relapse within a short-time of discontinuation of therapy leading to catheter removal.

Case Description: A 55-year-old man with a history of IgA nephropathy, on PD for 2 years without any prior peritonitis, presented with a large ulcer surrounding the exit site with hypertrophied granulation tissue. M. abscessus was isolated from the exit site without any evidence of peritonitis. Because of patient's strong desire to continue PD to maintain his sailing lifestyle, IP amikacin and imipenem with oral azithromycin was commenced. IP antimicrobial levels were serially checked and amikacin was discontinued after 3 weeks because of ototoxicity. Because of clear clinical improvement and absence of peritonitis, the patient was continued on imipenem and azithromycin for a total of 9 months and discontinued once the ulcer appeared healed circumferentially. Within one month of discontinuation of therapy, he suffered an ESI relapse with expanding erythema and ulcer margins. This led to surgical removal of the PD catheter, surgical debridement, conversion to HD, and need for intravenous and oral therapy.

Discussion: We report an unusual case of M. abscessus ESI in an otherwise immunocompetent patient with no previous history of peritonitis or ESI. We found that though an extended course of IP antimicrobial therapy led to ostensibly complete ESI resolution, rapid relapse occurred once treatment was discontinued. In conclusion, extended courses of IP antimicrobial therapy with attention to therapeutic drug monitoring may enable successful therapy of certain infections in PD patients. However, for patients with M. abscessus ESI, PD catheter removal should be strongly considered.

PUB715

Treatment of Acyclovir Neurotoxicity for a Patient with ESRD on Peritoneal Dialysis

Jana Havranova, Satyam Arora. *St. Luke's University Hospital, Bethlehem, PA.*

Introduction: Neurotoxicity is a rare side effect of acyclovir therapy. Because of its renal clearance, adjustment of acyclovir dosage is necessary for patients with End Stage Renal Disease (ESRD) on hemodialysis or peritoneal dialysis. We report a case of the successful treatment of acyclovir neurotoxicity in a patient on peritoneal dialysis (PD).

Case Description: A 39 year old female with a past medical history of ESRD on PD was hospitalized because of new onset agitation, anxiety, visual and auditory hallucinations. Two days prior to initiation of symptoms, patient was unfortunately started on acyclovir with dosage of 1000mg three times a day for herpes zoster. CT and MRI of the head and blood work did not reveal any abnormalities. Neurotoxicity of acyclovir was suspected. Acyclovir blood level however, was 2.6 (normal therapeutic level 0.12-10.8). Since no other obvious cause, acyclovir was discontinued and patient was initiated on CAPD with 2.5% Dianeal 1.5 liters fills and every 4 hours exchanges. After 2 days of CAPD acyclovir blood level decreased to zero. Symptoms of agitation, anxiety and hallucination improved in 24 hours and resolved in 48 hours after initiation of more frequent PD treatments.

Discussion: In this case, successful treatment of acyclovir toxicity with peritoneal dialysis was achieved without having to transition to hemodialysis. Herpes zoster is a common condition seen quite often in the offices of primary care providers or urgent clinics and obvious care needs to be taken when prescribing acyclovir to patient with ESRD. In addition to discontinuing acyclovir and close neurological monitoring, we validate that acyclovir neurotoxicity will improve by increasing manual PD exchanges and is an acceptable approach in treatment of this potentially fatal complication. We do also suggest that more research needs to be done to validate therapeutic acyclovir drug levels in patients with ESRD.

PUB716

Tuberculous Peritonitis Masquerading as Diabetic Gastroparesis

Kishore Patcha,[1] Divya Raghavan,[1] Laith Al-Rabadi,[2] Josephine Abraham.[1] *[1]University of Utah, Salt Lake City, UT; [2]University of Utah hospital, Salt Lake, UT.*

Introduction: The incidence of tuberculosis (TB) in patients from industrialized nations is relatively low. However, patients on dialysis have a five to fifteen times higher risk of developing TB compared to the general population. This is attributed to malnutrition, alterations in cellular immunity and associated comorbidities.

Case Description: A 42-year-old male Filipino immigrant with end stage renal disease secondary to diabetic nephropathy on peritoneal dialysis (PD) was admitted with hypotension, progressive weakness and worsening abdominal pain. He had been hospitalized multiple times previously with anorexia, weight loss, nausea, vomiting and abdominal pain. After extensive work up, his symptoms were attributed to gastroparesis. A week prior to admission, the patient underwent peritoneal fluid testing for worsening hypotension which showed WBCs >200/μL and he was started on intraperitoneal vancomycin and ceftazidime. Blood and peritoneal fluid cultures remained negative. Repeat peritoneal fluid analysis on admission showed WBC 265/μL with 56% neutrophils, 13% lymphocytes and 19% monocytes. He was started on IV vancomycin and ceftazidime and the PD catheter was removed. A tunneled hemodialysis catheter was placed and patient was transitioned to hemodialysis. Interferon (IFN)-gamma release assay was indeterminate, but peritoneal fluid acid fast bacillus culture came back positive for Mycobacterium tuberculosis. Treatment was initiated with Rifampicin, Pyrazinamide, Isoniazid and Ethambutol. Two months after treatment for peritoneal TB, he was readmitted with back pain. MRI demonstrated osteomyelitis of T5-T6 with complex paraspinal abscess and epidural extension causing spinal canal narrowing. Infectious disease service recommended a total of 9 months of treatment for his vertebral tuberculosis.

Discussion: Peritoneal TB is less commonly reported than other forms of TB. It is very challenging to diagnose since regular aerobic cultures do not grow the organism and even culture for acid fast bacillus has a yield of only 15-30%. The diagnosis of tuberculous peritonitis in PD patients is frequently delayed and this increases morbidity and mortality. It is important to consider this differential diagnosis in the setting of culture negative peritonitis in patients from endemic regions.

PUB717

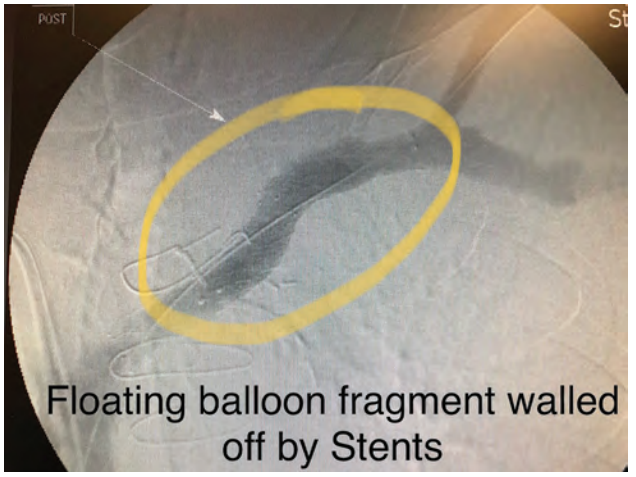
Successful Management of Dislodged/Floating Venous Hardware in ESRD Patients

Loomee Doo,[1] Phillip Ribeiro,[2] Rizwan A. Qazi.[3] *[1]Internal Medicine, University of Nevada Las Vegas, Las Vegas, NV; [2]Nephrology, Vanderbilt University, Nashville, TN; [3]KSOSN, Las Vegas, NV.*

Introduction: Interventional nephrology procedures are performed to maintain functional hemodialysis accesses. A functional access is critical in ESRD patients and complications associated with interventional nephrology procedures include arterial and venous ruptures, clot embolizations, dislodged vascular stents, and ruptured balloon fragments. We present two cases of successful management of dislodged and floating venous hardware in ESRD patients.

Case Description: Case 1: A 80 year old female on hemodialysis for more than 7 years with a left upper arm brachial cephalic fistula who was referred for left upper extremity swelling. Angiogram revealed 80% stenosis of the left innominate vein (in STENT stenosis), and angioplasty was done with a 14x40mm balloon which ruptured and then degloved in the process of being removed. A sizeable portion of the balloon was free floating in the left innominate vein distal to the previously placed stent. Multiple retrieval attempts with a snare were unsuccessful. At this time a second 14x60mm Bard E. Luminexx bare metal biliary stent was placed and seated with a 14x40mm Vaccess balloon. Post angiogram showed good results with re-established flow (see figure1). Case 2: A 67 year old male with ESRD on hemodialysis via a left femoral thigh AVG who presented with a clotted access. In the process of placing a 8x50mm FLAIR stent graft, the stent dislodged and ended up in the left Iliac vein. Multiple retrieval attempts with a snare were unsuccessful. A WALLSTENT by Boston Scientific was placed and the floating stent was prevented from wandering into the pulmonary artery. For both cases, six week follow-up revealed a functional access and no extremity swelling.

Discussion: Dislodged vascular stents and ruptured balloon fragments are unfortunate complications of interventional nephrology procedures. Both of these complications can be successfully managed by placement of a second stent and in essence walling it off from the circulation.



Post Angiogram

PUB718

Preemptive Treatment with Sodium Thiosulfate May Offer Value as Prophylactic Treatment for Calciphylaxis

Shawn L. Marein, Natallia Maroz. *Internal Medicine, Kettering Hospital, Kettering, OH.*

Introduction: Calciphylaxis is a poorly understood disease process which has challenged the medical community since its discovery and continues to plague patients to this day. Although previously considered rare, incidence appears to be rising with current prevalence of ~4% in end stage renal disease (ESRD) patients. Optimal treatment for calciphylaxis is unknown, but sodium thiosulfate (STS) appears to be an emerging therapeutic option. Traditionally, this agent has been utilized once disease has already manifested as well as for secondary prevention following resolution. Here we describe two cases in which ESRD patients were treated with STS infusions preemptively before the development of painful wounds and have thus far avoided materialization of the disease.

Case Description: Case#1 28 years old black female with ESRD from lupus nephritis developed bilateral painful thigh lesions. She was hemodialysis dependent for 9 years, and required systemic anticoagulation with Coumadin since 2015 following aortic valve replacement. At the time of symptoms development patient had tertiary hyperparathyroidism which prompted partial parathyroidectomy. Preemptive therapy with STS was initiated and after 15 infusions patient had significant improvement in pain. She has not developed open wounds even though hard subcutaneous lesions are persistent. Her PTH have not improved significantly and complete parathyroidectomy is planned. Anticoagulation alternative to Coumadin have not been approved by hematology. Patient is now status post 22 STS infusions and stable. Case#2 37 year old black female with ESRD from lupus nephritis developed bilateral lower extremities hard painful lesions involving thigh and lower calves. She was on peritoneal dialysis for 18 months at the time of symptoms development. She had poorly controlled secondary hyperparathyroidism. MRI of lower extremities demonstrated calcified areas, Doppler was negative for thrombosis. Preemptive infusions of STS were initiated for 12 treatments. Patient had significant improvement in pain and almost completer resolution of subcutaneous hardening. Cinacalcet was used for suppression of hyperparathyroidism. She is at present sustains in remission for almost two years.

Discussion: Given the highly morbid nature of calciphylaxis, further investigation into preventative strategies and prophylactic agents such as STS are worthwhile.

PUB719

A Novel Use of Teduglutide in Treating Persistent Hypomagnesemia

Derian Lai, Jose J. Perez. *Baylor College of Medicine, Houston, TX.*

Introduction: We present a patient with hypomagnesemia due to chronic diarrhea and proton pump inhibitor (PPI) use. She required weekly intravenous (IV) magnesium infusions. In 2017, she was given a trial of Gattex® (Teduglutide) which improved her magnesium levels and provided better symptom control.

Case Description: Our patient is a 59 year old woman referred to nephrology clinic in 2012 for evaluation of hypomagnesemia. She reported abdominal pain and loose stools since 2009. Upper endoscopy revealed gastric ulcers. Omeprazole was prescribed. Colonoscopy showed collagenous colitis in 2010. Despite controlling her loose stools to a manageable level with budesonide and supplementing with oral magnesium, her low magnesium persisted. In 2013, her urine Magnesium was <42mg, indicating appropriate renal conservation of Magnesium. She had gained 25 pounds in the last 5 years. Her serum albumin is 4g/dL. Celiac's disease serologies were negative. Her other nutritional deficiencies included iron deficiency and vitamin D deficiency. Omeprazole therapy was not able to be discontinued due to recurrence of pain. In 2015, she was started on weekly IV magnesium replacement. Her magnesium remained in the 0.5mg/dL to 1mg/dL range. In November 2017, her gastroenterologist referred her to a Gattex® (Teduglutide) representative to test the efficacy of Teduglutide in reducing her symptoms. She was able to take the drug for 2 months before she could no longer afford the medication. Remarkably, her loose stools decreased and her magnesium levels were maintained at the highest levels in 5 years (1.5md/dL to 1.9mg/dL). Unfortunately, after she discontinued the medicine her loose stools have returned and her magnesium levels have dropped once again.

Discussion: Our patient's low magnesium is likely multifactorial from her PPI use as well as chronic diarrhea. Teduglutide was FDA approved to treat Short Bowel Syndrome in 2012. Teduglutide is a glucagon like peptide 2 analog that promotes intestinal growth and reduces the necessity for parental infusions in patients with malabsorption. Despite not having generalized malabsorption, our experience suggests that Teduglutide may have a role improving magnesium absorption in those with hypomagnesemia due to gastrointestinal losses. Further studies on its safety profile and efficacy in other nutritional and electrolytes deficiencies are warranted.

PUB720

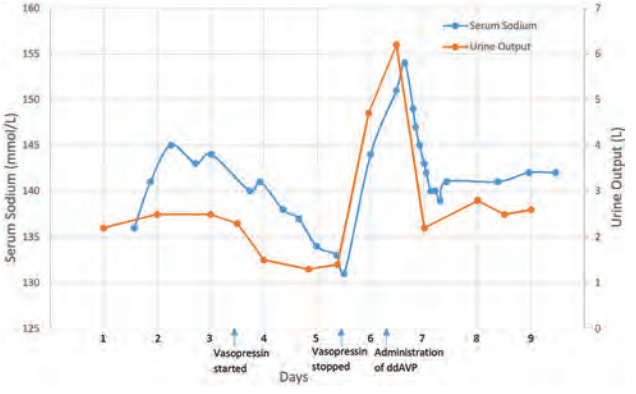
Iatrogenic Diabetes Insipidus

Alice Chedid, Mohamad A. Hanouneh, John Sperati. *Johns Hopkins University School of Medicine, Division of Nephrology, Batimore, MD.*

Introduction: Arginine vasopressin (AVP) is a peptide hormone with multiple critical roles. Exogenous AVP is often used in the treatment of septic shock, ventricular arrhythmia, and diabetes insipidus (DI).

Case Description: A 23 year old woman was admitted with septic shock due to MRSA bacteremia. On physical examination, temperature 37.3°C, HR 90 beats per minute, BP 90/50 mmHg, RR 30 per minute, and oxygen saturation 96% on FiO2 70%. Examination was otherwise unremarkable. She received intravenous vancomycin, cefepime, and norepinephrine. On day 3, ivs vasopressin was added for refractory hypotension. Prior to vasopressin, creatinine was 0.6 mg/dL, sodium (Na) 144 mmol/L, and urine output 2.5 L in preceding 24 hours. Over the next 48 hours, Na decreased to 131 mmol/L, with decrease in urine output to 1-1.5 L per day (Figure 1). Vasopressin was discontinued on day 5, and sNa rose from 131 to 154 mmol/L in 24 hours with urine output of 6 L. Measured serum osmolality was 317 mOsm/kg with simultaneous urine osmolality 76 mOsm/kg. Serum AM cortisol level was 22 mcg/dL. Non-contrast head CT was unremarkable. Transient DI upon vasopressin withdrawal was diagnosed. A single 4 mcg iv dose of desmopressin acetate was administered in addition to iv 5% dextrose water (D5W) at 200 ml/hour. A total of 4 L D5W was given over the next 24 hours, and urine output decreased to 2-3 L with normalization of the Na to 140 mmol/L. Her Na remained 138-143 mmol/L for the remainder of her hospitalization.

Discussion: Transient DI is a very rare event. The precise mechanisms, however, are unknown. Leading mechanistic theories include insufficient endogenous AVP production, as well as downregulation of renal V2 receptors upon prolonged intense vasopressin exposure. In the latter, the abrupt withdrawal of exogenous vasopressin may result in inadequate V2 receptor signaling. Providers should be knowledgeable of this uncommon but serious side-effect of vasopressin.



PUB721

A Rare Cause of Hypercalcemia Post Influenza Vaccination

Arun Rajasekaran,[1] Anil Navani,[2] Pran M. Kar.[3] *[1]University of Central Florida College of Medicine, Kissimmee, FL; [2]Nephrology, Florida Hospital, Kissimmee, FL; [3]VA Medical Center Orlando, Orlando, FL.*

Introduction: Multiple myeloma (MM) is characterized by the neoplastic proliferation of immunoglobulin-producing plasma cells. Several cytokines, including IL-1, IL-6 and TNF-beta, derived from myeloma cells are thought to accelerate osteoclastic bone resorption and cause hypercalcemia through a paracrine mechanism.

Case Description: A 65 year old female presented with subjective myalgias lasting 2 days. She had received an inactivated influenza vaccine 5 days ago. Vital signs were stable. CBC & BMP were unremarkable. Serum calcium was 10.8 mg/dl. She was discharged on supportive therapy. She presented a day later with persistent flu-like symptoms. Labs revealed serum calcium being above 22 mg/dl, normal renal function, total protein, albumin, ACE levels; clear UA with no albuminuria; low PTH and 1, 25-(OH)2-Vitamin D3 levels; elevated PTHrP & viscosity levels. 24-hour urine collection revealed proteinuria (550 mg). Peripheral blood smear revealed rouleaux formation. CT scans of the chest, abdomen and pelvis revealed no obvious malignancy. Quantitative immunoglobulins revealed elevated IgA (2415 mg/dl), and concurrent suppression of IgG and IgM levels. Quantitative serum light chain measurement revealed normal levels of kappa and lambda, with an elevated Kappa:Lambda ratio of 2:1. SPEP, UPEP, and serum immunofixation

revealed IgA-Kappa MM. Given her severe-symptomatic hypercalcemia, she was treated with aggressive intravenous crystalloids, loop diuretics, calcitonin, pamidronate, and hemodialysis. Her calcium subsequently normalized to 10.1 mg/dl. Bone-marrow biopsy revealed intracytoplasmic kappa-restricted monoclonal plasma cells that occupied 40% of the marrow. Bone survey was negative for lytic lesions. She was started on bortezomib, lenalidomide, dexamethasone and monthly zoledronic acid; and she has not attained remission from myeloma yet.

Discussion: Our case is unique in that the patient initially had a normal serum calcium level that had increased rapidly to over 22 mg/dl within a period of 24 hours, had no renal failure or any bone involvement; and had a normal quantitative serum light chain measurement. It is theorized that the inactivated influenza vaccine given prior to presentation unmasked an atypical presentation of MM. This may be attributed to a vaccination induced cytokine storm, especially IL-6 mediated, that may be the key in the pathophysiology of hypercalcemia related to MM.

PUB722

Cryptogenic Adrenal Infarction

Krishna A. Agarwal,[1] Nayan Agarwal.[2] *[1]UMass Medical School-Baystate, Springfield, MA; [2]University College of Medical Sciences and GTB Hospital, Delhi, New Delhi, India.*

Introduction: Adrenal infarction is a rare event in pregnancy and in most reported cases, it is bilateral and associated with a thrombophilic state such as antiphospholipid syndrome. We report the first case of unilateral adrenal infarction in a pregnant female, without thrombophilia, secondary to paradoxical embolization.

Case Description: 21-year-old obese G1P0 female presented at 28 4/7 week of gestation with 1-week history of worsening, right-sided abdominal pain associated with nausea and non-bloody non-bilious emesis. No history of thrombophilia, denied smoking or OCP use. No family history of clotting disorders or spontaneous abortions. Physical exam significant for pregnant abdomen with right upper and lower quadrant tenderness. Lab work revealed Hgb 8.0g/dL, Hct 28%, WBC count 13.5k/mm3 and alk. phos. 124U/L. MRI abdomen/pelvis showed a normal appendix and gallbladder but an abnormal right adrenal gland with increased T2 signal and surrounding edema concerning for non-hemorrhagic adrenal infarct. This was confirmed by a contrast-enhanced CT. She was started on anticoagulation with enoxaparin. An extensive thrombophilia workup including lupus anticoagulant, anti-cardiolipin & anti-beta-2 glycoprotein antibodies and JAK2 mutation were negative; haptoglobin and homocysteine levels were within normal limits; lower extremity duplex did not reveal any deep vein thrombosis. A morning cortisol level of 16.3ug/dL ruled out adrenal insufficiency. An echocardiogram with bubble study revealed a patent foramen ovale (PFO). She delivered a healthy neonate at 39 weeks. Following delivery, she was bridged to coumadin for a total 6-week course and started on lifelong aspirin therapy for the PFO.

Discussion: Unilateral adrenal infarction in pregnancy is extremely rare, with only 5 cases reported in medical literature so far. Diagnosis is challenging because of presentation as an acute abdomen with a broad differential further complicated by pregnancy. MRI and CT scan are preferred imaging modalities for the adrenal glands. Once the diagnosis is made, anticoagulation is of paramount importance to prevent recurrent thrombotic events and LMWH like enoxaparin is preferred in pregnancy as it does not cross the placenta. Management of PFO is controversial with unclear benefit of surgical closure vs. medical therapy.

PUB723

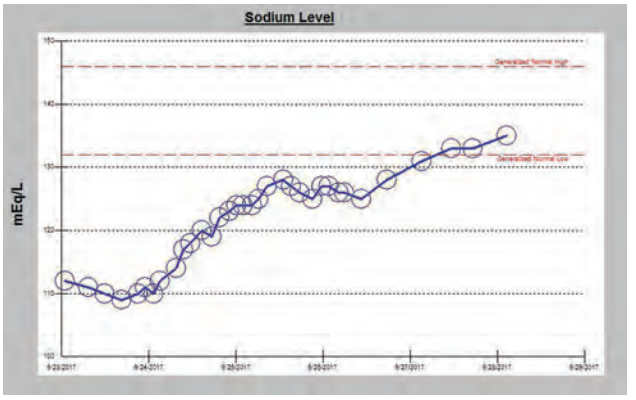
Drugs Masking Follicular Lymphoma as the Cause of Severe Symptomatic Hyponatremia

Muhammad O. Saleem,[1] Peomia C. Brown,[1] Anita M. Rao,[1] N. Stanley Nahman,[1,2] Rajan Kapoor.[1] Nephrons@AU *[1]Medical College of Georgia, Augusta University, Augusta, GA; [2]Norwood VAMC, Augusta, GA.*

Introduction: The Syndrome of Inappropriate Antidiuretic Hormone (SIADH) is a common cause of hyponatremia. It may be predisposed by certain drugs, nervous system disorders or pulmonary diseases. Malignancy especially small cell lung cancer has also been related to SIADH. Finding the underlying etiology is critical in management.

Case Description: A 58 year old Caucasian lady with a past medical history of depression presented with acute neurological symptoms of headache, dizziness and unsteady gait. CT scan head was reported negative for any acute abnormality. Routine investigations revealed hypotonic hyponatremia with hyperosmolar urine. Careful review of home medications identified Citalopram and Trazodone. The diagnosis of hypo-osmolar euvolemic hyponatremia secondary to SIADH was established and thought to be caused by anti-depressants. The drugs were stopped and she was successfully treated with hypertonic saline with appropriate correction of hyponatremia and complete resolution of symptoms. Later, significant weight loss of 20 lbs in last one year prompted work up to rule out underlying malignancy as a cause of SIADH. She underwent CT scan chest, abdomen and pelvis which showed enlarged mesenteric lymph nodes. Subsequent CT guided biopsy confirmed Grade II Follicular lymphoma. PET scan revealed pleura and cervical lymph nodes involvement.

Discussion: SIADH induced hyponatremia is a common presentation, but the underlying cause needs to be carefully investigated. In our case, initially drugs were thought to be associated with SIADH. But later detailed work up revealed a rare and serious etiology of metastatic follicular lymphoma. Few cases have been previously reported where lymphomas were associated with SIADH. We suggest an open minded and aggressive approach to look for underlying malignancy in all patients irrespective of obvious associations, in order not to miss the dire causes.



Serum Na correction with hypertonic saline

PUB724

Unusual Etiology of Hypokalemia in a Patient with New Onset of Diabetes Mellitus

Sushma Edara, Madhu Kandarpa. *Kidney care specialists, Beavercreek, OH.*

Introduction: Hypokalemia can be due to renal or non-renal wasting. Here we are presenting a patient with hypokalemia due to rare cause of renal wasting.

Case Description: 27-year-old healthy male patient presented with generalized weakness, lower extremity edema and shortness of breath gradually worsening over three weeks. He was diagnosed with Diabetes mellitus about a month prior to this presentation. His blood glucose levels remained elevated despite treatment with Metformin and diabetic diet. Past medical and surgical history are negative. Family history is unknown as patient is adopted. Patient is non-smoker, no history of alcohol or recreational drug use or licorice ingestion. On examination temperature 97F, heart rate 93 bpm, regular, BP 144/93mmHg. Patient is noted to have 1+bilateral pitting pedal edema, proximal muscle wasting and areas of ecchymosis over back. Examination is otherwise unremarkable. Laboratory data: Sodium 140mEq/l, Potassium 2.2mEq/l, Chloride 91mEq/l, Bicarbonate 39meq/l, BUN 16mg/dl, Creatinine 1.0mg/dl, Glucose 334mg/dl, Calcium 8.2mg/dl, WBC 17.5/µl, neutrophils 93%, HB 14.8g/dl, Urine Potassium 45.9mmol/l, Transtubular Potassium Gradient (TTKG) 14.46, AM cortisol- 69.9ug/dl, ACTH: 325pg/ml, TSH, free T4, T3: low. Intact PTH, Renin, Aldosterone, FSH, LH, CEA, prolactin, IGF-1, c peptide is within normal limits. Low and high dose dexamethasone suppression test did not suppress ACTH and cortisol levels. Echocardiogram LVEF 55- 60%, trivial pericardial effusion; CT chest, MRI Brain and Abdomen (with and without contrast) normal without any lung mass, pituitary tumor or adrenal mass respectively.

Discussion: Elevated TTKG is suggestive of renal potassium wasting. The generation of hypokalemia, metabolic alkalosis and hypertension are likely the result of sustained activation of mineralocorticoid receptors by high levels of circulating cortisol. Elevated ACTH levels in this case is either due to ectopic ACTH secretion or pituitary microadenoma. Patients with ectopic ACTH secretion often lack the clinical manifestations of Cushing's syndrome as in this patient. Management from Nephrology standpoint is maintaining potassium levels within normal limits and treating the underlying cause. Ectopic ACTH secretion is a rare cause of hypokalemia. Prognosis depends upon the underlying cause.

PUB725

Severe Hypercalcemia Secondary to Histoplasmosis: A Report of an Interesting Case

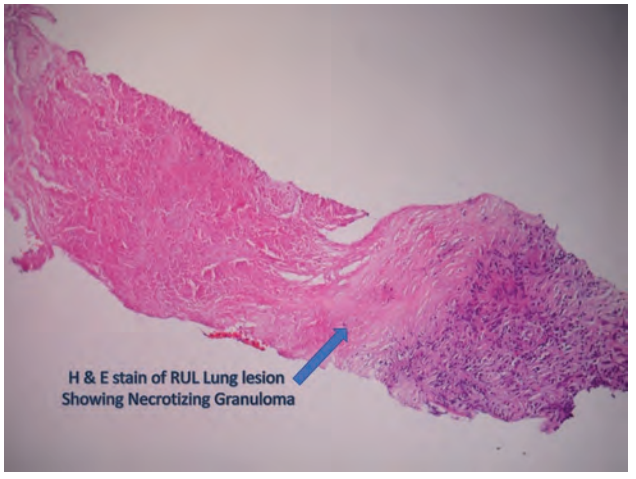
Azka Arif,[2,1] Ahmad Hassan,[3] Muhammad Moosa Niazi,[3] Leena Syed,[4] Talal A. Khan.[6,5] *[1]Internal Medicine, Freeman Health System, Joplin, MO; [2]Internal Medicine, Kansas City University of Biomedical Sciences, Joplin, MO; [3]Rawalpindi Medical College, Rawalpindi, Pakistan; [4]Quaid-e-Azam Medical College, Bahawalpur, Pakistan; [5]Nephrology, Kansas City University of Biomedical Sciences, Joplin, MO; [6]Nephrology & Hypertension, Freeman Health System, Joplin, MO.*

Introduction: Hypercalcemia(↑Ca^{+2}) is an uncommon presentaion of Histoplasmosis. ↑Ca^{+2} associated with Histoplasmosis is usally mild.Here in we present an interesting case of severe ↑Ca^{+2} leading to diagnosis of Histoplasmosis.

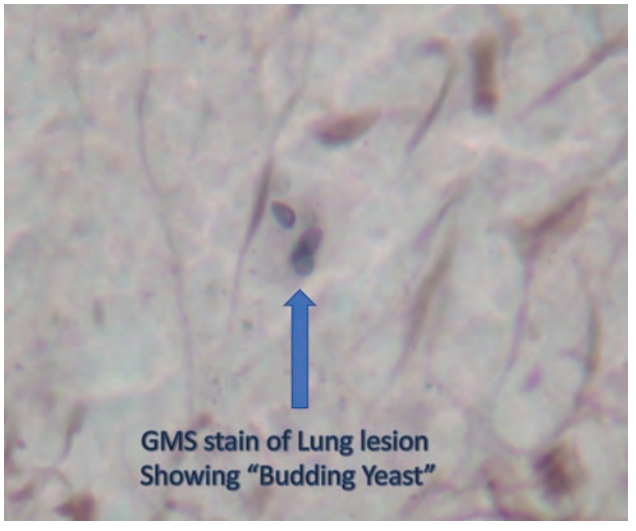
Case Description: 76 yr old female PMH significant for HTN, hypothyroidism, smoker, chronic cough & weight loss presented with syncope & fall, found to have serum Ca^{+2} of **17.7mg/dl** & creatinine of **2.3mg/dl**. PTH was suppressed at 5.4 pg/ml. Urine Ca^{+2} /Cr ratio was 0.26. 25-OH Vit D was 81ng/ml & 1-25-OH VIT D3 was 32pg/ml. PTH-rp was normal at 25 pg/ml. TSH was normal, SPEP/UPEP & serum immunofixation were negative. She was taking oral Ca^{+2} supplementation. She was found to have a RUL Lung mass. She underwent RUL biopsy showing necrotizing granuloma with Budding yeast identified as Histoplasmosis.She was treated for ↑Ca^{+2} with aggressive IV fluids and calcitonin. She was evaluated by ID & was started on itraconazole & oral Ca^{+2} was stopped. Her Ca^{+2} came down to 8.8 mg/dl & creatinine improved to 1.2mg/dl eventually.

Discussion: Histoplasmosis like other granulomatous diseases can cause ↑Ca^{+2} through increased intestinal calcium reabsorption. But severe ↑Ca^{+2} is uncommon. Our case depicts a rare presentation of Histoplasmosis with severe hypercalcemia behaving

like a malignancy. To our knowledge this is the **highest Ca^{+2} level reported** in literature associated with non metastatic Histoplasomosis.



Necrotizing Granuloma



Budding Yeast

PUB726

Marginal Zone B-Cell Lymphoma: A Rare Cause of Central Diabetes Insipidus

Ruby Zhao, Kamal Nayyar, Win Win Moe, James Drakakis, Nobuyuki (Bill) Miyawaki. *NYU Winthrop Hospital, Mineola, NY.*

Introduction: While hyponatremia is often considered in association with paraneoplastic syndromes including SIADH, hypernatremia from central diabetes insipidus (CDI) is a rare neoplastic complication. Metastasis to hypothalamus-pituitary region from breast cancer, lung cancer, acute myelocytic leukemia and disseminated squamous cell carcinoma have been previously described. Leukemia and lymphoma rarely affect the pituitary gland with an estimate of 0.6%. This is the first reported case of CDI from splenic marginal zone lymphoma (MZBCL).

Case Description: A 67-year-old female with a relatively new diagnosis from 6 months ago of splenic MZBCL was admitted to the hospital with thirst, generalized weakness and vertigo and increased urination over 1 week despite doing well prior on Rituxan maintenance therapy for her splenic MZBCL. Her admission Na was normal. Serum Na hovered between 145-149mEq/L on admission days 2-10. With worsened nausea and inability to keep oral intake, Na level suddenly soared from 147 to 169mEq/L overnight accompanied by severe thirst without notable reduction in urine output. Her serum potassium level was 4.2mEq/L, CO2 35mEq/L and creatinine was 0.6 mg/dL. Concurrently obtained urine osmolality was inappropriately low to 224mOsm/L with urinary Na of 62 mEq/L. After administration of dDAVP 2 micrograms IV, urine osmolality increased to 457mEq/L overnight as the serum Na improved from 169 to 143mEq/L over the next 12 hours. The patient subjectively noted a significant decrease in urine output though accurate output was not kept. MRI showed a new enhancing inferior hypothalamic lesion and further testing confirmed the diagnosis of splenic MZBCL with central nervous system involvement.

Discussion: Splenic MZBCL account for less than 1% of non-Hodgkin lymphomas, and are often indolent in nature. Cerebral localized MZBCL has been reported as a rare cause of CDI but our literature search failed to discover CDI or hypothalamic complication from splenic MZBCL. As MZBCL can present with fevers mimicking infections, especially with hemophagocytic lymphohistiocytosis, development of hypernatremia may be inappropriately dismissed as simple case of 'dehydration' without proper history and diagnostic assessments. Concurrence of vertigo with CDI may indicate neoplastic disorder involvement of CNS, including extremely rare entities such as splenic MZBCL.

PUB727

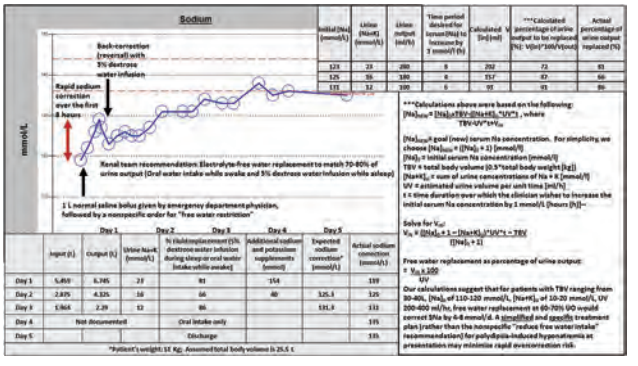
A Simple Approach to the Management of Chronic Polydipsia-Induced Hyponatremia

Raghu Konanur venkataram,[1] Kathy Khaing,[1] Susana M. Mendoza,[1] Phuong-Thu T. Pham,[2] Phuong-Chi T. Pham.[1] *[1]Olive View-UCLA Medical Center, Los Angeles, CA; [2]UCLA Medical Center, Los Angeles, CA.*

Introduction: Chronic polydipsia-induced hyponatremia (cPIH) is often rapidly overcorrected due to inappropriate strict free water restriction. Current recommendation to "reduce free water intake" (e.g. 500 ml less than daily urine output [UO]) is difficult to apply due to the lag of daily UO measurement.

Case Description: 48-year old female with chronic allergies presented with increasing lethargy and unsteady gait. Patient reports 12-20 L of water intake daily. Medication: diphenhydramine, up to 2 "bottles" daily in recent weeks Exam: Blood pressure 132/97 mmHg, pulse 90/min; oriented, drowsy; moist mucosa, unremarkable cardiopulmonary, abdominal, and extremity exams; neurological exam nonfocal Labs/imaging studies: Brain CT, chest X-Ray: negative Serum Na 119, K 3.3 mmol/L, osmolality 250 mosm/kg, blood urea nitrogen 7 mg/dl, creatinine 0.49 mg/dl. Thyroid stimulating hormone and morning cortisol levels: normal In the emergency room, patient received 1L normal saline bolus, followed by strict free water restriction. Serum Na increased to 129 mmol/L within 8 h. Renal team was consulted. Hyponatremia was attributed to the increased thirst associated with high dose diphenhydramine (anticholinergic). Free water was given to reverse the rapid correction. Urine studies revealed urine Na+K persistently <25 mmol/L and urine osmolality <100 mosm/kg; UO ranges at 200-350 ml/h. Further recommendation was to match 70-80% of patient's UO with electrolyte-free water (calculations were based on estimated UO rate and urine Na+K concentrations, Figure). Patient's serum Na steadily and safely corrected and UO tapered nicely over 3 days.

Discussion: cPIH may be rapidly overcorrected with inappropriate free water restriction. In this condition, patient continues to lose high volume of electrolyte-free UO despite being water restricted due to the loss of optimal renal concentrating ability. Our simple recommendation to replace free water at a specified percentage of UO to the primary care team allowed for a steady and safe correction of the presenting hyponatremia.



PUB728

Back to the (Acidosis) Basics: CRRT Masking DKA

Elizabeth Kotzen, Gerald A. Hladik. *University of North Carolina at Chapel Hill, Chapel Hill, NC.*

Introduction: We present a case of diabetic ketoacidosis (DKA) obscured by continuous venovenous hemofiltration (CVVH).

Case Description: A 33-year-old male with type I diabetes mellitus (DM) and ESRD was admitted with cardiac ischemia and had urgent coronary artery bypass grafting. Postoperatively, he required continuous renal replacement therapy (CRRT) because of persistent hypotension. CVVH was initiated at 25 ml/kg/h using NxStage PureFlow dialysate (glucose 100 mg/dL). His diabetes was managed with an insulin infusion titrated via a computerized glucose management system. On postoperative day 5, the patient developed worsening metabolic acidosis. Laboratory studies revealed arterial pH 7.17, PaCO2 38 mmHg, sodium 141 mEq/L, potassium 5.0 mEq/L, chloride 109 mEq/L, total CO_2 15 mmol/L, glucose 140-185 mg/dl, anion gap 17, albumin 3.2 g/dl, and lactate 1.0 mmol/L. Despite glucose levels <200 mg/dL, the serum beta-hydroxybutyrate (BHB) level was found to be elevated to 7.9 mmol/L, consistent with euglycemic DKA. Further review of his record revealed that he was receiving minimal calories via tube feed. In addition, the rate of the insulin infusion rate averaged only 0.2 Unit/hr over the preceding 72 hours. The patient was started on dextrose infusion until tube feeds could be advanced to goal and the insulin rate was increased accordingly. His acidosis resolved and the BHB level normalized.

Discussion: Euglycemic DKA describes the clinical triad of anion gap metabolic acidosis, positive serum or urine ketones, and serum glucose <250 mg/dl. Coutrot *et al.* described 18 cases of euglycemic DKA in patients receiving CRRT with glucose-free replacement fluids. We are not aware of previously described cases in which near

normalization of serum glucose by CRRT using glucose-containing replacement fluid yielded euglycemic DKA. In this case, the development of DKA was multifactorial, including inadequate provision of insulin and carbohydrates. The diagnosis was initially missed by an experienced critical care staff because glucose levels were <200 mg/dL. Methodical acid-base analysis prompted measurement of BHB, confirming the diagnosis of DKA. In this case, the near normalization of serum glucose by CVVH masked the diagnosis of this common acid-base disturbance. An increased suspicion for DKA is warranted in patients with insulin-dependent DM on CRRT even when glucose levels are <200 mg/dL. Reference: Coutrot, Intensive Care Med. 2018.

PUB729

Water Balance Disorders as an Early Sign of Acute Myeloid Leukemia

Tarek Ashour,[1] Rana R. Asmar,[2] Juan C. Calle.[3] *[1]Cleveland clinic foundation, Beachwood, OH; [2]Lebanese American University, Beit Mery, Lebanon; [3]Cleveland Clinic, Beachwood, OH.*

Introduction: Central diabetes insipidus (DI) commonly is idiopathic or may be due to tumors, infections, trauma or infiltrative diseases affecting the brain. It is rare in patients with acute myeloid leukemia (AML).

Case Description: A 52 year old female with past history of high risk myelodysplastic syndrome was admitted because she progressed to AML. She was started on IV Cytarabine. Her serum sodium (Na) was 139 mEq/L on admission. She became steadily more hypernatremic, her Na peaked at 167 mEq/L, then improved to 156 mEq/L with IV dextrose. She reported polyuria and polydipsia of 4-6 L of water daily for few weeks prior to presentation. Initially her urine output (UOP) was not adequately recorded but later she was noted to make 5L of urine a day. Labs showed normal kidney function, serum osmolarity of 320 mOsm/L and urine osmolarity of 104 mOsm/L. DI was highly suspected so DDAVP test was done with marked drop in UOP and rise in urine osmolarity to 534 mOsm/L. All were consistent with Central DI. Other workup showed low serum ADH, FSH, LH, ACTH and TSH. MRI head showed pituitary stalk thickening of 6 mm. She was started on intranasal DDAVP at night time and her serum Na normalized. Her hospital stay was complicated by septic shock due to E.coli bacteremia, AKI and hyponatremia. DDAVP was stopped and she was started on CRRT. She continued to deteriorate and died shortly thereafter.

Discussion: DI may occur any time in the course of AML, but often precedes initial diagnosis. The mechanism is unknown but one theory is that leukemic cells infiltrate the hypothalamic-pituitary stalk, however some patients have such infiltration without DI and vice versa. Thrombocytosis can lead to pituitary micro-infarction. It may lead to platelet dysfunction with increased risk of pituitary hemorrhage. Also may interfere with ADH action because > 90% of circulating ADH is bound to platelets. Leukostasis can lead to pituitary infarction as well. Association with specific chromosomal abnormalities has also been reported in AML. Anomalies of chromosome 3, particularly 3q26 breakpoint with inv(3)(q21q26), in AML patients have been associated with DI. Outcomes are poor in patients with AML who present with DI, regardless of the cytogenetic profile. AML diagnosis should be suspected in the evaluation of patients with central DI with hematologic abnormalities. It can be a good clue for early diagnosis and treatment.

PUB730

A Case of Nafcillin Induced Hypokalemia

Fernando E. Casado-Castillo, Rabih Nasr. *Bronx Care Hospital Center, Bronx, NY.*

Introduction: Hypokalemia is a frequent clinical finding. Most common causes are diuretic use and gastrointestinal losses; Less common causes include: RTA, DKA, insulin excess, ectopic ACTH production and medications.

Case Description: We present a case of severe hypokalemia secondary to treatment with Nafcillin for a Methicillin Sensitive Staphylococcus aureus (MSSA) infection. Patient presented with right sided weakness and bilateral shoulder pain for 1 day. Physical examination showed decreased muscle power in both lower extremities; upper extremity strength was preserved. MRI of cervical spine showed an epidural abscess. Initial laboratory tests were: pH 7.43, Na^+ 133 mEq/L, K^+ 4.0 mEq/L, HCO_3^- 23 mEq/L, BUN 20 mg/dL, Creatinine 0.7 mg/dL. Patient was started on Vancomycin, Ceftriaxone, Metronidazole and cord decompression/abscess drainage was performed. Blood/abscess cultures were positive for MSSA and Nafcillin was started. As showed in graphic and table 1, the patient persisted hypokalemic in despite of repeated replacement with high doses of intravenous Potassium Chloride. A 24 hours urine electrolytes showed: K^+ 63.9 mEq/L and Mg^{+2} 102 mg/dL. Oral K^+ and Mg^{+2} supplements were started, and thereafter both serum K^+ and Mg^{+2} normalized.

Discussion: Reviewed literature suggests that drug-related hypokalemia is rare after starting therapy with penicillin antimicrobials (i.e, Nafcillin) and baseline serum K^+ level is a key determinant. Nafcillin associated hypokalemia is related to non absorbable ion effects in the distal tubule and/or intracellular redistribution due to volume depletion. Hypokalemia in this setting needs aggressive K^+ replacement and may be also corrected by decreasing the dose of Nafcillin. Clinicians should be aware of hypokalemia when using Nafcillin.

Treatment of Refractory Metabolic Alkalosis and AKI with Reinfusion of Gastric Drainage

Li Pang,[2] Gurleen Kaur,[1] Jiasheng Wang,[3] James T. Someren.[1] *[1]Emory, Decatur, GA; [2]Tongji University, Shanghai, China; [3]Metro Health Medical Center, Cleveland, OH.*

Introduction: Gastrointestinal (GI) hydrogen loss is a common cause of metabolic alkalosis. It is usually treated with proton pump inhibitor (PPI) or H2 blocker along with volume replacement. For refractory patients, methods such as dialysis or intravenous (IV) infusion of hydrochloric acid (HCl)/ ammonium chloride can be considered. We describe a case of severe metabolic alkalosis caused by massive gastric drainage that was successfully treated by reinfusion of the drainage into the jejunostomy tube.

Case Description: A 50-year-old female was admitted with 3 days of worsening confusion. She had a complicated surgical history after a jejunal diverticulum perforation. As a result, her small intestine was left in discontinuity, with a duodenostomy draining tube, a jejunostomy tube and a venting gastrostomy tube. She had been receiving a liquid diet as well as total parental nutrition (TPN). Six days prior to the admission, her TPN was taken out for a break. On admission, she complained of markedly increased gastric drainage of about 2.5L daily from the duodenostomy tube. Further evaluation revealed pH 7.52, HCO3 51.6 mmol/L, base excess 24.0 mmol/L, Na 119 mmol/L, K 2.3 mmol/L and Cl 48 mmol/L with creatinine of 6.67 mg/dL (baseline 0.8mg/dL). She received IV fluids, PPI and TPN with potassium chloride repletion. Her electrolyte disturbances quickly corrected. However, she remained in metabolic alkalosis with high GI output of around 3L. Given the acidic nature of her gastric drainage (pH < 5), we decided to re-infuse the gastric drainage from the duodenostomy tube into the J tube to correct the metabolic alkalosis. The patient's acid-base disturbance and renal function normalized over the next few days.

Discussion: Conventionally, metabolic alkalosis caused by excessive GI fluid loss is treated with H2 receptor blocker or PPI, along with IV fluids. However, they were ineffective in our patient. IV HCl or ammonium chloride is the next line of therapy; but they are associated with narrow therapeutic windows and fatal complications. Reinfusion of gastric secretion into distal small bowel has been well described, but mainly for the purpose of nutritional support in patients with high output fistula or stoma to eliminate the dependence of TPN. Our report shows this could be a practical alternative in patients to treat refractory metabolic alkalosis as well.

PUB732

Hyponatremia in ESRD: Look Before You Leap

Mayanka Kamboj,[1] Amir Kazory.[2] *[1]University of florida, Gainesville, FL; [2]University of Florida, Gainesville, FL.*

Introduction: Hyponatremia in patients with end stage renal disease (ESRD) who receive hemodialysis (HD) is frequently attributed to interdialytic fluid intake as they primarily depend on HD for removal of excess water. Measuring serum sodium (SS) as a part of plasma component, instead of plasma water content (PWC), can lead to erroneously low SS measurement.

Case Description: A 76-year-old ESRD patient treated with HD, anoxic brain injury, and recurrent bacteremia presented with severe hyponatremia despite lack of access to free

water. In order to avoid rapid correction of SS, low dialysate sodium (135 mmol/L) was used albeit with no notable impact. Persistence of hyponatremia and patient's physical inability for excessive water intake prompted further evaluation that revealed a serum osmolality of 285 mOsm/Kg in the presence of SS of 127 mmol/L. Further work up showed total protein 10.4 g/dL with albumin 2.9 g/dL. Interestingly, serum protein electrophoresis found large and broad polyclonal hypergammaglobulinemia due to multiple chronic infections, with IgG 5106 mg/dL (N: 635-1616), Ig A 1310 mg/dL (N: 70-433). Total serum lipid level (including triglycerides) was 450 mg/dL. PWC was then calculated [PWC=0.991–(0.73Xprotein Kg/L)-(1.03Xlipid Kg/L)] which revealed reduction in PWC (i.e. 91%) as the source of erroneously reported SS.

Discussion: Plasma dilution technique is used for conventional SS measurement; sodium concentration is adjusted by a fixed factor of 0.93, taking into consideration that the usual plasma composition is 93% water and 7 % solids. This method could result in clinically relevant measurement artifacts even with trivial changes in PWC due to significant increase in plasma lipids or plasma proteins such as in this patient. This case is a reminder that erroneous reporting due to PWC changes should be considered for unexpected low SS levels. This is particularly relevant in ESRD patients where a chronically modified HD approach might portend potentially adverse consequences.

PUB733

Metformin-Associated Lactic Acidosis (MALA): A Rare but Fatal Clinical Entity

Monzurul Chowdhury,[1] Ritu K. Soni.[2] *[1]UMASS Memorial, Worcester, MA; [2]University of Pittsburgh Medical Center, Pittsburgh, PA.*

Introduction: Metformin is widely used as first line therapy for type 2 diabetes mellitus and is the most prescribed oral hypoglycemic agent in the world. While metformin reduces the risk of diabetic complications and cardiovascular mortality, it is also associated with the risk of life-threatening lactic acidosis, particularly in patients with renal or hepatic insufficiency. Metformin associated lactic acidosis (MALA) is a rare but serious complication with a remarkably high mortality rate of 30-50% in affected individuals. The incidence of MALA is reported to be about 4-9 cases per 100,000 patient-years in metformin users. We report a case of metformin associated lactic acidosis in the setting of renal insufficiency.

Case Description: A 55-year-old man with past medical history of DM II, HTN, CKD III presented with sudden onset of dyspnea, chest and abdominal pain associated with nausea, vomiting and poor oral intake for a few days. He takes metformin, losartan and atenolol at home. His vital signs were notable for a temperature of 35.5 C, blood pressure of 176/94, pulse of 94 and oxygen saturation of 99% on BiPAP. He was in moderate respiratory distress and had a resting tremor in his distal upper extremities bilaterally. The rest of his systemic examination was unremarkable. He was initially started on hemodialysis but subsequently developed hypotension requiring transition to continuous venovenous hemofiltration (CVVH). His renal function, metabolic acidosis and hemodynamics improved within 24 hours of treatment with CVVH. He subsequently recovered from lactic acidosis. His renal function improved to his previous baseline upon discharge and he did not require long-term renal replacement therapy.

Discussion: In the setting of renal insufficiency, metformin can induce lactic acidosis by promoting the conversion of glucose to lactate in the splanchnic bed of the small intestine and also inhibits mitochondrial respiratory chain complex 1, leading to decreased hepatic gluconeogenesis from lactate and pyruvate. There is no specific antidote for metformin overdose. Gastrointestinal decontamination with activated charcoal can be used in acute overdose but not in patients with chronic toxicity. Extracorporeal treatment (ECTR) is the key component of management, hemodialysis being the modality of choice.

PUB734

Pseudohyperkalemia - A Hoax

Usman A. Khan,[1] Kai Lau,[1] Aemen S. Khakwani,[1] Sardar H. Ijaz.[2] *[1]University of Oklahoma Health Science Center, Oklahoma City, OK; [2]internal medicine, University of Oklahoma Health Sciences Center, Oklahoma city, OK.*

Introduction: Pseudohyperkalemia is a factitious elevation of serum potassium (K^+) which is caused by many factors including mechanical trauma due to blood draw, due to reagent of blood collection tube, delay in collected sample transport to the lab, leakage of K^+ from the hypermetabolic cells in vitro (i.e. myeloproliferative disorders).

Case Description: A 63 years old Afro-American male with history of Mantle Cell Lymphoma status post 13 cycles of chemotherapy got admitted for stem cell transplant with a white blood cell (wbc) count of 276000/uL. He was persistently hyperkalemic K^+ of 6.4> 8.0 > 9.8 mEq/L; got reversed on dialysis but reappeared again. All causes of hyperkalemia were excluded. He had normal EKG, normal creatinine 0.97mg/dl and had good urine output. K^+ q4h and wbc count daily were monitored. Interestingly observation was distinct when blood sample turnaround time to laboratory for K^+ check was 5 minutes, K^+ value turned out to be normal as opposed to value reported after regular 4-hour delay from a lab technician draw. Therefore, unnecessary dialysis and medical treatments for high K+ were discontinued. When his WBC count came down from 276000/ul to 31000/ul with chemotherapy his K^+ became normal.

Discussion: K^+ leak from hypermetabolic cells (leukemia, lymphoma, thrombocytosis, Polycythemia Vera) occurs in vitro while no changes seen in vivo. Serum K^+ in cases of hyperkalemia especially in setting of myeloproliferative disorders should be evaluated to differentiate true hyperkalemia from pseudohyperkalemia by minimizing the time delay in turnaround of samples to the laboratory. ***Key Words***: Pseudohyperkalemia, myeloproliferative disorders

PUB735

Voriconazole Induced Refractory Hyperkalemia and Adrenal Insufficiency

Usman A. Khan, Sardar H. Ijaz, Aemen S. Khakwani, Joe Ghata. *OUHSC, Oklahoma City, OK.*

Introduction: Voriconazole, member of the azole family, acts by inhibiting lanosterol 14-alpha-demethylase, a cytochrome P450 dependent enzyme. It demonstrates enhanced activity against aspergillus and superior activity against certain fluconazole-resistant candida species. Hepatotoxicity is common side effect of the azoles with neurotoxicity and cardiac arrhythmias more specific to voriconazole. Electrolyte abnormalities and adrenal dysfunction have been reported with voriconazole. In our literature review we found a case report of adrenal insufficiency associated with the concomitant use of voriconazole and inhaled glucocorticoids [1], a case series of severe hyponatremia associated with voriconazole use [2] and a case of iatrogenic Cushing syndrome associated with concomitant use of voriconazole and budesonide [3]. Hyperkalemia is a rare adverse reported not well reported in the literature. We present here a case of intractable hyperkalemia resulting from voriconazole use.

Case Description: A 47-year-old Caucasian male presented with progressively worsening shortness of breath that required mechanical ventilation within 24 hours of presentation. The patient was diagnosed with acute respiratory distress syndrome and was empirically treated with broad spectrum antibacterial coverage but failed to show improvement. Voriconazole was added to his regimen for anti-fungal coverage. Over the next 3 days the patient developed worsening hyperkalemia with normal renal functions and output, not responding to standard pharmacological treatment and emergent continuous renal replacement therapy was instituted. Voriconazole was stopped and the patient could be taken off continuous renal replacement therapy with no further electrolyte imbalances. Throughout this entire period his kidney function remained normal and his urine output was excellent.

Discussion: Hyperkalemia resulting from voriconazole use is an uncommon adverse effect occurring in less than 2% of cases but is important because of the serious and potentially life-threatening consequences. It should be kept in mind whenever initiating treatment especially in patients with compromised renal function; in kidney transplant recipients receiving tacrolimus and other hyperkalemia inducing drugs requiring careful serum potassium monitoring.

PUB736

Hypoparathyroidism Concomitant with Macrothrombocytopenia in an Elderly Woman with 22q11.2 Deletion Syndrome

Hsiu-Chien Yang,[1,2] Chih-Chien Sung,[1] Shih-Hua P. Lin.[1] *[1]Tri-Service General Hospital, Taipei, Taiwan; [2]Internal Medicine, Zuoying Branch of Kaohsiung Armed Forces General Hospital, Kaohsiung, Taiwan.*

Introduction: Although hypocalcemia is common, its etiology is complex. Common causes of hypocalcemia are vitamin D deficiency, hypomagnesemia, critical illness, drugs, and hypoparathyroidism. Among these, congenital hypoparathyroidism has rarely been reported. Chromosome 22q11.2 deletion syndrome (22q11.2DS) associated with congenital hypoparathyroidism can result in hypocalcemia and hyperphosphatemia.

Case Description: We describe the case of a 62-year-old woman with schizophrenia and intellectual disability, who presented with intermittent muscle cramping for 2 weeks. A dysmorphic face and a positive Trousseau's sign, but without ecchymosis or petechial lesion were noted. Laboratory data revealed impaired renal function (creatinine level = 1.6 mg/dL), severe hypocalcaemia (total calcium level = 5.7 mg/dL) with low urinary calcium excretion (13.2 mg/day), hyperphosphatemia (phosphate level = 7.3 mg/dL), and low intact parathyroid hormone level (52.5 pg/mL)—indicating primary hypoparathyroidism. A blood smear revealed thrombocytopenia (30,000 thrombocytes/μL) and giant platelets—indicating macrothrombocytopenia. Chromosome 22q11.2 deletion syndrome (22q11.2DS) in the deficient chromosome 22 was confirmed using multiplex ligation-dependent probe amplification showing haploinsufficiency in *GP1BB* and *TBX-1*.

Discussion: The estimated prevalence of 22q11.2DS is 1:2000 to 1:6000. The clinical manifestations of 22q11.2DS are characterized by facial dysmorphism, congenital cardiac defect, palatal abnormalities, thymic hypoplasia and immunodeficiency, parathyroid hypoplasia, developmental delay and learning disability, schizophrenia, and hearing loss. However, another one of its manifestations, macrothrombocytopenia, has rarely been discussed. Cooccurrence of hypoparathyroidism and macrothrombocytopenia in 22q11.2DS is rare and can easily be misdiagnosed as idiopathic thrombocytopenia purpura. Inappropriate splenectomy or chemotherapy can aggravate hypoparathyroidism. Early diagnosis of 22q11.2DS, characterized by hypoparathyroidism and macrothrombocytopenia, in elderly patients with schizophrenia can facilitate in avoiding circuitous diagnosis and inappropriate management.

PUB737

Dramatic Changes of Water Metabolism

Krystahl Z. Andujar,[1] Fatima B. Cintron-Rosa,[1] Ileana E. Ocasio Melendez,[1] Andrea G. Del toro diez,[2] Nicolle M. Canales-Ramos,[2] Stephanie Colon Lopez,[1] Jose C. Lopez Puebla.[2] *[1]Nephrology, University of Puerto Rico, San Juan, Puerto Rico; [2]University of Puerto Rico, Medical Sciences Campus, San Juan, PR.*

Introduction: Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and central diabetes insipidus are recognized complications following craniotomy or craniectomy.

Case Description: A 29-year-old man with prior resection of metastatic left frontal poorly differentiated sarcoma on dexamethasone 4 mg orally every 4 hours, presented with altered mental status associated with bulging of his left eye and seizures three weeks after procedure. History included end stage renal disease status-post renal transplant in 2011. He was hemodynamically stable without tachycardia or fever. Physical exam revealed left eye proptosis and euvolemia. Due to altered mental status, he was placed on mechanical ventilation. Laboratories revealed sodium 131 mEq/L, creatinine 1.0 mg/dL, urine osmolarity 682 mOsm/Kg, urine sodium 181 mmol/L and TSH levels were normal. Since patient was clinically euvolemic, SIADH was diagnosed and fluid restriction started. Despite fluid restriction, serum sodium levels continued to decrease, and a 3% hypertonic saline solution was started. Serum sodium levels rose 15 mEq/L in a 72-hour period, the patient became more alert and hypertonic saline was discontinued. In addition, transplant immunosuppression was decreased, and doxorubicin initiated. Despite therapy, he had a rapid deterioration in mental status and another emergent decompressive craniectomy was done. At the time of surgery, sodium levels were 143 mEq/L. Within 24 hours, he developed urine output higher than 300 mL/hr associated with serum sodium levels of 162 mEq/L and urinary specific gravity of 1.006. Volume repletion was started, and desmopressin provided, which reduced polyuria and raised urine specific gravity to 1.025. Brain imaging revealed transtentorial and tonsillar herniation. Rapid progression of malignancy may have been associated with pituitary ischemia, resulting in decreased antidiuretic hormone secretion.

Discussion: Our case highlights dramatic changes of water metabolism that patients with brain lesions undergoing neurosurgery can experience. In the post-operative period, frequent monitoring of serum sodium levels is essential including close attention to urine output and tonicity to avoid dysnatremia and delay in treatment.

PUB738

Biopsy Proven Acute Interstitial Nephritis in a Patient with Hashimoto's Thyroiditis Presenting with Concurrent Distal Renal Tubular Acidosis (dRTA) and Severe Lower Extremities Weakness

Rachana Mandru,[1] Stephen J. Knohl,[1] Syed Hammad Alam.[2] *[1]Suny Upstate Medical University, Syracuse, NY; [2]Upstate Medical University, Syracuse, NY.*

Introduction: Distal RTA is a common clinical manifestation of a multitude of autoimmune disorders like Sjögren's syndrome, Chronic active hepatitis, Takayasu arteritis and SLE. dRTA is also a common presenting feature of chronic tubule-interstitial nephritis from any cause; however, there is scant data on the association of autoimmune thyroid disease and lymphocytic interstitial nephritis. Our case is unique in a manner that a patient presenting with no other autoimmune processes except for Hashimoto's comes to have a positive biopsy finding favoring acute interstitial nephritis as being the cause of her dRTA.

Case Description: 39 year old Female with history of Hashimoto's thyroiditis status hemi thyroidectomy and CKD stage 2 presented with severe weakness of her lower extremities. Her admission relevant pertinent labs had revealed a potassium (K+) of 2.1mmol/L and bicarbonate (Hco3-) of 12mmol/L. Her TSH levels were found to be subtherapuetic at <0.03 thought to be as a result of unmonitored thyroxin use. Concurrent Bicarb and potassium supplementation improved her muscle weakness while endocrinology managed her hyperthyroid state. Despite the above measures, hypobicarbonatemia persisted with Nephrology evaluation revealing a urine pH>7.0 and a UrineNa+K (92.8)> UrineCl (83). With the above findings, the diagnosis of dRTA was made with a recommendation of autoimmune evaluation. Serologic studies were only positive for speckled ANA (250) while Ophthalmologic exam was unrevealing for uveitis. Given the above and the ongoing reduced GFR, a renal biopsy was performed which revealed the presence of a lymphoplasmacytic interstitial process with an element of tubulitis as well as some tubular atrophy and fibrosis.

Discussion: Recent studies show that thyroid hormones have several effects on expression of acid-base transporters and are associated with defects in distal nephron handling of acid-base balance. An underlying autoimmune etiology is almost always associated with dRTA, although the exact mechanism is unknown. Our report highlights the importance of recognizing the autoimmune association of dRTA and that there is likely an as-of-yet unidentified autoimmune condition vs currently-known, but serologically negative autoimmune disease resulting in both hypothyroidism and dRTA.

PUB739

Incomplete Proximal Tubular Dysfunction in Acute Myeloid Leukemia (AML): Thinking Outside the Box

Justin Lee Loy, Gajapathiraju Chamarthi, Rupam Ruchi. *Division of Nephrology, Hypertension and Renal Transplantation, University of Florida, Gainesville, FL.*

Introduction: Acute kidney injury (AKI) is common in hematological malignancies. AML in particular can cause acquired defects within the kidney, notably the proximal tubule which results in wasting of amino acids, uric acid, bicarbonate, sodium, potassium and phosphate. In this report, we present a patient with complex myelo-monocytic AML who developed an unusual kidney complication of his malignancy with its associated electrolyte abnormalities.

Case Description: A 58 yo male presented to ER for syncope. Labs revealed BUN 37 mg/dl, serum creatinine (Cr) 5.0 mg/dl, potassium 3.3 mmol/L, phosphate 4.0 mg/dl, uric acid 16.1 mg/dl, LDH 1500 IU/L, WBC 156,000, Hb 10.0 g/dl and platelets 36,000. His AKI was deemed pre-renal and creatinine improved to 0.9 by day 10, with intravenous fluid administration. Flow cytometry confirmed AML. He completed 1 session of leukapheresis and began chemotherapy. By day 13, he developed hypophosphatemia (1.9 mg/dl), hypokalemia (3.3 mmol/L) and hypouricemia (<1.5 mg/dl). Urine pH was 6.0, with new-onset glycosuria >500 mg/dl and proteinuria. Spot urine phosphate was 63 mg/dl, with fractional excretion 38% confirming urinary wasting. Repeat urinalysis continued to exhibit glycosuria in the setting of normoglycemia. 24-hour urine showed phosphaturia of 2.1 g/d (normal 0.9-1.3 g/d) and proteinuria (3 g/d). These findings pointed to the diagnosis of Fanconi's Syndrome except his serum bicarb was 27, with arterial pH 7.43 and pCO 40 mmHg. Serum lysozyme concentration on day 23 was normal. Simultaneous WBC was 900. He was determined to have incomplete proximal renal tubular acidosis, due to lysozyme mediated tubular injury, which persisted despite the lysozyme levels that presumably returned to normal. His serum phosphate improved with oral phosphate replacement to 3.3 mg/dl at discharge.

Discussion: Lysozyme originates from monocytes and macrophages. Increased levels are seen in monocytic leukemia. When excreted in large quantities in the urine various types of renal tubular dysfunction are observed. The combination of AKI, proteinuria, hypokalemia, and hypophosphatemia appears to be characteristic for patients. Our patient's initial AKI masked the typical electrolyte imbalances, which became apparent as his kidney function improved. Even after chemotherapy and normalization of lysozyme levels, the proximal tubular damage persisted.

PUB740

Sporadic Hypocalciuric Hypercalcemia Caused by De Novo CaSR Mutation

Ping-Huang Tsai, Chih-Chien Sung, Tsui-Hua Wang, Shih-Hua P. Lin. *Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan.*

Introduction: Hypercalcemic disorders with hypocalciuria are caused primarily by chronic thiazide or lithium use, acquired antibody to the calcium-sensing receptor (CaSR), familial hypocalciuric hypercalcemia (three types: type 1 (*CaSR*), type 2 (*GNA11*) and type 3 (*AP2S1*)) or sporadic type. It is crucial to distinguish among these causes due to different treatment strategy.

Case Description: A 51-year-old man was referred because of hypercalcemia of unknown cause for > 5 years and progressive decline in eGFR. Family and personal history were non-revealing. There were no obvious symptoms related to hypercalcemia but easy fatigue, constipation and deteriorating renal function. Laboratory testing revealed hypercalcemia (12.5 mg/dL; range, 8.6-10.2) with hypocalciuria (spot urine Ca/Cr ratio was 0.019 in mg/dl/mg/dl, 24-hour urinary calcium excretion was 32 mg/day), and inappropriately elevated iPTH (65 pg/mL; range, 10.0-69.0). Parathyroid and abdominal sonography was normal. Direct sequence analysis of the relevant genes inclusive of *CaSR*, *GNA11*and *AP2S1* showed a heterozygous missense T>A nucleotide substitution at c.1661, resulting in an amino acid change I554N in the extracellular domain of CaSR. I554 is well conserved in all species and this novel mutation is not inherited from his parents. In addition, this *CaSR* gene mutation was not found in 200 healthy subjects and should be pathogenic based on the predictive tools via PROVEAN and Polyphen2 score. Calcimimetics with cinacalcet (25 mg daily) reduced his serum calcium concentration to 11.2 mg/dL and iPTH level to 9.7 pg/mL, coupled with an increased urine calcium excretion (spot urine Ca/Cr ratio to 0.06) and eGFR four months later.

Discussion: Genetic diagnosis for idiopathic or sporadic hypocalciuric hypercalcemia is warranted. Calcimimetics by sensitizing the CaSR to calcium rather than parathyroidectomy can be used to treat symptomatic or moderate to severe hypercalcemia patients with loss of function mutation in CaSR.

PUB741

A Fatal Prescription: Metformin Associated Lactic Acidosis

Ryan P. Flood. *Nephrology, University of Colorado, Denver, CO.*

Introduction: Metformin has become the most widley prescribed type two diabetes medication in the United States, Europe, and Australia. A Cochrane review, and accompanying conclusion, found that the incidence of metformin associated lactic acidosis is 5 cases per 100,000 patient years. This review's conclusions were drawn from patients taking metformin per an established study protocol. Of concern, is the patient population that have a metformin exposure outside the defined prescribing parameters with risk factors for the development of MALA.

Case Description: 58 year old male with end-stage renal disease (ESRD) from unknown etiology, non-insulin dependent type two diabetes, and coronary artery disease presented to a tertiary care medical intensive care unit in trasfer from rural emergency department for managmeent of severe metabolic acidosis and cardiogenic shock. A high anion gap acidosis of 46 and serum osmolar gap of 23 were present on admission which was concerning for toxic alcohol ingestion. Patient was immediately treated with CVVHD in addition to Fomepizole. Approximately 6 hours after admission to the ICU the patient was found to be hemorrhaging from multiple sites and was diagnosed with disseminated intravascular coagulation. 8 hours after admission the patient developed PEA cardiac arrest and expired. Toxic alcohol levels returned negative prompting further post-mortem investigation and a serum metformin level was collected from admission blood work was found to be at a toxic level.

Discussion: The patient had been living transiently through various states receiving compassionate dialysis for several months after being newly diagnosed with ESRD. His fragmented care lead him to continue to take a previously prescribed metformin prescription. This lead to chronic metformin accumulation and the development of MALA, cardiogenic shock, and DIC.

Syndrome of Inappropriate Antidiuretic Hormone Secretion Preceding the Diagnosis of Occult Tonsil Cancer

Ping-Huang Tsai, Chih-Jen Cheng, Shih-Hua P. Lin. *Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan.*

Introduction: Syndrome of inappropriate secretion of ADH (SIADH) is associated with broad spectrum of malignancy, most notably small cell lung cancer and brain tumors. Still, SIADH patients who lack signs of overt malignancy could be a daunting challenge. Simple correction of hyponatremia without further investigation could miss true etiology of hyponatremia and delay the diagnosis of underlying malignancy. Here we present a case presenting with unexplained SIADH, which led to the diagnosis of occult tonsil cancer.

Case Description: A 59-year-old man presented with chronic dizziness and hyponatremia for two years. He had no previous medical and family history. Review of medication did not find possible offending drugs. He was euvolemic, nonedematous, and normotensive. Cardiac, abdominal and neurologic exams were unremarkable. Laboratory investigations showed serum Na^+ 113 mmol/L, K^+ 4.1 mmol/L, Cl^- 90 mmol/L and osmolality 243 mOsm/kg.H_2O. Serum cortisol, thyroid function and ACTH were normal. Urine biochemistries were osmolality 407 mmol/kg.H_2O, Na^+ 140 mmol/L, K^+ 9.7 mmol/L and Cl^- 157 mmol/L. Chest x-ray, MRI of brain and CT scan of chest were unremarkable. SIADH was diagnosed by the inappropriately concentrated urine during serum hypotonicity and exclusion of hormonal disorders. His hyponatremia was refractory to fluid restriction and loop diuretics. Selective vasopressin receptor antagonist with tolvaptan raised the serum Na^+ to 130 mmol/L. However, hyponatremia recurred quickly after the discontinuation of tolvaptan. To search for occult malignancy, whole body positron emission tomography (PET) scan using 18F-fluorodeoxyglucose identified strong uptake at tonsillar regions. Tonsillectomy was performed and the pathological exam proved the diagnosis of moderately differentiated squamous cell carcinoma. Immunohistochemical staining of ADH was negative in the tumor cells. The patient received concurrent chemoradiotherapy, and his hyponatremia resolved eventually.

Discussion: Thorough workup for the hidden malignancy is important in patients with unexplained SIADH. PET scan could be a useful tool in catching occult cancer, which may not easy to be found by conventional image. Early diagnosis and treatment of the underlying malignancy, instead of simply correcting serum Na^+, should always be kept in mind while managing patients with unexplained SIADH.

PUB743

Hidden Type B Lactic Acidosis in a Patient with Known Underlying Malignancy

Sushma Edara, Madhu Kandarpa. *Kidney care specialists, Beavercreek, OH.*

Introduction: Type B lactic acidosis is an uncommon recognized acid base disorder in patients with malignancies including leukemia and lymphoma. We present a patient with non-Hodgkin's lymphoma and monoclonal gammopathy of undetermined significance (MGUS) with mixed acid base disorder including type B lactic acidosis.

Case Description: 83-year-old female patient with multiple medical problems including stage IV low grade non-Hodgkin lymphoma, double band IgM kappa monoclonal gammopathy of undetermined significance (MGUS), hypertension, type 2 diabetes mellitus and dementia presented with altered mental status worsening over three days. On arrival to Emergency Room patient was minimally responsive, afebrile with a heart rate 120 bpm, blood pressure 110/62 mmHg, respiratory rate 23/min. Her initial BUN 96 mg/dl, creatinine 2.4 mg/dl, Sodium 145 mEq/l, Potassium 5.8 mEq/l, Chloride 105 mEq/l, Bicarbonate 31 mEq/l, Lactic acid 4 mmol/l, anion gap 9 mEq/l, Albumin 2.4 g/dl, Lactate dehydrogenase 688 U/l. Arterial blood gas PH 7.09, CO2 77 mmHg, PO2 95 mmHg, bicarbonate of 22.7 mg/dl. Patient required dialysis for oliguria, uremia and severe acidosis which didn't respond to medical treatment. We felt it is more likely to be type B lactic acidosis as patient was not significantly hypotensive and not septic. Patient's mental status improved to her baseline.

Discussion: Type B lactic acidosis is a rare complication of solid tumors and hematological malignancies. Patient has respiratory acidosis with compensated metabolic alkalosis, Despite the elevated lactic acid level, the anion gap was within normal limits even after correcting for albumin. Increased anion gap metabolic acidosis was hidden even with significant lactic acidosis and uremia. Patient's anion gap was 3 after resolution of lactic acidosis and acute kidney injury. Low anion gap in MGUS is probably the reason why her anion gap was within normal limits despite elevated lactic acid level. Type B lactic acidosis in patients with cancer seems to be a marker of poor prognosis regardless of the treatment offered. Limited studies are available specifically addressing management of type B lactic acidosis.

PUB744

Ifosfamide-Induced Fanconi Syndrome in a Patient with von Recklinghausen's Disease

Maria Andrievskaya, Junior Uduman. *Division of Nephrology and Hypertension, Henry Ford Hospital, Detroit, MI.*

Introduction: Ifosfamide is an alkylating agent used to treat many solid tumors. Fanconi syndrome secondary to ifosfamide use has been described in the pediatric literature. We report an unusual case of ifosfamide-induced Fanconi syndrome with self-remitting and recurrent proximal tubulopathy with each chemotherapeutic cycle in an adult patient with neurofibromatosis.

Case Description: A 36-year-old female with history of von-Recklinghausen's disease underwent laparotomy and resection of retroperitoneal malignant nerve sheath tumor arising from a neurofibroma. She was initiated on chemotherapy with doxorubicin and Ifosfamide at a dose of 5 gm/m^2 and Mesna for prophylaxis of hemorrhagic cystitis. Of note, 10 years ago she was treated with same chemotherapy agents and had received 2 doses of ifosfamide at 9 g/m^2. She had normal renal function and electrolytes at baseline. A week following chemotherapy, she was admitted for neutropenic fever, and she was noted to have hypokalemia and hypophosphatemia which were refractory to electrolyte replacement. Other laboratory data revealed: sodium 136 meq/l, chloride 109 meq/l, bicarbonate 18 meq/l, BUN 14 mg/dl, Cr 0.55 mg/dl, magnesium 1.5, glucose 94 mg/dl. Urine studies showed pH of 8.5, glucosuria, albuminuria and evidence of urine phosphorus wasting. She was diagnosed with ifosfamide induced proximal tubular injury. Her electrolyte and urinary abnormalities improved over the next week. With the second cycle of chemotherapy a week later, she developed similar pattern of self-remitting proximal tubular injury. She received a third cycle of non-modified chemotherapy with which she had persistent proximal tubulopathy at 4 week follow up.

Discussion: Ifosfamide-induced tubular toxicity is common among children under 4 years and cumulative doses greater than 60 g/m^2. Mechanisms of ifosfamide-induced proximal tubular injury are not well understood, but chloroacetaldehyde, a metabolite of ifosfamide, is implicated. Oxidative stress mediated by glutathione depletion by both ifosfamide and mesna may also contribute. The older age and limited cumulative dose makes this an interesting presentation. Although the long term renal prognosis is good, caution should be exerted in repeated exposure. Apart from dose reduction, limited data is available for other preventive therapies. Cimetidine and n-acetylcysteine are potential options that lack clinical data.

PUB745

Hyponatremia: The Key to Diagnosing a Lung Abscess in an Asymptomatic Patient

Ela Banerjee,[1] Ari B. Geller.[2] [1]*Internal Medicine, University of Connecticut, Farmington, CT;* [2]*Nephrology, St. Francis Hospital, Hartford, CT.*

Introduction: Lung pathology such as malignancy or infection can commonly result in inappropriate ADH secretion, causing hyponatremia. This case highlights a unique presentation of a lung abscess, where hyponatremia was the key clinical abnormality suggesting the infectious process.

Case Description: 85 y/o F with PMH of smoking, bronchiectasis, bladder cancer (in remission) presented to the hospital with a chief complaint of acute on chronic lower back pain with new onset radiation to right leg and associated weakness. She was incidentally found to have severe hyponatremia of 120 mmol/L on admission labs. The patient denied any recent illness, fever, chills, confusion, seizure-like activity, productive cough, hematemesis, night sweats or weight loss. On admission, she was afebrile with HR of 89, RR 22, BP 125/106 and O2 of 95% on RA. On exam, she was frail-appearing, with moist mucous membranes, regular heart rate and rhythm, clear lung fields bilaterally and no lower extremity edema. Additional lab work showed serum osmolality of 269 mOsm/kg, urine sodium of 118 and urine osmolality of 467. Uric acid was 3.5 mg/dL, TSH 4.35 uIU/ml and cortisol was not checked. She had leukocytosis of 18.9 K/uL with 95.7% neutrophils. Lumbar spine and femur x-rays were negative for fracture and a right leg duplex ultrasound was negative for DVT. Based on these labs, SIADH was diagnosed and the patient was placed on a 1.5L fluid restriction. On day 2 of hospitalization, Urea-Na 15 g/d was added by nephrology and later increased to 30 g/d for persistent hyponatremia. As part of the SIADH work-up, a Chest CT was performed to rule out lung malignancy due to the patient's history of smoking and bladder cancer. It revealed a 3.4 x 3.9 cm mass in the right middle lobe. The patient underwent a CT guided biopsy of the mass demonstrating an abscess, which grew Pseudomonas aeruginosa. She was started on a prolonged course of Ciprofloxacin and continued on Urea-Na 30 g/d with a fluid restriction. This resulted in a sodium correction to 128 at discharge, and to 135 after completing one month of antibiotic therapy for the lung abscess.

Discussion: Lung abscesses can cause hyponatremia due to SIADH. However, only a few cases are reported. This asymptomatic patient's severe hyponatremia helped identify the lung abscess, hence guiding therapy.

PUB746

5-Oxoprolinemia - An Underdiagnosed Cause of High Anion Gap Metabolic Acidosis

Sanjay Kumar,[2] Malvika Kaul,[1] Ann M. Canelas.[1] [1]*MacNeal Hospital, Oak Park, IL;* [2]*Macneal Hospital, Berwyn, IL.*

Introduction: 5-oxoprolinemia was first identified in 1989 as a cause of high anion gap metabolic acidosis (HAGMA) but is rarely considered as a part of initial differential. After ruling out important causes of HAGMA, one can consider this rare entity in patients with certain risk factors such as malnutrition, pregnancy, vegan diet, and hepatic or renal disease. 5-oxoprolinemia is caused by deficiency of glutathione synthetase and 5-oxoprolinase deficiency related to drug toxicity like acetaminophen. Our case highlights the importance of considering 5-oxoprolinemia early in patients with unclear etiology of HAGMA.

Case Description: 71 year old female with recently treated gallstone pancreatitis, pancreatic abscess status post drain placement was readmitted for 5 days of abdominal pain and vomiting. On admission, she was in acute distress with unstable vital signs (heart rate-113, respiratory rate-30) with diffuse abdominal tenderness. Initial laboratory data showed: HCO3 4mmol/l, Creatinine 1.89 mg/dl, glucose 242 mg/dl, anion gap(corrected) 22, white blood cell count 26.9 KU/L, lipase 2323 U/L, INR 1.7, lactic acid 3.6mmol/l, negative urine and serum ketones, and an arterial blood gas showing pH 6.81, PaCO2 27 mmHg, HCO3 <7.9 mg/dl. Imaging showed improved peripancreatic fat stranding compared to previous CT scan. She was treated with IV fluids, antibiotics and a bicarbonate infusion. Despite above measures, her HAGMA persisted, prompting consideration of other causes including drugs. Her serum acetaminophen level was 240.8mcg/ml thus she was started on N-acetylcysteine and her liver function test were monitored. Due to worsening INR, she was transferred to a liver transplant center for evaluation. High acetaminophen level with concurrent high 5-oxoproline level in setting of malnutrition identified acetaminophen as the culprit for this HAGMA.

Discussion: 5-oxoprolinemia is an important cause of HAGMA, hemolytic anemia and central nervous system dysfunction. Higher acetaminophen level leads to increase in 5-oxoproline levels by directly depleting glutathione levels in the liver. Treatment is mainly IV hydration and N-aceytlcysteine (regenerates glutathione). Meticulous history and awareness of rare etiologies is important and can significantly reduce morbidity and mortality in patients with HAGMA.

PUB747

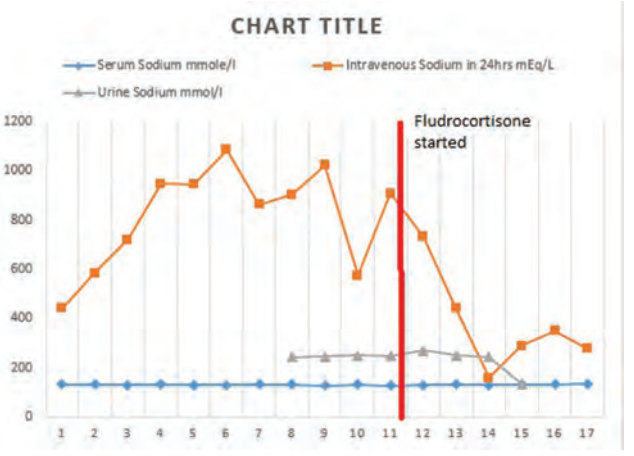
Cerebral Salt Wasting in Neurosurgical Patient

Vipulkumar Bhalara, Smita Mahendrakar, Franklin D. Ponce-Herrera. *Nephrology, Rutgers New Jersey Medical School, Newark, NJ.*

Introduction: We report a case of cerebral salt wasting as an uncommon cause of hyponatremia. Making the diagnosis rapidly is vital as its treatment requires volume and sodium restoration rather than the water restriction as in SIADH. Hyponatremia is common in neurosurgical patients and is associated with substantial morbidity and mortality. Diagnosis of the cause and its correction are essential to prevent severe hyponatremia, which can substantially worsen cerebral edema and increase risk of seizures.

Case Description: 44 yr old male with past medical history of traumatic brain injury at 14 yrs of age with multiple infections of ventriculo peritoneal shut in the past admitted with altered mental status. VP shunt was removed along with washout of ventricle due to repeat CNS infection. Post op serum sodium 131 mmol/L started on 3% NaCl to prevent cerebral edema, serum and urine osmolality were 265 and 569 respectively with urine sodium 245mmol/L. We suspected CSW due to clinical volume depletion, low CVP, urine sodium >200 and large volume urine output. Fractional excretion of Uric acid and phosphorus were high 33%, 29% respectively. After starting fludrocortisone on day 11 his requirement of IV Na and urine Na improved.

Discussion: CSW is a disorder of sodium and water homoeostasis which occurs as a result of cerebral disease in the setting of normal renal function. CSW results in inappropriate primary sodium losses which are not related to volume expansion. The pathogenesis of CSW remains unclear; however any injury to the brain cells releases atrial, brain C type and dendroapsis natriuretic peptides appears to be the driving factor in pathogenesis of CSW. It is postulated that these substances reduces the efficacy of aldosterone and leads to decreasing ability of the kidneys to resorb sodium causing very high urine sodium concentration, a high urine output leading to low volume state. High fractional excretion of uric acid and phosphorus occurs CSW.



PUB748

Renal Salt Wasting (RSW) with Normonatremia Secondary to Acquired Mineralocorticoid Deficiency

Hassan B. Attique,[1] Silya Mazigh,[2] Ruchir D. Trivedi.[1] [1]*Uconn Health, Farmington, CT;* [2]*UCONN Health, Farmington, CT.*

Introduction: RSW is a syndrome represented by hypovolemia, hyponatremia in face of excess urinary sodium loss resulting in ECV contraction. We demonstrate a case of Polyuria with excess urinary sodium loss without significant hyponatremia (net water gain from excess ADH).

Case Description: 44-year-old male with PMH of HTN presented with persistent fevers and AMS. He was found to have bacterial meningitis and brain abscess. His hospital course was complicated by septic shock requiring vasopressor support but baseline urine output remained roughly around 3 L per day, with evidence of euvolemia and normal renal function. Following improvement of his hemodynamics and overall clinical status, he developed significant polyuria as well as renal salt wasting coupled with hypovolemia and hypotension not explained by intake and previously infused crystalloid.

Discussion: The literature addressing etiology of polyuria in the ICU population is scarce. In such contexts, the differential diagnosis should include auto-diuresis from previously given IV fluids, polyuria of sepsis, polyuria of recovery from ATN, diabetes insipidus (DI), cerebral salt wasting (CSW), and mineralocorticoid deficiency among others. In this particular patient, given his normonatremia, DI and CSW alone would not explain these findings; however, a combination of the two is possible. On Day 3, patient had urine output of 9.5 L with urine sodium of 166 mEq/L resulting in total sodium loss of 1577 mEq (1577/154 = 10.2 L of 0.9% saline). This degree of ECV salt loss is associated with profound hemodynamic instability and cannot be replaced without massive volume repletion. In this situation given preserved renal function, acquired transient mineralocorticoid deficiency from sepsis appears to be the best plausible explanation, hence decision to start low dose Fludrocortisone was made with dramatic clinical and hemodynamic response. Absence of hyponatremia can possibly be explained by not allowing to progress to the threshold for ADH release (10-15% ECV volume loss) by constant 0.9% saline and probably hampered CRH and ADH production resulting in decreased ACTH and adrenal steroid production. This case highlights complexity of polyuria in critically ill patients. Fludrocortisone presents a reliable alternative of massive volume repletion in select cases with acquired transient mineralocorticoid defect of sepsis.

PUB749

A Case of Cisplatin Induced Salt Wasting Nephropathy

Rami M. Azem, Michael Lioudis, Sevag Demirjian. *Cleveland Clinic, Cleveland, OH.*

Introduction: Salt wasting nephropathy is a rare cause of polyuria and hyponatremia and is associated with cisplatin and other platinum based chemotherapy. Patients with salt wasting nephropathy typically present with hyponatremia, hypovolemia and orthostatic hypotension. This is a case of a patient who presented with salt wasting nephropathy secondary to cisplatin.

Case Description: A twenty-eight year old male with history of recurrent non-seminoma testicular cancer with metastasis to the lungs presents to the hospital with a right sided empyema. He underwent decortication and washout and was admitted to the intensive care unit for hypoxic respiratory failure. On admission, serum sodium was 133 mmol/L. His sodium worsened to 126 mmol/L one month into hospitalization. At that time, the hyponatremia was suspected to be due to low solute intake along with SIADH in the setting of paroxetine use and malignancy. His urine sodium was 73 mmol/L and urine osmolality was 490 mOsm/kg. Paroxetine was tapered off and sodium improved to 136 mmol/L. He was also receiving cisplatin chemotherapy for cancer treatment. Shortly after his initial hyponatremia resolved, he developed polyuria of 9 L in 24 hours. At onset of polyuria, serum sodium was 124 mmol/L, urine sodium was 95 mmol/L, and urine osmolality was 292 mOsm/kg. His urinary losses were replaced with fluids at a one to one replacement rate. Over the next two days, his urine sodium rose to 180 mmol/L and urine osmolality rose to 402 mOsm/kg. He continued to make between 9 and 15 L of urine daily, so replacement rate of fluids was decreased to two thirds of urinary losses. Despite this, four days later his urine osmolality was 381 mOsm/kg, which led to high suspicion for salt wasting nephropathy. In addition, he was orthostatic and tachycardic, further correlating with salt wasting nephropathy.

Discussion: Salt wasting nephropathy is a rare cause of chemotherapy induced hyponatremia and can be seen with cisplatin and other platinum based chemotherapy. In one study of 70 patients treated with cisplatin for 18 months, 7/70 developed salt wasting nephropathy. All of these patients presented with severe orthostatic hypotension. Their urine sodium ranged from 85-145 mmol/L and urine osmolality ranged from 340-619 mOsm/kg. It is important to recognize salt wasting nephropathy, as management includes replacing water and salt loss.

PUB750

Diabetes Insipidus: Diagnosing Dilemma in a Patient with Cerebral Palsy

Eric Pitts, Aisha Khattak. *University of Texas Health Science Center at Houston, Houston, TX.*

Introduction: Diabetes Insipidus (DI) is a disease in which the secretion of or the response to the pituitary hormone vasopressin is impaired, resulting in the production of large amounts of dilute urine, often associated with dehydration and avid thirst. DI can be central vs nephrogenic (CDI and NDI respectively) subdivided further into partial vs complete. In general, a stepwise approach will help differentiate in most adult patients. Here we present a challenging case in which an accurate diagnosis was delayed in part related to the patient's mental and physical disability.

Case Description: 33 year old Latin male with history of cerebral palsy epilepsy and inflammatory arthritis, presented with sepsis secondary to pneumonia. Due to the patient's mental disability, history was obtained from his mother. He was started on Methotrexate, leflunomide, and steroids approximately 7 months ago. In addition, persistent polyuria of 12-15 diaper changes per day and polydipsia started around the same time. Labs on admission showed a sodium 152 mmol/L, potassium 3.5 mmol/L, chloride 116 mmol/L, bicarbonate 26 mmol/L, glucose 95 mg/dL, and creatinine of 0.47 mg/dL. Urinalysis: specific gravity 1.002, pH 7.0, negative glucose, ketones, blood, RBC or WBC. Hemoglobin A1C was 4.4%. He was volume replete with crystalloids for sepsis, however hypernatremia remained and polyuria persisted. Desmopressin (DDAVP) was given on day 2 of admission with only mild decrease in urine output (UOP) and rise in urine osmolality. Water deprivation test was not possible due to agitation and insomnia, so another approach was taken. DDVAP and intravenous fluid were withheld for 2 days, and patient was allowed to drink to thirst. Urine and serum osmolalities with electrolytes were trended showing reoccurrence of hypernatremia and polyuria. Prior to giving DDAVP again, urine osmolality automatically improved from 131 to 451, and after restarting DDAVP, there was further rise in urine osmolality. This data suggested Partial CDI, so MRI brain was done which showed a central germinoma infiltrating the posterior pituitary stalk.

Discussion: This case shows the difficulty in diagnosing partial NDI vs partial CDI in patients with mental disabilities who are unable to comply with routine methods used for diagnostic purposes. DDAVP will increase urine osmolality with overlapping values in both partial CDI and partial NDI which makes diagnosis a challenge.

PUB751

Central Diabetes Insipidus Preceding Thrombocytosis Caused by Acute Myelogenous Leukemia

Kuangyu Wei, Chih-Chien Sung, Tsui-Hua Wang, Shih-Hua P. Lin. *Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan.*

Introduction: Central diabetes insipidus (CDI) is commonly caused by organic lesions affecting the hypothalamic-pituitary regions. However, CDI preceding the thromobocytosis uncovering acute myeloid leukemia (AML) was rarely reported and could go unrecognized, leading to delayed diagnosis with inappropriate treatment

Case Description: A 61-year-old man was referred for the unknown cause of CDI with sudden polyuria, polydipsia, and thirst for 3 months. His family and personal history were unremarkable. There was no visual field defect. CDI was confirmed by water deprivation and desmopressin test. Magnetic resonance imaging of the brain revealed loss of the posterior pituitary bright spot on T1 weighted sequences without other abnormality. At that time, a thorough examination including complete blood count, immune, tumor, infection, and inflammation survey was non-revealing. On laboratory examination, a markedly high platelet count (1,038,000μL) was found despite normal platelet counts 3 months ago. The leucocyte count was 19,400μL with 62.3% blast. Bone marrow examination showed hypercelluler marrow plus megakaryocytes and infiltration with 25% blast cells. The immunohistochemical and flow cytometry results were consistent with AML-M2. He achieved complete remission with resolution of CDI after induction and consolidation chemotherapy. To date, there were only five cases presenting with CDI, thrombocytosis and AML, all showing the association with chromosome 3 or 7 abnormalities. Cytogenetic analysis in this patient was normal despite positive CEBPA and negative FLT3 and NPM1 gene mutations.

Discussion: CDI may be the preceding and presenting feature of thrombocytosis and/or AML. A regular check-up of complete blood count test is necessary for early diagnosis of hematologic abnormalities. The mechanism connecting abnormality of the hematopoietic cells, impact on the neurohormonal cells in the hypothalamus, chromosomes abnormality and platelets warrants further investigation.

PUB752

Unique Case of Severe Metabolic Alkalosis from a Gastro-Ileal Fistula: The Role of PPIs

Sandheep Venkataraman, Lin N. Lwin. *Montefiore Medical Center, Bronx, NY.*

Introduction: Metabolic alkalosis is the most common acid-base abnormality seen in-hospital. It results from the loss of extracellular acids or the gain of bicarbonate. Persistent vomiting has been known to cause alkalosis through the loss of hydrochloric acid rich gastric secretion. We report a case of gastro-ileal fistula causing severe alkalosis through a similar mechanism.

Case Description: 53-year old man with history of rectal cancer, Crohn's Disease with total colectomy, ileostomy, and short gut syndrome, was admitted for severe hypokalemia (serum potassium 2.3 mEq/L) and metabolic alkalosis with bicarbonate of 49 mEq/L. He reported increased quantity of watery stool in his ileostomy for one month. Exam was significant for dry oral mucosa, and ileostomy bag with clear liquid. Labs revealed acute kidney injury (creatinine 1.20 mg/dL from baseline of 0.77 mg/dL) and normal anion gap. Arterial gas showed pH of 7.567 and pCO2 50.0. Urinalysis was normal with pH of 7.0. Ileostomy content was very acidic with pH less than 6.0 and beyond the lab range. CT abdomen with oral and IV contrast showed normal appearing bowel loops and ileostomy. However, there was no trace of oral contrast. Acidic ileostomy fluid, electrolyte abnormalities, and absence of oral contrast on imaging were suggestive of gastro-ileal fistula. Severe metabolic alkalosis was thought to be due to continuous loss of gastric hydrochloric acid. Electrolytes were replaced and he was aggressively hydrated. He was started on a proton pump inhibitor (PPI), and his alkalosis improved rapidly in 48 hours. Ileostomy output decreased and labs normalized over the next 5 days. He was discharged on pantoprazole.

Discussion: Acidity of the GI tract varies based on location with the lowest pH in the stomach which gradually increases down the small bowel. In our patient, severe alkalosis was thought to be due to the continuous loss of gastric acid containing a significant amount of H+ ions. Hypovolemia and hypokalemia also contributed to his alkalosis. PPIs are pro-drugs which concentrate in the gastric parietal cell canaliculi and bind irreversibly to the H+/K+ pumps. They have been shown to induce profound hypochlorhydria in the stomach, with a single dose shown to raise the pH from 2.0 to 6.0 in the stomach. This supported the use of PPI in our patient to prevent the acid loss, preserve H+ ions, and help correct the alkalosis.

PUB753

Acid-Base Disorder in Extremis

Srijan Tandukar. *University of Pittsburgh Medical Center, Pittsburgh, PA.*

Introduction: In physiological conditions, normal acid-base homeostasis is maintained by an interplay of respiratory or metabolic compensation to counteract the primary disorder. We present a case of severe acute on chronic hypercapneic respiratory acidosis that was compensated to near normal pH by an extreme elevation of serum bicarbonate.

Case Description: A 43-year-old male with a history of chemoradiation for recurrent Hodgkin's lymphoma complicated by pulmonary fibrosis and right hemidiaphragmatic paresis leading to chronic respiratory acidosis on BiPAP treatment at home, and constrictive pericarditis treated with pericardiectomy presented with increased somnolence. He was on bumetanide 3 mg twice a day at home. On exam, he was afebrile, hemodynamically stable with an oxygen saturation of 100% on room air. He was difficult to arouse, oriented to time and person with normal cardiorespiratory exam and 2+ lower extremity pitting edema. His blood gases showed a pCO_2 of 126 mmHg, bicarbonate of 68 mEq/L and pH of 7.34 on arrival. Renal function was normal with creatinine of 0.6 mg/dL and potassium and chloride were low at 3.4 mEq/L and 77 mEq/L respectively. Given that his pCO_2 in prior admissions had always been >110 mmHg and bicarbonate >55 mEq/L with near normal pH and no symptoms, it was decided to lower pCO_2 only slightly using intermittent BiPAP in a controlled fashion with concomitant acetazolamide for a brief alkaline diuresis. The patient's mental status rapidly improved with this intervention and at the time of discharge his blood gas showed pH 7.46, pCO_2 99 mmHg and bicarbonate 69 mEq/L. Given his persistent fluid overload, he was maintained on a reduced dose of bumetanide 2 mg orally twice a day to avoid diuretic-induced metabolic alkalosis.

Discussion: In patients with chronic respiratory acidosis secondary to pulmonary diseases, obstructive sleep apnea and obesity hypoventilation syndrome, it is not unusual to find some degree of metabolic compensation in the presence of normal renal function. However, it is rare to find an asymptomatic patient who has chronic respiratory acidosis with a pCO_2 consistently above 100 mmHg and a serum bicarbonate above 60 mEq/L as compensation with near normalization of pH. In treating such patients, caution should be exercised in correcting chronic respiratory acidosis aggressively as the resulting severe metabolic alkalosis can lead to life-threatening complications such as disorientation, seizures and coma.

PUB754

A Puzzling Case of Severe Hypokalemia in Pregnancy

Samaya J. Anumudu, Jasmine A. Pascoe, Bhamidipati V. Murthy, Jingyin Yan. *Baylor College of Medicine, Houston, TX.*

Introduction: Hypokalemia is a dangerous electrolyte disturbance in pregnancy. It is defined as a serum potassium level less than 3.5 mmol/L and is associated with EKG abnormalities, arrhythmias, or rarely rhabdomyolysis. We present an interesting case of a 25-year-old pregnant female with severe hypokalemia.

Case Description: A 25-year-old G1P0 female at 32 weeks gestation was admitted with potassium less than 1.8mmol/L. She had decreased oral intake, nausea, and vomiting for four days which was initially thought to be the cause of hypokalemia. However, she also had polyuria with urine output up to 400 cc/hr. She had hypernatremia (Na of 147 mmol/L). Liver function tests were elevated and CK trended up to 28,786 U/L. EKG revealed prolonged QT interval. Urinalysis showed +1 protein, +3 ketone, and pH 6.5. Urine potassium and sodium were 77.9 and 152 mmol/24 hours respectively with dilute urine (65 mosm/kg H_20) likely in the setting of diabetes insipidus (DI) despite no known prior history. In addition to pain in lower extremities, she had jaw pain and headache. MRI brain was notable for diffuse myositis of the muscles of mastication and nonvisualization of T1 hyperintensity of neurohypophysis. Hypotonic Intravenous fluids were used initially with both oral and IV potassium supplementation. Urine output decreased and urine osmolality rose to 228 mosm/kg H_20 after a dose of desmopressin (DDAVP). Serum potassium improved with continued oral supplementation and high potassium diet. Her pain and hypernatremia resolved. She was discharged home on oral potassium and nasal DDAVP with close follow up.

Discussion: This case highlights the complex etiology of hypokalemia and associated complications in pregnancy including unusual presentation of rhabdomyolysis for which clinicians should remain vigilant. Our patient's combination of polyuria with increased urinary potassium loss in the setting of likely prior undiagnosed diabetes insipidus and gastrointestinal losses led to severe hypokalemia. As a result, she developed the rare complication of rhabdomyolysis affecting the muscles of mastication as well. She will need MRI imaging of the pituitary after delivery to confirm central DI diagnosis. Such patients need close monitoring throughout pregnancy in a multidisciplinary approach for effective treatment and avoidance of complications.

PUB755

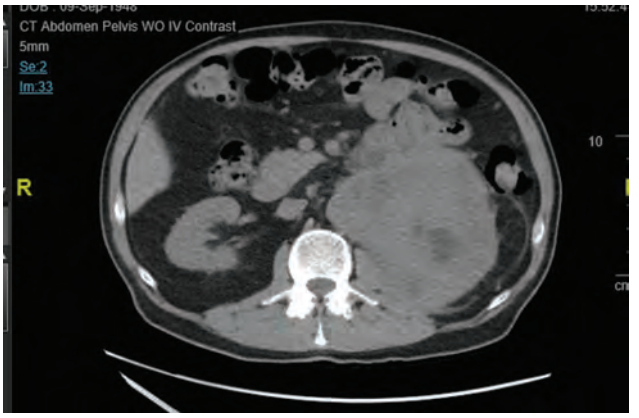
Hypercalcemia as Presentation of Renal B Cell Lymphoma

Ifeoma Okadigbo, Sairah Sharif, Basma O. Merhi. *Brown University, Mineola, NY.*

Introduction: Primary renal lymphoma (PRL) is a rare condition that mimics renal cell carcinoma. We describe a patient who presented with hypercalcemia and acute renal failure who was found to have a large mass in his kidney that was biopsied and showed diffuse large B cell lymphoma (DLBCL). He was started on rituximab, cyclophosphamide, vincristine, doxorubicin prednisone (R-CHOP) and radiation. We report this case to highlight the pitfalls in diagnosis of this rare entity as well as the peculiar presentation of hypercalcemia

Case Description: 69 year old man with history of hypertension presented with 4 months of nausea, weakness, and weight loss. He was found to have serum calcium 13.3mg/dL and serum creatinine of 4mg/dL (baseline 0.9mg/dL 6 months ago). Workup showed suppressed PTH, and PTH-rp, a normal ACE, vitamin D 25 and mildly elevated vitamin D1, 25. His paraprotein workup was negative. He received 0.9% normal saline, calcitonin and pamidronate. CT scan abd/pelvis showed a 15 cm mass in the left renal fossa. There was high suspicion of renal cell carcinoma but due to technical difficulty in surgical approach, a decision was made to do a renal biopsy instead of nephrectomy. Kidney biopsy was consistent with DLBCL. A PET scan showed a large area of intense FDG uptake only in the left renal lesion. He completed 6 cycles of R-CHOP with improvement in serum creatinine to 1.3mg/dl, normal calcium and a repeat PET scan after R-CHOP completion that showed improved FDG uptake. He is to receive radiation.

Discussion: PRL are extremely rare extranodal lymphoma. It usually presents as flank pain, hematuria, renal failure and diagnosed after nephrectomy. This is an aggressive cancer with grave prognosis. This case is unique as our patient presented with hypercalcemia, got a renal biopsy, was started on chemotherapy and radiation and responded well. We highlight the importance of high index of suspicion when faced with renal mass and hypercalcemia, to think about PRL as the management is completely different from renal cell carcinoma



PUB756

Seminoma Presenting as Acute Renal Failure and Hypercalcemia

Aileen Wang, Purnima R. Tripathy, Ranjani N. Moorthi, Ayman Hallab. *Indiana University School of Medicine, Indianapolis, IN.*

Introduction: Hypercalcemia is commonly associated with various solid and hematologic malignancies, but rarely associated with seminoma. Similarly rare is 1,25 dihydroxyvitamin D (calcitriol) mediated hypercalcemia, which is more commonly associated with lymphomas and sarcoid-related granulomatous disease. Here we describe an atypical presentation of a patient with seminoma patient presenting with acute renal failure and hypercalcemia.

Case Description: The patient is a 55-year-old Caucasian male with history of left orchiopexy for undescended testis as a child presented to the nephrology clinic for acute renal failure with Cr to 2.37 mg/dL on a routine laboratory test with no recent baseline. His only complaint was a dull abdominal discomfort and constipation for 2 months. Abdominal exam revealed a fixed large abdominal mass. CT scan showed a 9.4 cm x 15 cm x 18.4 cm retroperitoneal mass and mild left hydronephrosis. Serum calcium (SCa) elevated at 12.3 mg/dL. His SCa rapidly normalized with IV saline infusion, and Cr downtrended. Work up revealed suppressed PTH (3 pg/mL), normal 25-OH Vitamin D3 (30.3 ng/mL), low PTHrP (1.1 pmol/L), and an elevated 1,25 dihydroxyvitamin D level to 119 pg/mL. Serum ACE level elevated to 73 units/L. Pathology showed a metastatic seminoma. Patient received Cycle 1 of cisplatin and etoposide (CE). He was discharged with SCa of 8.0 mg/dL with no additional therapy and improved kidney function (Cr 1.28 mg/dL). Patient recently underwent cycle 2 of chemotherapy with stable renal function and normal SCa.

Discussion: This case is unique in illustrating an atypical cause of acute renal failure due to hypercalcemia associated with seminoma due to a tumor sarcoid-like reaction. Hypercalcemia normalized with CE chemotherapy regimen which included steroids, the typical treatment of sarcoid-associated hypercalcemia.

PUB757

Isolated Hyperkalemia During Anesthesia

Sourab Dhungel,[1] Jean Lee.[2] *[1]Temple University Hospital, Mickleton, NJ; [2]Temple University, Philadelphia, PA.*

Introduction: Hyperkalemia can occur during anesthesia even in the absence of renal failure and may result in cancellation of surgery. We would like to present a case and discuss possible mechanisms.

Case Description: A 62 year old African American male with a past medical history of hypertension, type 2 diabetes mellitus, chronic hepatitis C and recently diagnosed duodenal cancer was admitted for elective pancreaticoduodenectomy. This was his first time receiving general anesthesia. He was not on an ACE inhibitor because of a single episode of hyperkalemia in the past. Pre-operative potassium from 2 weeks prior was normal as were several other measurements in the past. His CKD-EPI eGFR was 93 ml/min/1.73 m2. In the operating room, he was given Isoflurane, Sevoflurane, Propofol, Rocuronium and Vecuronium. He was found to have hyperkalemia (7.0-7.6) on intra-operative blood gases repeated x3. A basic metabolic panel confirmed a serum potassium of 7.3 meq/L with tall tented T waves on electrocardiographic monitoring. There was no evidence for tumor lysis, rhabdomyolysis, hemolysis or hematoma. He also did not develop any features of malignant hyperthermia during observation. Surgery was cancelled before the first scalpel. Hyperkalemia resolved with furosemide administration.

Discussion: There may be several reasons for isolated hyperkalemia in this patient. Firstly, he may have had impairment of extra-renal potassium disposal secondary to increased alpha adrenergic tone as has been described in the past. Secondly, he may have had a genetic predisposition to hyperkalemia as is found in patients who develop malignant hyperthermia in association with anesthetic agents. However, the whole syndrome of malignant hyperthermia was not present in this patient.

PUB758

Much Ado About Nothing

Avantika Chenna.[2,1] *[1]Nephrology, southwest georgia nephrology----, Albany, GA; [2]Nephrology, phoebe putney medical center, Albany, GA.*

Introduction: Sirolimus is a mTOR (mammalian target of rapamycin) inhibitor that is used for immunospression in solid organ transplant recipients. Common side effects include pancytopenia, thrombotic microangiopathy, proteinuria and delayed wound healing. We present a case of massive hemothorax following automated implantable cardioverter-defifrillator (AICD) placement from sirolimus use.

Case Description: 49 year old female with history of childhood glomerulonephritis (unkown etiology) with third kidney transplant and h/o 2 failed kidney transplants in the past, who presented for elective AICD placement. During immediate post operative period, patient developed massive bleeding from AICD site causing hemothorax requiring bilateral chest tube placement. Past medical history includes: diabetes mellitus, hypertension, asthma and schizoaffective disorder. Her labs include: BUN/CR 49/1.8 mg/dl (baseline 1.1 mg/dl prior to procedure). Hemoglobin was 8.1 g/dl, platelets 202,000/UL, WBC 11,400/UL. Her albumin level was 1.3 g/dl. Donor specific antibody was not elevated. Renal ultrasound showed increased resistive indices without hydronephrosis. Home immunosupression includes: mycophenolate 750 mg twice a day, prednisone 5 mg and sirolimus 2 mg daily. Nephrology was consulted for the management of postoperative acute kidney injury following the procedure. We first recommended to hold sirolimus and started patient on tacrolimus 1 mg twice a day. Patient required 18 units of PRBC transfusion and multiple units of fresh frozen plasma. Hospital course was complicated by respiratory failure requiring intubation, hemodnamic acute tubular necrosis requiring dialysis. After a prolonged ICU stay, patient continued to fail spontaneous breathing trials. She was thus transferred to longterm assisted care with tracheostomy and on maitenance hemodialysis three times a week.

Discussion: This is the first case of massive hemothorax following AICD placement from sirolimus use per our literature review. Through this case we would like to suggest that sirolimus should be held for atleast 2-4 weeks prior to any kind of surgical procedure. Nephrology has to be involved early in the preoperative care of kidney transplant recipients even when they are going for minor elevtive procedures.

PUB759

The Effects of Rituximab on Atherosclerotic Biomarkers in Kidney Transplant Recipients

Numuna Aliyeva,[5] Erol Demir,[1] A. Ucar,[1] Halil Yazici,[1] Yasar Caliskan,[1] Sebahat Akgul,[2] Ayse Erol,[3] Sonay Temurhan,[2] Berna Yelken,[6] Fatma Savran Oguz,[4] Aydin Turkmen.[1] *[1]Division of Nephrology, Istanbul School of Medicine, Istanbul, Turkey; [2]Department of Medical Biology, Istanbul School of Medicine, Istanbul, Turkey; [3]Department of Medical Biology, Istanbul University Faculty of Medicine, Istanbul, Turkey; [4]Department of Medical Biology, Istanbul School of Medicine, Istanbul, Turkey; [5]Division of Nephrology, Istanbul School of Medicine, Istanbul, Turkey; [6]Gaziosmanpasa University, Tokat, Turkey.*

Background: Cardiovascular disease is the leading cause of mortality in renal transplant (tx) recipients. Rituximab is widely used in kidney transplantation. There are few reports about the relationship between rituximab and atherosclerotic process in rheumatologic disorders. The aim of the study was to evaluate the efficacy of rituximab on atherosclerotic biomarkers in kidney tx recipients.

Methods: Forty renal tx patients who did not have a history of cardiovascular event were included to study. All of the patients in the treatment group (n:27) were received at least of one dose of 375 mg/m^2 rituximab. The control group (n:13) were selected by historically and donor type matched patients. Quantitative measurement results were compared between rituximab and control group of kidney tx recipients for atherosclerotic biomarkers: interleukin-10 (IL-10), tumor necrosis factor alpha (TNF-alpha), transforming growth factor beta (TGF-beta) and oxidized low-density lipoprotein (anti-oxLDL) antibody. Counts of B lymphocytes, T lymphocytes and natural killer cells were measured in both groups.

Results: Demographic parameters, laboratory results of the patients were demonstrated in Table. Counts of B, T lymphocytes and natural killer cells were significantly lower in rituximab group compared to control group. Serum IL-10 levels were significantly higher in the rituximab group compared to the control group, although anti-oxidized low-density lipoprotein levels were lower in the rituximab group compared to the control group though this did not achieve statistical significance.

Conclusions: Rituximab treatment may decrease lymphocyte counts and IL-10 levels, however significant decreases in all atherosclerotic biomarkers has not been shown.

Demographic parameters, laboratory results of the patients

Antioxidant Capacity in Mexican Kidney Transplant Recipients

Diana Ramirez flores,[1] Victoria G. Maldonado,[1] Milagros M. Flores Fonseca,[1] Adriana Banda Lopez,[1] Salvador Mendoza Cabrera,[1] Gilberto Velázquez,[2] Ana C. Ramirez anguiano,[2] Sandra F. Velasco.[2] *[1]Centro Medico Nacional de Occidente, Guadalajara, Mexico; [2]Universidad de Guadalajara, Guadalajara, Mexico.*

Background: Kidney transplant (KT) offers a better quality of life in patients with Chronic Kidney Disease (CKD). Despite the benefits of KT, long-term survival rates have shown none satisfying status due to graft failure. KT prone to oxidative stress mediated injury by diverse pre- and post- transplant conditions affecting the allograft and other clinical disorders in kidney recipients. The aim of this study was to determine the total antioxidant capacity in post transplantation anemia kidney transplant recipients (KTR).

Methods: The study included 41 adult patients during the maintenance period (>1 year) following renal transplantation, treated with different combinations of immunosuppressive agents. The total antioxidant capacity (TAOC) of plasma was measured using Trolox-equivalent antioxidant capacity (TEAC) assay

Results: A higher proportion of female KTR, mean age was 29.53 ± 7.24 years. They had a TAOC 326.77 - 473.12 ± 399.95 µmol/L. There was a significantly negative correlation between TAOC and plasma creatinine (R^2 = -0.551, p = 0.033) and a positive correlation between TAOC and hematocrit in patients treated with tacrolimus but not with cyclosporine.

Conclusions: This study could asses that TAOC values were associated with immunosuppressive therapy and anemia, and these could be determinant risk factors to increase of oxidative stress. Further studies are needed to determine oxidative stress pathways and if it can improve the allograft survival.

Considering Kidney Function When Screening for Hepatitis C Virus at Temple University Hospital

Chelsey Fix,[2,1] Emily Levine,[4] Crystal A. Gadegbeku.[3] *[1]NephCure Kidney International, King of Prussia, PA; [2]Temple University, Philadelphia, PA; [3]Temple University, Philadelphia, PA; [4]Temple University Hospital, Philadelphia, PA.*

Background: State mandates have prompted hospitals to implement Hepatitis C Virus (HCV) screening programs to capture high-risk individuals and facilitate treatment. It is not standard to screen kidney function before treating HCV, despite evidence of increased risk of chronic kidney disease (CKD). Individuals living with HCV and CKD may eventually require a kidney transplant, and can receive a cadaver HCV positive kidney significantly sooner if they delay HCV treatment until after the transplant.

Methods: The goal of this project was to identify the proportion of HCV patients with kidney disease at Temple University Hospital (TUH) and use that data to design a tool within the hospital's electronic health record system to facilitate proper nephrology care. Data were collected from the electronic health records of HCV patients at TUH that were seen for the first time in 2017 for HCV treatment. Demographic information, data about kidney function, and information about the referring department were collected. Patients that would have benefitted from a nephrology consultation before HCV treatment were identified.

Results: Of the 637 patients seen for HCV treatment at TUH, 29 (4.6%) were seen by a nephrologist. An additional 84 (13%) patients were identified as having an estimated glomerular filtration (eGFR) rate less than sixty, making them candidates for nephrology care before HCV treatment. Twenty-five patients were found to have an eGFR less than thirty, warranting urgent nephrology care.

Conclusions: New technology to identify late stage CKD patients would increase the number of HCV patients receiving nephrology care at TUH.

PUB762

Comparison of Immunohistochemical Staining for Large T Antigen and VP1 in Polyomavirus Nephropathy After Kidney Transplantation

Kosuke Masutani,[1,2] Yuta Matsukuma,[2] Akihiro Tsuchimoto,[2] Keizo Kaku,[3] Atsushi Doi,[3] Yasuhiro Okabe,[3] Kazuhiko Tsuruya,[4] Toshiaki Nakano,[2] Takanari Kitazono.[2] *[1]Nephrology and Rhaumatology, Fukuoka University, Fukuoka, Japan; [2]Medicine and Clinical Science, Kyushu university, Fukuoka, Japan; [3]Surgery and Oncology, Kyushu university, Fukuoka, Japan; [4]Nephrology, Nara Medical University, Kashihara, Japan.*

Background: Banff Working Group on Polyomavirus Nephropathy (PVN) proposed a new histological classification consisting of pvl and ci scores, and recently demonstrated that the classification is a useful predictor of graft dysfunction. Most transplant centers use SV40 large T antigen (TAg) staining for pvl scoring, while the expression of TAg is decreased and VP1 is increased on the course of viral replication in the tubular epithelial cells (TECs). In addition, TAg and VP1 staining in biopsy specimen of PVN has not been clearly compared.

Methods: From 1996 through 2017, 16 patients developed biopsy-proven PVN in Kyushu University Hospital. We performed immunohistochemical staining using commercially available anti-SV40 TAg and anti-BKV VP1 antibodies in the serial sections of 16 index biopsies and 12 follow-up biopsies. We compared the patterns of positive staining, and the number of positive tubulus (%) in all biopsies. In 16 index biopsies, we investigated the correlation between serum creatinine increase from the baseline and the number of positive tubulus determined by SV40 TAg and BKV VP1 staining.

Results: In BKV VP1 stained section, positive staining was observed not only in the nuclei of TECs, but also in the cytoplasm, cells shedding into the lumen, and intratubular casts. Two of 28 biopsies (7.1%) showed negative staining for BKV VP1, in which SV40 TAg positive tubulus were detected in less than 1%. The median (interquartile range) percentage of positive tubulus was 2.8 (0.7-9.8) % in SV40 TAg and 1.4 (0.5-3.9) % in BKV VP1 staining (P=0.2). In 16 index biopsy, serum creatinine increase significantly correlated with the number of BKV VP1 positive tubulus (r=0.49, P<0.05), while it did not with the number of SV40 TAg positive tubulus.

Conclusions: In BKV VP1 staining showed various pattern of positive cells, but it could detect approximately half as many tubulus as SV40 TAg staining, which might cause a false negative results in the specimen with minimal BKV replication. On the other hand, increased BKV VP1 positive staining means advanced damages of TECs and has possible association with graft dysfunction.

PUB763

Predonation Laparoscopic Sleeve Gastrectomy for Morbid Obese Kidney Donors

Vivek Pathak. *Nephrology, Kovai Medical Center and Hospital, Coimbatore, India.*

Background: The prevalence of obesity is increasing in the general population so number of living donor transplants due to elevated BMI have declined by 13%. This procedure is required to reduce the future complications of the donor including CKD and increase the donor pool. According to a study by Locke et al obese donors had a 1.9 fold increased risk of ESRD post donation and this cohort was free of diabetes and hypertension at the time of donation which are conditions known to contribute to ESRD. This data suggests that obese living donors should be counseled for weight loss programme. Laparoscopic sleeve gastrectomy(LSG) is used as a procedure for treating morbid obesity. However we have seen very few reports of LSG as a procedure for weight loss to improve chances of donation in a morbidly obese donor. Published analysis(Brooks et al) suggests that a live donor though obese is more cost effective than a deceased donor even if LSG is used to reduce the weight.

Methods: We intentionally performed LSG in preparation of kidney donation. We reviewed charts of these ten donor nephrectomy patients who were subjected to LSG between 2012 and 2017.

Results: The age range of donors was 32 to 65 years(mean 41.1 years). Presurgery BMI ranged from 35.3kg/sqm to 46kg/sqm(mean 41) and post surgery BMI ranged from 27 to 36 kg/sqm (mean 32.3kg/sqm) at the time of donation. LSG did not give rise to significant perioperative complications. Two donors became non-diabetic and weight loss continued in the subsequent months following surgery also. It did not influence the subsequent laprascopic donor nephrectomy(LDN).

Conclusions: This procedure allowed morbidly obese donors to donate and subsequently expanded the donor pool without impacting the outcome of subsequent LDN. We will recommend this for obese live kidney donors.

Demographics of donors who underwent LSG before laparoscopic donor nephrectomy

Case	Age (Yrs)	Sex	Time interval with donation (Months)	Pre-BMI (kg/ m2)	Post-BMI (kg/ m2)	Weight loss, %	Comorbidity

Explant Biopsy and Allocation Based on Remuzzi Scoring Permits Selection of Extended Criteria Donor Kidneys for Single Implantation with Excellent Outcomes

Sobhana Thangaraju,[1] Anantharaman Vathsala,[2] Hersharan Sran,[2] Angeline Goh,[2] Rachel Teo,[2] Hwai-Liang Loh,[1] Fang jann Lee,[1] Valerie H. Gan,[1] Thomas P. Thamboo,[2] Hoyee Tiong,[2] Benjamin Goh.[2] *[1]Singapore General Hospital, Singapore, Singapore; [2]National University Health System, Singapore, Singapore.*

Background: While Extended Criteria Donors (ECD) increase deceased donation (DD) rates, allocation of ECD kidneys is challenging due to difficulty in predicting post-transplant outcomes.

Methods: Since November 2009, kidney DDs were stratified as ECD if Age>60(ECDAge); if meeting UNOS criteria(ECDUNOS); Diabetic(ECDDM) or other renal conditions(ECDOthers); the rest were Standard Criteria Donors(SCD). ECD underwent explant biopsy, rapid biopsy processing and histological scoring of Glomeruli, Tubules, Interstitium and Arteries to derive a Total Remuzzi Score (TRScore). TRScore of 0-4 or 5-7 were generally allocated as single (ECDSingle) or dual Implants (ECDDual) respectively. This study evaluated impact of our allocation strategy on longterm outcomes. Of 118 DD, 55(46.6%) were ECD; 21(38.2%), 11(20%), 12(21.8%) and 11(20%) were ECDAge, ECDUNOS, ECDDM and ECDOthers. After evaluating TRScores, 30 ECD(54.5%) were allocated as ECDDual, preferentially to kidney transplants (KTX)>45 yrs. After excluding 1 ECDSingle with staghorn calculus that was discarded and 5 SCD that were allocated to paediatric KTX, 200 adult KTX (30 ECDDual, 49 ECDSingle and 121 SCD) were analysed.

Results: TRScores from ECD explant biopsies and from 61 of 63 SCD with implant biopsies were 5.2±1.2, 2.8±1.1 and 2±1.7 for ECDDual, ECDSingle and SCD respectively (P<0.001). ECD KTX were older (52.4±7.5, 49.1±9.4 and 47±9 yrs for ECDDual, ECDSingle and SCD respectively; p=0.01), but sex, ethnicity, incidence of Delayed Graft Function (DGF) and Biopsy Proven Acute Rejection by 6 mths (BPAR6) were not significantly different between groups. 5 yr overall survival was worse for ECDDual (64.4%, P=0.05), but comparable for ECDSingle and SCD (84.8% and 84.7% respectively). After adjusting for age, gender, ethnicity, DGF and BPAR6, ECDSingle had lower hazard for overall failure (OR 0.29, [95%CI 0.114-0.741]).

Conclusions: Stratifying ECD with explant biopsy and allocation based on Remuzzi scoring yields outcomes comparable to SCD for ECD Single kidneys.

PUB765

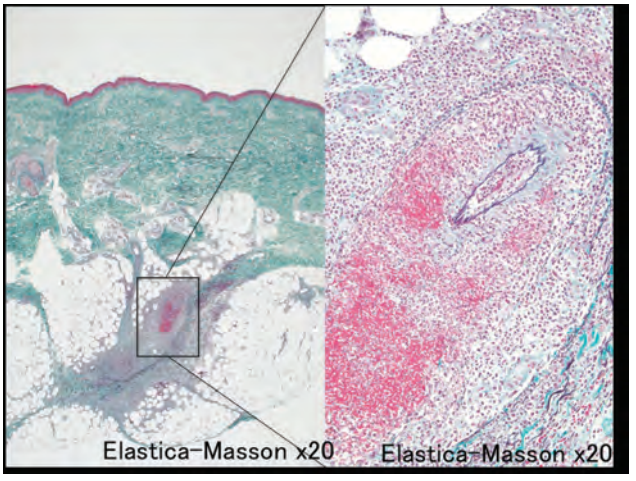
Cutaneous Polyarteritis Nodosa (PAN) After Kidney Transplantation: A Case Report, Sepsis Induced or Primary Disease?

Hitoshi Miyasato, Genta Uehara, Satoshi Akao, Norihiro Nishioka. *Okinawa Chubu Hospital, Uruma City, Japan.*

Introduction: Polyarteritis nodosa (PAN) is a systemic vasculitis characterized by necrotizing inflammatory lesions that affect medium and small-sized arteries. The pathogenesis of PAN is not well known, but Hepatitis B virus (HBV) and other viruses are thought to be causative agents. We present a biopsy proven case of PAN, which developed 20 months after a kidney transplant. Development of an autoimmune disease after transplant is a rare phenomenon.

Case Description: A 53 year-old woman received a living kidney transplant on March, 2016. Her kidney disease was speculated to be caused by IgA nephropathy. The patient's perioperative course was uneventful. Her induction regimen was basiliximab, mycophenolate mofetil (MMF), tacrolimus, and prednisolone. Nineteen months after transplantation, the patient had a parathyroidectomy for primary hyperparathyroidism. She was discharged on postoperative day 4. One day after discharge, the patient returned to our hospital for Escherichia coli (E.coli) urinary tract infection (UTI) and sepsis (extended-spectrum beta-lactamase). The patient was treated with carbapenem and second generation cephem antibiotics for14 days. Twenty-one days after discharge, she presented to our hospital for second time with a UTI caused by E.coli, but not associated with sepsis. On this second presentation, Carbapenem was initiated with resolution of the UTI symptoms. On hospital day13, the patient noticed pain in her bilateral lower legs as well as in her left forearm and right arm. On day15, a small painful nodule appeared, which was biopsied.

Discussion: PAN is a very rare complication after transplant. We found six other cases of PAN after transplantation in the literature; one case was related to HBV infection. Take away points: In a transplant patient, de-novo autoimmune diseases, such as PAN, may present atypically.



PUB766

Late Onset JC Virus Allograft Nephropathy (JCVAN)

Manpreet Samra, Ignatius Y. Tang. *Internal Medicine/Nephrology, University of Illinois Health, Chicago, IL.*

Introduction: JC virus (JCV) is a member of the Polyomaviridae family. Few studies were published regarding the replication of JCV in transplant recipients. The incidence of JCV viruria, viremia, and allograft nephropathy is unknown. Most reported cases of JCV infection occurred during the first 24 months after transplantation. We describe two cases of JCVAN occurring beyond 24 months post-transplant.

Case Description: CASE 1: 66-year-old Polish male with ESRD due to hypertensive nephrosclerosis on hemodialysis for 6 years and peritoneal dialysis for 1 year, underwent a deceased donor kidney transplant in 4/2014. His post-operative course was complicated by nephrolithiasis that required a nephrostomy tube. In 11/2017, he developed acute kidney injury (AKI) with a creatinine of 2.1mg/dl. Renal allograft biopsy showed Polyoma Virus allograft nephropathy (PAVN). His immunosuppression at that time was Astagraf and Myfortic. His Myfortic dose was reduced. Blood BK virus PCR was not detected. Blood JCV PCR was 270,000 copies/ml and urine JCV PCR >100 million copies/ml. His Astagraf dose was reduced to maintain a trough of 3-5ng/ml. His Myfortic was stopped. Prednisone 10mg daily was added. Two-months follow-up JCV PCR was 338,000 copies/ml. He did not exhibit neurologic symptoms. His creatinine remained around 2mg/dl. CASE 2: 48-year-old Filipino male with a history of polycystic kidney disease underwent deceased donor kidney transplant in November 2003 with stable good kidney function on maintenance tacrolimus and mycophenolate mofetil (MMF). He underwent a renal allograft biopsy in 6/2017 to evaluate AKI, microscopic hematuria, and albuminuria. The biopsy showed PAVN. Blood BK virus PCR was undetectable. Blood JCV PCR peaked at 4,200 copies/ml and urine JCV PCR 24 million copies/ml. His MMF was stopped, prednisone 7.5mg daily was added, and tacrolimus dose was adjusted to maintain a trough level between 2 and 5ng/ml. Blood JCV PCR decreased to 1,500 copies/ml and urine JCV PCR decreased to 9.9 million copies/ml 11 months after diagnosis of JCVAN. He continues to have stable renal allograft function with no neurologic symptoms.

Discussion: PAVN should be considered as a cause of late-onset AKI in kidney transplant recipients. JCV should be considered as the cause of PAVN, particularly when BK virus infection is excluded. Neurologic symptoms are absent. Reduction in immunosuppression remains the mainstay of management of JCVAN.

PUB767

A Significance of Serum Albumin in Kidney Transplant Recipient: Association with Cardiovascular Event and Mortality

Akihiro Tsuchimoto,[1] Yuta Matsukuma,[1] Yasuhiro Kawai,[1] Kenji Ueki,[1] Kaneyasu Nakagawa,[1] Shunsuke Yamada,[1] Yasuhiro Okabe,[1] Kosuke Masutani,[2] Toshiaki Nakano,[1] Takanari Kitazono.[1] *[1]Kyushu University, Fukuoka, Japan; [2]Fukuoka University, Fukuoka, Japan.*

Background: Serum albumin is a marker of malnutrition, inflammation and proteinuria. The aim of this study is to investigate the association between serum albumin and outcomes in kidney transplant (KT) recipient.

Methods: We reviewed a total of 387 patients over 15 y.o. who received KT from 2006 through 2012 in Kyushu University. The patients divided into 3 groups according to serum albumin one year after KT (ALB1y); T1 1.4-4.1 g/dL, n= 93, T2: 4.1-4.3 g/dL, n=145, T3: 4.4-5.6 g/dL, n=149. We investigated various events after one year, consisting of all cause mortalities, new onset cardiovascular disease (CVD), graft dysfunction (doubling serum creatinine and/or development of end-stage kidney disease), new onset malignancy and infectious episode need administration.

Results: The patients consisted of 233 male and 154 female with median age (IQR) of 44 (35-56) years. A number of patients received transplantation from deceased donors was 56, those with diabetes mellitus as primary disease was 82. ALB1y was associated positively with LDL cholesterol and eGFR, and negatively with age, dialysis duration, proportion of diabetic mellitus as primary disease, incidence of rejection episode within one year, and C reactive protein. Cox hazard models revealed all cause mortalities and new onset of CVD in T1 was significantly worse than those in T3. Hazard ratio (HR) for mortalities was 4.82 and 95% confidential interval (95%C.I.) was 1.62-17.70, and P=0.004 for T1 vs T3. HR for CVD was 5.20, 95%C.I. was 2.12-14.60, and P=0.0002 for T1 vs T3. The association between ALB1y and graft dysfunction was weak; HR of T1 was 2.16, P=0.042. However, ALB1y was not associated with malignancy nor infectious episodes.

Conclusions: Low serum albumin was a strong risk factor of all cause mortalities and new onset CVD.

Outcomes	Event	n	Mutivariate model HR (95%CI)	P Value	P for trend
All cause mortality					
T3	4	149	(Reference)		
T2	5	145	1.32 (0.35-5.38)	P=0.680	0.005

Outcomes of Switching Renal Transplant Recipients to Generic Mycophenolate Mofetil: A Single Center Study

Mohammad Zaitoun, Khalid Al-Alsheikh, As'ad T. Ibrahim. *Armed Forces Hospitals Southern Region, Khamis Mushayt, Saudi Arabia.*

Background: The aim of the study was to investigate the clinical and economic outcomes of switching clinically stable renal transplant recipients to a lower-cost generic Mycophenolate Mofetil.

Methods: From January 2017, all renal transplant patients receiving mycophenolate mofetil (CellCept, Roche) were switched to same doses of another generic (APO-Mycophenolate, Apotex) at the Armed Forces Hospitals Southern Region, Khamis Mushait, Saudi Arabia. Patients were followed up for one year for changes in serum creatinine, incidence of infections, acute tubular necrosis, renal biopsy, acute rejection, changes in tacrolimus or ciclosporin levels and death. Besides, direct cost saving was calculated.

Results: During the study period, 161 renal transplant patients (58.4% males, 41.6% females, mean age = 45.5 ± 15.5 years, mean duration since transplantation = 11.4 years) were switched to APO-Mycophenolate. Among them, 19 patients were diagnosed before switching with chronic allograft nephropathy (CAN). The baseline serum creatinine of the study sample was 100.24 ± 42.64 mcmol/l. After switching, serum creatinine did not change significantly after 3 months (94.48 ± 57.62), 6 months (98.97 ± 59.5), 9 months (99.75 ±56.93) and one year (106.21 ± 76.34) (p=0.5). For the CAN patients, the serum creatinine also did not change significantly from baseline (185±52.63 mcmol/l) till the end of the study period (220.74 ± 139.3 *p=0.76)*. For the patients on Tacrolimus (n=101), trough levels did not differ significantly before and after one year of switching (5.63 ± 1.44 ng/ml vs 5.62 ± 1.49 ng/ml, p=0.73). Similarly, C0 for Ciclosporin patients did not change significantly (265.54±245.22 vs 270.27 ± 277.84, p=0.87). Fifteen patients developed 16 infectious episodes, one of which was life threatening (cerebral toxoplasmosis). Four patients experienced Gastrointestinal symptoms (2.48%) that lead to mycophenolate discontinuation in two of them (1.24 %). No patients underwent renal biopsy, experienced acute tubular necrosis/acute rejection or died during the study period. Besides, Use of APO-Mycophenolate was associated with a direct cost saving of 431309 Saudi Riyals compared to Cellcept.

Conclusions: Using generic Mycophenolate Mofetil in clinically stable renal transplant recipients was associated with similar efficacy and safety profile with significantly reduced cost.

PUB769

Can You Reject Your Own Kidney?

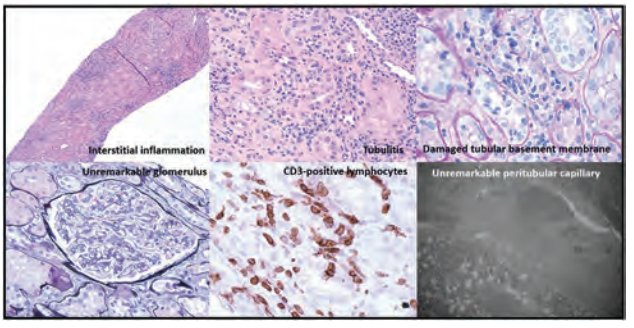
Abhilash Koratala, Mark S. Segal, Xu Zeng. *University of Florida, Gainesville, FL.*

Introduction: Renal involvement secondary to Graft-versus-host disease (GVHD) is considered rare and membranous nephropathy and minimal change disease are considered to be the most common glomerular lesions associated with GVHD. Herein, we present a unique case of renal GVHD with isolated involvement of the tubulointerstitium.

Case Description: A 64-year-old Caucasian woman was seen for evaluation of proteinuria and gradually worsening serum creatinine (Scr) over a period of 4 months. Her medical history was significant for hypertension, diabetes and myelofibrosis s/p matched

unrelated donor peripheral blood allogenic stem cell transplant 2 years ago. Her post-transplant course was complicated by severe chronic GVHD involving skin, buccal mucosa, eyes and lung, all manifested within the first year of transplant. Chronic GVHD was initially managed with tacrolimus, ruxolitinib (JAK inhibitor), prednisone and extracorporeal photopheresis. 3 months prior, tacrolimus was switched to sirolimus due to recurrent non-melanoma skin cancers. Scr was 1.94 mg/dL and 24-hour urinary total protein was 3.5 g (~1.6 g albumin) at presentation. Because of the persistent tubular proteinuria despite ACEI therapy and decrease in sirolimus dosage, renal biopsy was obtained. It demonstrated severe GVHD resembling an acute T-cell mediated rejection in a transplanted kidney [Figure]. The disease was confined to tubulointerstitium without any glomerular lesions or peritubular capillaritis, confirmed by EM. As there is no clear consensus on the optimal management of renal GVHD, our patient was treated with 3 days of pulse steroids, in line with treatment of acute cell-mediated rejection in a renal allograft. A week after the treatment, 24-hour urinary protein improved to 1.1 g.

Discussion: Renal GVHD may be underdiagnosed in patients with HCT, as they are not frequently biopsied owing to multifactorial nature of the renal dysfunction and relative contraindications to biopsy such as low platelet counts. Keeping low treshold for biopsy may pave way for the development of better and effective treatment regimens.



PUB770

Hypercalcemia and Pneumocystis Pneumonia After Kidney Transplantation: A Non-Fortuitous Association

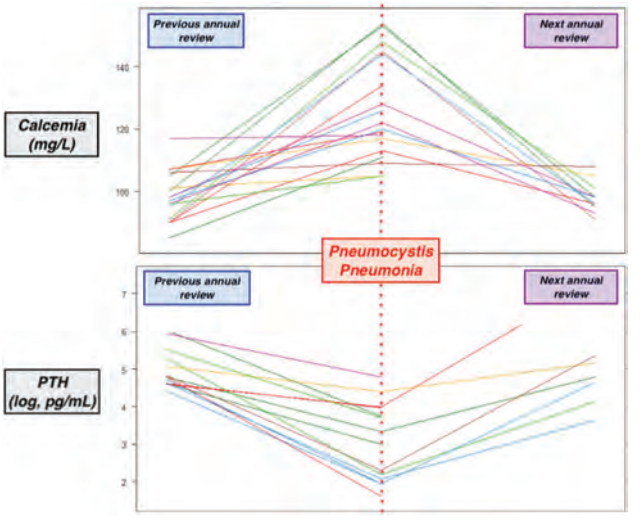
Aghiles Hamroun,[1] Linh Bui,[1] Remi Lenain,[1] Paul Chamley,[1] Séverine Loridant,[2,3] Yann Neugebauer,[4] Arnaud Lionet,[1] Marc Hazzan.[1] *[1]Nephrology, Lille University Hospital Center, Lille, France; [2]Parsitology and Mycology Laboratory, Microbiology Institute, Lille University Hospital Center, Lille, France; [3]LIRIC-UMR 995 INSERM, Lille University, Lille, France; [4]Nephrology, Douai Hospital Center, Douai, France.*

Background: Hypercalcemia may persist beyond the first year after transplantation in 5 to 10% of the kidney transplant recipients (KTR), mainly due to persistent hyperparathyroidism. Recently, a few scattered observations of hypercalcemia associated with *Pneumocystis* pneumonia (PCP) in KTR have been reported but its prevalence and potential pathophysiological mechanisms remain unknown.

Methods: This retrospective cohort collected all proven cases of PCP in adult KTR, that occurred between January 2005 and August 2017 in our center.

Results: Among the 49 confirmed cases of PCP, 18 patients experienced hypercalcemia (12.0±1.6 mg/L), which represented a prevalence of 36.7%. The clinical presentation was different between hypercalcemic and normocalcemic patients (29.4% only presented febrile dyspnea *versus* 66.7%, respectively, p=0,02). In the hypercalcemic group, eGFR was significantly lower (26.5±10 *versus* 36.1±16.2 mL/min/1.73m^2, p=0.013), while 25-OH vitamin D levels and calciuria-on-creatininuria-ratio were higher (respectively 28.1±8.8 *versus* 14.2±8.6 ng/mL, p=0.008 and 0.28 [0.16-0.39] *versus* 0.05 mg/mg [0.02-0.07], p=0.001). In the hypercalcemic group, 1,25-OH vitamin D levels, also higher at the time of PCP, collapsed after healing, while PTH levels, initially lower, increased secondarily after PCP (Figure).

Conclusions: To the best of our knowledge, this is the first reported cohort of adult KTR suffering from PCP-associated hypercalcemia. The evolution of vitamin D and PTH levels around the infectious episode pleads in favour of an extra-parathyroid mechanism and suggests a granulomatous reaction. Acute hypercalcemia after renal transplantation may be related to PCP and should lead to enlightened investigations, even in the absence of infectious or respiratory symptoms.



Evolution of calcium and PTH serum levels before and after PCP.

PUB771

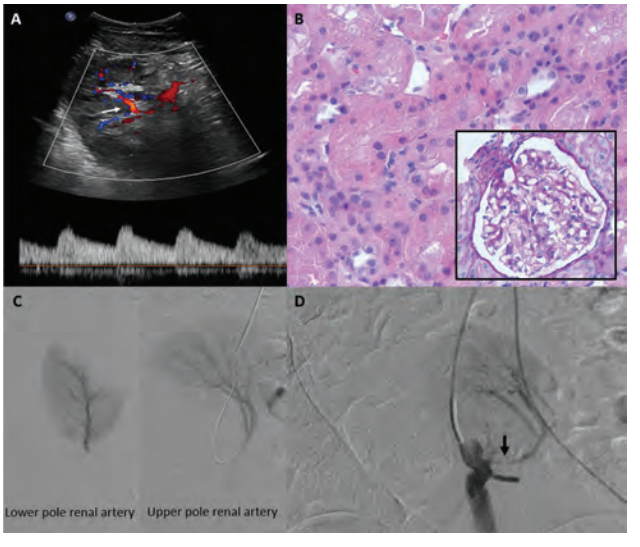
An Unusual Cause of AKI in a Renal Transplant Recipient

Abhilash Koratala, Gajapathiraju Chamarthi, Xu Zeng, Kawther F. Alquadan. *University of Flroida, Gainesville, FL.*

Introduction: Acute kidney injury is one of the major determinants of graft survival in kidney transplantation and has to be promptly addressed with appropriate investigations.

Case Description: A 43-year-old Asian man with a history of ESRD, status post deceased donor kidney transplantation in China 3 months ago, was sent to the ER for elevated Scr of ~3.1 mg/dL. Reportedly, his post-transplant baseline creatinine was about 1.5 mg/dL. He was told in China that the blood vessel supplying the transplanted kidney was 'shrunk'. Doppler ultrasonography of the allograft done in the ER demonstrated a single renal artery with slight blunting of the systolic upstroke, but otherwise unremarkable flow [Figure-1A]. There was no evidence of renal infarction and the resistive indices were wnl. His BP was well controlled. As the renal function failed to improve with supportive measures, a biopsy of the allograft was performed, which showed no evidence of acute rejection or tubular injury [Figure-1B]. Based on the patient's history that something might be wrong with his renal artery, a carbon dioxide (CO_2) angiogram of the pelvic and renal arteries was performed, which revealed 2 separate renal arteries anastomosed to the right external iliac artery [Figure-1C]. There was good flow through the lower pole renal artery with minimal pressure gradient across the anastomosis but the upper pole artery demonstrated more than 75% stenosis with a significant pressure gradient of 107 mmHg. The gradient reduced to 21 mmHg after successful balloon angioplasty [Figure-1D]. The patient's Scr improved back to the baseline value of 1.5 mg/dL at 1-week follow up.

Discussion: Take home message from our case: High index of suspicion is required for ischemic nephropathy in renal transplant patients presenting with unexplained acute kidney injury, as it is potentially reversible.



PUB772

Performance on Longevity Matching Using Current KAS

Shan Shan Chen,[1] Igor Litvinovich,[2] V. Shane Pankratz,[3] Mark L. Unruh,[1] Rawan T. Al-Odat,[1] Christos Argyropoulos,[1] Yue-Harn Ng.[1] *[1]University of New Mexico, Albuquerque, NM; [2]The University of New Mexico, Albuquerque, NM; [3]UNM Health Sciences Center, Albuquerque, NM.*

Background: To improve longevity matching, current kidney allocation system(KAS) allots top 20% Kidney Donor Profile Index(KDPI) kidneys to top 20% Estimated Post Transplant Survival(EPTS) recipients. Among KDPI<85% kidneys, some fulfil Expanded Criteria Donor(ECD) status. We evaluate the outcome of ECD kidneys compared to standard criteria donor(SCD) ones and in whom ECD kidneys are transplanted.

Methods: Using data from Scientific Registry of Transplant Recipients, we retrospectively calculated EPTS of recipients and KDPI, SCD/ECD status of kidneys transplanted from 1/02 to 9/16. We assessed the graft outcome of KDPI<85% kidneys stratified by ECD vs SCD status and determined the distribution of these kidneys across EPTS deciles.

Results: Among 146,912 kidneys with KDPI<85%, 15,820(11%) were ECDs. Significant differences existed in baseline characteristics of recipients(Table1). ECD kidneys had 65% higher risk of graft failure than SCD ones and were transplanted across all EPTS deciles(Figure1).

Conclusions: As ECD kidneys have worse allograft survival and are transplanted across all EPTS deciles, we recommend to 1)identify individuals who may not benefit from receiving ECD kidneys 2)counsel those who will receive them about higher risk of graft failure.

Funding: Commercial Support - Dialysis Clinic Inc

Histomorphometric Analyses of Preimplantation Needle Biopsies of Paired Kidneys from the Same Deceased Donors

Marcin Adamczak,[1] Katarzyna Kwiecien,[1] Magdalena E. Szotowska,[1] Wojciech Wystrychowski,[2] Robert Król,[2] Andrzej Wiecek.[1] *[1]Department of Nephrology, Transplantation and Internal Medicine, Medical University of Silesia, Katowice, Poland, Katowice, Poland; [2]Department of General, Vascular and Transplant Surgery, Medical University of Silesia, Katowice, Poland, Katowice, Poland.*

Background: Both donor and recipient factors influence kidney graft function. Integrated histo-morphometric assessment of transplanted kidney might better predict graft survival. The aim of the study was to determine differences in histomorphometric analyses of preimplantation needle biopsies of paired kidneys from the same donors.

Methods: Forty pairs of kidneys harvested from 40 donors (17F/23M; median age 42.3 and 95% CI 37.6-47.0 years) in which diagnostic preimplantation biopsies were done, were included into the analysis. Mean glomerular volume, mean glomerular density and mean capillaries density in the interstitium were estimated. For statistical analyses Wilcoxon tests were used. Results were presented as mean and 95% CI.

Results: Paired kidneys harvested from the same deceased donor did not differ in mean glomerular volume [2.59 (2.24-2.93) vs 2.49 (2.15-2.84) μm^3 x10^6], glomerular density [3.43 (3.07-3.80) vs 3.24 (2.87-3.61) n/mm^2] and capillaries density in the interstitium [233.58 (211.26-255.90) vs 217.80 (199.45-236.47) n/mm^2].

Conclusions: In daily clinical practice assessment of only one from both harvested kidneys from the donor seems to be sufficient for histomorphometric analysis.

Post-Transplant Vitamin D Deficiency: Comparison of Two Repletion Regimens

William M. Bennett,[1] Thomas D. Batiuk,[1] Marilani S. Ching,[2] Jeffrey Chamberlain,[3] Danielle Boschetto,[5] Sarah Mcdaniel.[4] *[1]Legacy Good Samaritan Medical Center, Portland, OR; [2]Legacy Heralth System, Good Samaritan Hospital, Portland, OR; [3]Legacy Health Kidney Transplant Services, Portland, OR; [4]St. Luke's Elmore Medical Center, Mountain Home, ID; [5]Oregon Health and Science University, Portland, OR.*

Background: Vitamin D deficiency is common post-transplant associated with immune impairment and ongoing metablic bone disease.(1)

Methods: We randomized 62 patients who had 25-OH D levels < 20, 1 month post-transplant to vitamin D3 4000 units daily (low dose) or 50,000 units daily (high dose) for 30 days. Patients were followed for 2 years. Immunosuppression was 3 mg/kg thymoglobin induction followed by tacrolimus, mycophenolate and prednisone.

Results: There were no differences in graft or patient survival between groups. Only the high dose group had >100 ng/ml 25-OH D levels after 1 month (63%). There were no evident clinical sequelae.

Conclusions: Both regimens were safe and effective. There is a tendency for less rejection on the high dose regimen suggesting the possibility that vitamin D may have beneficial immune modulatory effects. This needs to be tested prospectively. Combined Polyoma Virus-Associated Nephropathy (PVAN) and Rejection Treated with Thymoglobulin and Brincidofovir (CMX) in a Renal Transplant Recipient

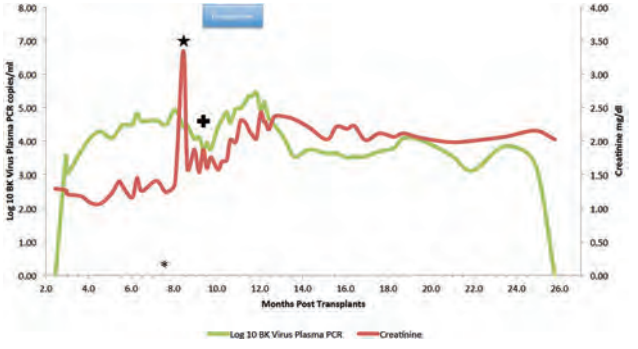
L Parker Gregg,[1,2] Nashila AbdulRahim,[1] Bekir Tanriover,[1] Ricardo M. La Hoz,[1] Venkatesh Kumar Ariyamuthu.[1] *[1]UT Southwestern Medical Center, Dallas, TX; [2]VA North Texas Healthcare System, Dallas, TX.*

Introduction: PVAN occurs in 1-10% of kidney transplant recipients. Concomitant rejection and PVAN is a challenging scenario for immunosuppression (IS) management. We present a case of biopsy-proven PVAN and acute cellular rejection (ACR) treated with CMX and aggressive augmentation of IS.

Case Description: A 49 year-old man with ESRD from type 2 diabetes and hypertension received a DDRT with ATG induction and maintained on tacrolimus (TAC)/MMF and Prednisone. Six weeks after his transplant he had a mild acute antibody-mediated rejection (AMR) that was treated with methylprednisolone, IVIG, and plasmapheresis. His serum BK PCR came positive in 6 months and reached 85,560 copies/mL in 8 months, and mycophenolate (MPA) was stopped, but continuing prior doses of Tac. Two weeks later, his creatinine rose to 3.3, and biopsy showed Banff 1B (ACR) and AMR. He was treated with steroids, plasmapheresis, and IVIG. His creatinine returned to a nadir of 1.9, but again rose to 2.1. BK titer at this time was 12,799 copies/mL. Repeat biopsy showed persistent ACR Banff 1B and AMR, and positive for SV40 staining and was treated with ATG 4.5 mg/kg, methylprednisolone and IVIG. He was also started on CMX100 mg twice a week. His creatinine decreased to 1.5 and he was discharged home on Tac, prednisone and MPA. Repeat kidney biopsy showed AMR and BKVAN. His IS was decreased and continued on CMX. In 3/2016 he developed leukopenia, BK titer rose to 269,659 copies/mL, and creatinine rose to 2.4 in the setting of sub-therapeutic tacrolimus levels. CMX and MPA were discontinued, and he was given IVIG. Over last 18 months his creatinine has been stable and his serum BK titers have most recently been just detectable.

Discussion: We report the first case when CMX was used with aggressive augmentation of IS for concurrent PVAN and ACR. We believe CMX allowed us to augment IS in the setting of PVAN and preserve the allograft.



Log$_{10}$BKV Plasma PCR and Serum Creatinine vs. Time post-transplantation

100% cPRA Renal Transplant Recipients Are at Increased Risk of Polyoma BK Viremia but Not Graft Loss

Grant Schalet,[1] David J. Conti.[2] *[1]Albany Medical College, Albany, NY; [2]Albany Medical Center, Albany, NY.*

Background: We investigated whether 100% cPRA sensitized kidney transplant recipients are at increased risk of polyoma BK viremia due to enhanced postoperative immunosuppression.

Methods: Plasma PCR monitoring for BKV was performed monthly in all recipients. Immunosuppression for all patients included thymoglobulin induction and maintenance sirolimus (rapamycin), low-dose CellCept (Mycophenolate Mofetil), and low-dose tacrolimus. BK viremia was defined as viral DNA >1,000 copies/mL. Recipients identified to have BK viremia underwent an immediate reduction in immunosuppression. We analyzed BK viremia rates in 100% cPRA recipients (19) versus non-100% cPRA recipients (96) between December 2014 and March 2017.

Results: Of the 100% cPRA patients, 31.6% were found to be positive for BK viremia versus only 15.6% with <100% cPRA (Fisher's exact test: p=0.112). Despite the increased incidence in BK viremia in 100% cPRA patients, the mean time to detection and mean serum creatinine at 12 months was not statistically significant (Two-sample t-test: p=0.302 and p=0.999). Through reducing immunosuppression, BKV resolved in all patients without progression to BK nephropathy or acute reactivation. None of the viremic patients experienced acute rejection following immunotherapy reduction.

Conclusions: BK viremia rate was greater in 100% cPRA recipients than those in the non-100% cPRA group. However, this was not detrimental to one-year graft survival and function over time with our monthly screening protocol. Graft survival and function in BKV positive 100% cPRA patients was similar to that of the non-100% cPRA group. This data indicates that monthly screening of BK viremia in 100% cPRA patients is effective in preserving one-year graft function outcomes.

Elimination of Chronic Hepatitis B in a Kidney Transplantation Recipient via Lamivudine Monotherapy: A Case Report

Sangeon Gwoo,[1] Mun Jang.[2] *[1]Department of Internal Medicine, MH Yeonse Hospital, Changwon-si, Gyeonsangnam-do, Republic of Korea; [2]Department of Internal Medicine, Yemidam Hospital, Cheongju-si, Republic of Korea.*

Introduction: Numerous studies have investigated lamivudine use for the treatment of hepatitis B virus (HBV) infection after kidney transplantation (KT). However, the efficacy and safety of lamivudine after KT remain unclear. A meta-analysis of 14 clinical trials (184 patients) demonstrated a hepatitis B envelope antigen (HBeAg) seroconversion rate of 27% (16 - 39%) and a HBV-DNA clearance rate of 91% (86 - 96%) in lamivudine-treated HBV-infected KT recipients; however, maintaining HBsAg clearance over 10 years has not been reported previously.

Case Description: A 56-year-old HBV-infected man had undergone KT for chronic glomerular nephropathy 20 years prior. Before KT, serological markers of HBV revealed that the patient was hepatitis B surface antigen (HBsAg)-positive and HBeAg-negative. A daily dose of 25 mg lamivudine monotherapy was started 8 weeks before KT. After KT, 100 mg of lamivudine was prescribed daily for 16 years, but was stopped 4 years prior to presentation. After 42 months of lamivudine treatment, HBsAg cleared, and 32 months later hepatitis B surface antibody (HBsAb) appeared. Four years after lamivudine therapy termination, serological markers revealed that the patient was HBsAg-negative, HBsAb-positive, and HBeAg-negative.

Discussion: HBsAg-positive KT recipients are at increased risk of mortality and graft failure compared to seronegative patients. Natural immunity to HBV may not protect against reactivation in immunocompromised patients. Currently, lamivudine is not the treatment of choice in chronic HBV-infected KT recipients because of its relatively lower treatment rate than other anti-viral agents. Furthermore, it can lead to increase in lamivudine resistance due to mutations in the tyrosine-methionine-aspartate-aspartate (YMDD) locus. We report a case in which chronic hepatitis B remission was sustained for over 10 years via lamivudine monotherapy without YMDD mutation and any adverse effects. This case describes a sustained cure of chronic HBV infection in a KT recipient without a YMDD mutation via lamivudine monotherapy.

PUB778

Significance of Donor-Specific Antibodies in Sequential Liver-Kidney Transplantation from the Same Donor

Mai Sato, Mureo Kasahara, Masao Ogura, Koichi Kamei, Kenji Ishikura. *National Center for Child Health and Development, Tokyo, Japan.*

Background: Donor-specific antibodies (DSA) occur in recipients of sequential liver-kidney transplantation from the same donor. In simultaneous liver-kidney transplantation, the liver's protective effect on the kidney results in a lower acute rejection rate and better renal allograft survival than in isolated kidney transplantation (KT). Our aim was to determine the significance of DSA in recipients of sequential liver-kidney transplantation from the same donor.

Methods: We retrospectively analyzed data on patients aged <20 years who underwent sequential liver-kidney transplantation from the same donor between November 2005 and March 2017 at our institute. All patients were screened for DSA using complement-dependent cytotoxicity, flow-cytometry crossmatch, flow panel reactive antigen, and Luminex single antigen before KT.

Results: The cohort included five recipients. The primary disease comprised autosomal recessive polycystic kidney disease (3 cases), primary hyperoxaluria (1 case), and nephronophthisis (1 case). The median age at liver transplantation (LT) and KT was 5.6 years (range 0.7-7.5) and 6.1 years (range 3.0-7.9), respectively. The median duration between the procedures and the median follow-up duration was 1.1 years (range 0.4-2.4) and 2.4 years (range 1.2-8.1), respectively. Four patients were positive for DSA after LT prior to KT and had the DQ6 (6592MFI) and DR15 (7050MFI), B44 (2892MFI) and DQ6 (8946MFI), DQ7 (21263MFI) and DR53 (22080MFI), and DQ6 (7088MFI) antigens. One patient received plasmapheresis and intravenous immunoglobulin, and two patients received rituximab, plasmapheresis, and intravenous immunoglobulin before KT. One patient did not receive desensitization therapy. All patients except one received standard immunosuppressant therapy with prednisolone, tacrolimus, and mycophenolate mofetil as did the non-sensitized patients. One patient was targeted for the ABO incompatible

protocol. Although two patients showed the DSA antigen after KT, they showed no histologic evidence of antibody-mediated rejection, and their allograft function was similar to that in non-sensitized patients. All patients had good liver function. Two patients who received a liver biopsy showed no sign of rejection.

Conclusions: In sequential liver-kidney transplantation from the same donor, DSA may not contribute to antibody-mediated rejection.

PUB779

Histopathological Examination of Removed Kidney Allografts: Is It Useful?

Kim Bunthof,[1] Eric Steenbergen,[2] Luuk Hilbrands.[1] *[1]Nephrology, Radboud University Medical Centre, Nijmegen, Netherlands; [2]Pathology, Radboud University Medical Centre, Nijmegen, Netherlands.*

Background: The rate of allograft nephrectomy after graft failure varies between 4.5% and 84.4%, reflecting the lack of a standard policy. The incidence and relevance of histological findings in removed grafts is unknown. In this study, we investigated the outcome of histopathological examination of removed grafts.

Methods: We performed a retrospective cohort study in patients who underwent a kidney transplantation between 1981 and 2015, and in whom the graft failed ≥ 3 months after transplantation. In these cases, our policy is to remove the graft only on indication (e.g. graft intolerance syndrome). We routinely send the removed graft for histopathological examination. In total, 198 allograft nephrectomies were performed. In 31 cases, no pathology report was available, leaving 167 cases for analysis. Pathology reports were especially reviewed for recurrences of primary disease and for unexpected findings. Moreover, the consequences for clinical management of these findings were examined in the patient charts.

Results: In 17 of the 167 examined grafts, gross necrosis due to infarction or thrombosis precluded adequate interpretation. Signs of acute and/or chronic rejection were reported in 137 of the remaining 150 allografts. Recurrence of the original disease was the main finding in 8 cases: primary focal segmental glomerulosclerosis (n=4) and membranoproliferative glomerulonephritis (n=4). In all cases, the recurrence was already known from prior kidney graft biopsies. Relevant secondary findings were present in 8 cases: renal cell carcinoma (n=2), urothelial cell carcinoma, candida pyelonephritis (n=2), PTLD, polyomavirus inclusions, and oxalate deposition. All these conditions were already diagnosed before the graft nephrectomy, with the exception of one case of papillary renal cell carcinoma of 0.8 cm. The clinical consequence of the latter finding was that retransplantation for this patient was withheld for 9 months.

Conclusions: As expected, acute and/or chronic rejection is the main histopathological finding in grafts that are removed after late graft failure. Unexpected secondary findings are very rare. We therefore question whether routine histopathological examination of removed kidney allografts is useful and cost-effective.

A Single Center Experience of Kidney Transplantation in Jehovah's Witness Patients

Muhammad O. Hanif,[1] Amanda A. Karasinski,[1] Abbas Raza,[1] Gregory Malat,[2] Lissa B. Levin Mizrahi,[1] Meera N. Harhay,[1] Karthik M. Ranganna.[1] *[1]Drexel University, PHILADELPHIA, PA; [2]Transplant, Hahnemann University Hospital, Philadelphia, PA.*

Background: Jehovah's witness patients refuse blood products due to religious implications, but they do accept organ transplantation, albumin, immunoglobulin and some even accept clotting factors. We present a case series of Jehovah's witness patients who successfully received renal transplantation in our bloodless center for surgeries and transplantation.

Methods: We performed a single center retrospective study of renal transplants in Jehovah's witness patients from 2001 to 2018.

Results: A total of 13 patients received renal transplantation. One recipient received a kidney from a living donor and the others received deceased donor kidneys. Donor quality (average kidney donor profile index scores reported 37 ± 29%). No patients required blood products. Nine received erythropoietic stimulating agents and 2 received IV iron. Eight patients received Basiliximab and 5 received thymoglobulin for induction. All were on calcineurin inhibitors, 12 were on mycophenolate mofetil, 1 was on sirolimus and 3 were on steroid withdrawal protocol. Two patients were treated for rejection: 1 had a combination of both cellular and humoral rejection and required additional thymoglobulin, plasmapheresis and IVIG in the first year, while the other was preemptively treated for cellular rejection with methylprednisolone. The average length of hospital stay was 7.7 days. Five patients required readmission within 30 days; no readmissions were related to anemia. Patient and graft survival at 1 and 3-year were 100%. 6 allografts continue to function, 2 died with functioning graft, 3 have failed allografts and 2 patients were lost to follow up.

Conclusions: Although kidney transplantation does not generally require blood products, except in the case of surgical complications, our experience showed that Jehovah's witness patients can safely undergo transplantation with similar allograft outcomes as the general population while respecting their religious beliefs.

Leptin and Adiponectin Serum Levels in Kidney Transplant Recipients: Preliminary Results

Omar I. Delgado-Ayon,[1,2] Andrea F. Aguilar,[3] Denisse Arellano-Mendez,[1,2] Godhy E. Hernandez Gonzalez,[1,2] Daril J. Herena monreal,[1,2] Renato Parra Michel,[4,2] Efrain Chavarria-Avila,[5] Jorge fernando Topete reyes.[1,2] *[1]Universidad de Guadalajara, Guadalajara, Mexico; [2]Nefrología, Instituto Mexicano del Seguro Social, Guadalajara, Mexico; [3]University of Guadalajara, Guadalajara, Mexico; [4]Universidad de Guadalajara, Centro Universitario de Ciencias de la Salud, Hospital General Regional No.46, Instituto Mexicano del Seguro Social, Guadalajara, Mexico; [5]Universidad de Guadalajara, Guadalajara, Mexico.*

Background: Adipokines modulate endocrine and immune processes; they are regulated in turn by nutritional parameters. There is controversy between the findings of diverse studies that evaluate outcomes in Chronic Kidney Disease and its association with adipokines, including kidney transplant. The aim of this study was to evaluate the relationship between adipokines serum levels with the type of rejection in patients with kidney transplant (KT) as well as their immunosuppressive treatment.

Methods: In this cross-sectional study, 36 patients with KT were included. The measurement of leptin and adiponectin were on serum samples with an ELISA Kit, these measures were compared with the result of the KT biopsy (Banff 2017 criteria), nutritional parameters and the type of immunosuppressant (Tacrolimus, Sirolimus, Ciclosporin). This study complies with the WMA Declaration of Helsinki, and Declaration of Istanbul on Organ Trafficking and Transplant Tourism.

Results: There was a tendency for patients treated with calcineurin inhibitors (CNI) to have higher levels of leptin (21.6 ng/ml) than those of sirolimus (18.2 ng/ml). Regarding adiponectin, it was inversely showing tendencies at higher levels those of the sirolimus group (13.1 µg/ml) with respect to the CNI (10.8 µg/ml). A positive correlation of adiponectin was found with the post transplant time (r=0.477, *P*=0.016) and with the Proteinuria/Creatininuria index (r=0.563, *P*=0.005). Regarding the type of rejection, no significant differences were found, but it was observed that patients with active humoral rejection had a tendency to lower leptin concentrations (15.5 ng/ml) and those with only IF/TA had higher concentrations (25.3 ng/ml). Likewise, patients who presented chronic humoral rejection showed intermediate values (20.5 ng/ml). Regarding the concentrations of adiponectin the values were homogeneous in the range of 12.4-13.1 µg/ml.

Conclusions: The immunosuppressive treatment would influence levels of adipokines. Chronicity changes of the allograft would be determined by leptin levels, but not by adiponectin, whose levels apparently did not influence the type of rejection or chronic changes inherent to the graft, however they are correlated with post-transplant time and proteinuria.

PUB782

Predictors and Outcomes of Calcium Oxalate Crystals in Kidney Transplant Recipients with AKI and Delayed Graft Function

Maha A. Mohamed. *University of Wisconsin School of Medicine and Public Health, Madison, WI.*

Background: The predictors of calcium oxalate (CaOx) deposits associated with Acute Kidney Injury (AKI) and Delayed Graft Function (DGF) and the impact of CaOx crystals on allograft survival are unclear. The aim of the study is to evaluate predictors and impact of CaOx crystals in kidney (KT), simultaneous liver kidney (SLK) and simultaneous pancreas and kidney (SPK) transplants with AKI and DGF.

Methods: We abstracted data for all KT, SLK, and SPK recipients who had for cause biopsies in a single center from 1994-2017. CaOx crystals were identified in 9 recipients with DGF and 15 recipients with AKI. These were matched on time since transplantation with 19 and 46 controls without DGF or AKI, respectively

Results: Median follow-up was 28 days for DGF and 502 days for AKI. Stepwise logistic regression models identified a nearly significant association between Banff i+t score (sum tubulitis and interstitial inflammation) and CaOx crystals in DGF (OR 9.9, p=0.072), while a history of native kidney nephrolithiasis was an independent predictor of CaOx in AKI (OR 20.03, p=0.037) table 1. CaOx was significantly associated with inferior death-censored allograft survival in both DGF (p<0.001) and AKI (p=0.01) fig 1 (a & b).

Conclusions: CaOx crystals in allograft biopsies with AKI and DGF are associated with inferior allograft survival. Pre-transplant nephrolithiasis, tubulitis, and interstitial inflammation may be risk factors for CaOx crystals in allograft with AKI and DGF. These observations suggest a need to better understand the pathogenesis of CaOx crystals to develop preventive and therapeutic strategies in kidney transplant recipients

Association of Anti-retroviral Therapy Following Kidney Transplantation on Incident BK Viremia

Abbas Raza,[1] Amanda A. Karasinski,[1] Jaime A. Baynes-Fields,[1] Gregory Malat,[2] Suzanne Boyle,[1] Meera N. Harhay,[1] Karthik M. Ranganna.[1] *[1]Drexel University, Philadelphia, PA; [2]Transplant, Hahnemann University Hospital, Philadelphia, PA.*

Background: BK polyomavirus is an opportunistic virus that can cause polyomavirus-associated nephropathy and graft failure after kidney transplantation (KT). Given interactions of anti-retroviral therapy (ART) with calcineurin inhibitors, many HIV+ KT recipients receive integrase inhibitor (II) based ART. We investigated BK viremia and nephropathy rates in HIV+ KT while on II ART.

Methods: We performed a single center retrospective study of 28 HIV+ KT recipients, transplanted between 2009 to 2017. We compared incidence of BK viremia after KT based on whether patients were on II-based ART or not. **Study Population:** All patients had undetectable HIV viral load and CD4 count > 200 cells/mm3. Standard HIV+ immunosuppression (IS) protocol at our center included basiliximab induction, CNI-based IS, mycophenolate, and steroid taper. After 2011, IVIG was added to induction IS. One recipient received anti-thymocyte globulin, secondary to increased PRA and re-transplantation. BKV monitoring was performed by protocol for all patients following KT.

Results: Of the 28 recipients, 12 (43%) were maintained on II-based ART after KT (table 1). One-year post-KT, BK viremia (range: 2770 - 71150 copies/ml) rates were higher in the II-based ART group compared to the non-II group (3/12,vs.0/16, p=0.067). No allografts were lost from BK virus nephropathy; Rejection was noted to be higher in non-II group (2/12 vs 9/16 vs p=0.054). Graft survival at 1- and 3- year follow-up was 100/100% in the II-ART group vs. 100/94% in the comparative group. Median eGFR at 1 year for both groups were > 60 mL/min.

Conclusions: BK viremia is generally uncommon in the HIV+ KT population. Based on our follow-up, we have seen a slight increase in the incidence of clinically relevant BK viremia. Long-term follow-up is needed to monitor this HIV+ KT cohort.

Table-1

	No Integrase Inhibitor (-) ART (16)	Integrase Inhibitor (+) ART (12)
BK viremia	0 (0%)	3 (25%)
Median Age	51 yrs (IQR)	48 yrs (IQR)
Male	13 (81%)	8 (67%)
African American	12 (75%)	10 (83%)
Deceased donors	14 (88%)	11 (92%)
Delayed graft function	6 (38%)	4 (33%)
Median KDRI scores	0.9166	1.074
Acute cellular rejection at 1 year	6 (38%)	1 (8%)
Acute antibody rejection at 1 year	3 (19%)	1 (8%)

PUB784

Continuation of Immunosuppression (IS) Protects Against Allosensitization in Recipients of Kidney Transplant (KT) After Previous Non-Liver Solid Organ Transplantation (SOT)

Sadeem Ali,[1] M. Lee Sanders,[1] Christie P. Thomas,[1] Roberto S. Kalil,[1] Elizabeth H. Field,[2] Sarat C. Kuppachi.[1] *[1]Transplant Nephrology, University of Iowa College of Medicine, Iowa City, IA; [2]Iowa City VA Health Care System, Iowa City, IA.*

Background: Following kidney allograft loss, current standard of care involves discontinuing IS to prevent risks of more exposure. We hypothesized that continuation of IS after graft failure in candidates for another transplant would lower the risk of allosensitization.

Methods: We retrospectively analyzed calculated panel reactive antibodies (cPRA) on KT recipients at our center from January 2009 to March 2017 after having undergone a prior non-liver SOT. Patients with > 2 prior KT's were excluded. We compared sensitization between those who continued IS, and those who did not, based on cPRAs at times of listing and pre-transplant, using Risk Ratio (RR) and Chi square or Fishers exact test for statistical significance.

Results: 87 cases met inclusion criteria. 70 had a prior KT, 10 simultaneous kidney and pancreas, 1 pancreas, 1 lung and 5 heart transplants before being listed for a second organ (KT). Table shows that in the 50 cases where IS was discontinued after failure of the first graft, 45 of 50 (90%) had a cPRA ≥ 20 at the time of their second organ (index kidney) transplant, whereas 18 of 37 cases with continued IS (48.6%) had a cPRA ≥ 20 (RR = 1.85 [1.31-2.61], p < .0001, for proportion of sensitized cases when IS was discontinued). Among the 42 cases with available cPRA results at listing for the first transplant and the index KT, discontinuing IS after failure of first graft significantly increased the interim sensitization level compared to continuing IS (RR = 2.36 [1.23-4.51], p = 0.0008).

Conclusions: In this single center retrospective analysis, continuation of IS protects against the risk of allosensitization at listing for a second transplant. Both the proportion of sensitized patients and the magnitude of sensitization are significantly greater in cases that discontinued IS. Additional studies of IS management after graft failure are needed to determine whether the benefit of continued IS in candidates eligible for a second KT includes improved access to transplant and reduced morbidity.

Comparison of cPRA in cases continuing versus discontinuing IS

IS Treatment	cPRA <20	cPRA 21-50	cPRA 51-80	cPRA 81-100	cPRA mean (SD)	Median
IS Continued	19	7	6	5	32.2 (35.8)	18.0
IS Discontinued	5	8	11	26	70.4 (34.3)	83.5

PUB785

Efficacy and Safety of Ultra-Low Dose Valganciclovir Chemoprophylaxis for CMV Infection in High Risk KTP

Jin ho Lee,[1] Seon Deok Hwang,[2] Seoung Woo Lee,[3] Woo Yeong Park,[7] Jeong Ho Kim,[8] Hee yeoun Kim,[4] Seong min Kim,[5] Joon Seok Oh,[6] Dongyeol Lee,[1] Yong hun Sin,[9] Joong Kyung Kim.[1] *[1]Bong Seng Memorial Hospital, Busan, Republic of Korea; [2]Inha University College of Medicine, Incheon, Republic of Korea; [3]Inha University Hospital, Inchon City, Republic of Korea; [4]Bongseng hospital, Busan, Republic of Korea; [5]Dongrae Bongseng Hospital, Busan, Republic of Korea; [6]Bong Seng Hospital, Korea, Dong-gu, Busan, Republic of Korea; [7]Dongsan Medical Center, Daegu, Republic of Korea; [8]Daejeon St. Mary's Hospital, Daejeon, Republic of Korea; [9]Bong Seng Hospital, Busan, Republic of Korea.*

Background: CMV syndrome and disease are one of the major causes of decreased graft and patient survival for kidney transplant(KT) recipients. CMV syndrome is defined as virus isolation or detection of viral proteins (antigens) or nucleic acid in any body fluid or tissue specimen. CMV disease consists of CMV syndrome plus the presence of sign or clinical symptoms in the end organs. Valganciclovir (VGCV) prophylaxis to prevent CMV infection is recommended for solid organ transplant patients. Most transplant centers perform universal prophylaxis only in high risk groups including ABOi KT and DDKT. Most studies recommend administration of VGCV 900 mg twice a day. However, compliance can be reduced due to expensive medication, or hematologic side effects can occur. Therefore, we studied whether an ultra-low dose and short duration of VGCV (450 mg,

every other day, 3 months after KTP) is sufficient to prevent CMV infection in ABOi KT and DDKT recipients

Methods: We retrospectively evaluated 74 CMV seropositive donor/seropositive recipient(D+/R+) adult ABOi KTP recipients and 78 CMV seropositive donor/seropositive recipient(D+/R+) adult DDKT recipients from June 2009 to July 2016 who received ultra-low dose VGCV (450 mg every other day) prophylaxis for 3months. The primary outcome was occurrence of CMV syndrome and CMV disease. The secondary outcome was patient survival and graft survival.

Results: Follow-up durations were 2 to 52 months, respectively. CMV syndrome occurred in 1 case (1.4%) in ABOi KT and 2 cases (2.7%) in DDKT, but this was not statistically significant(p-value = 0.38). However, CMV disease occurred in one case (1.4%) in the ABOi KTP group and in 12 cases (16%) in the DDKT group, which was statistically significant(p-value 0.001). The CMV disease in ABOi was CMV pneumonia. CMV pneumonia was found in 8/12 (66.6%) and CMV colitis in 4/12 (33.3%) among the CMV disease in DDKT. Patient survival and graft survival(Fig.1) did not differ significantly between the two groups

Conclusions: Using an ultra-low dose VGCV, CMV prophylaxis was found to be effective in ABOi KTP, but DDKT increases the incidence of CMV disease. To reduce CMV disease after DDKT, the dose or duration of VGCV may be increased or preemptive treatment may be more effective

PUB786

Nocardia Infection in Renal Transplant Patients: Report from Transplant Center in India

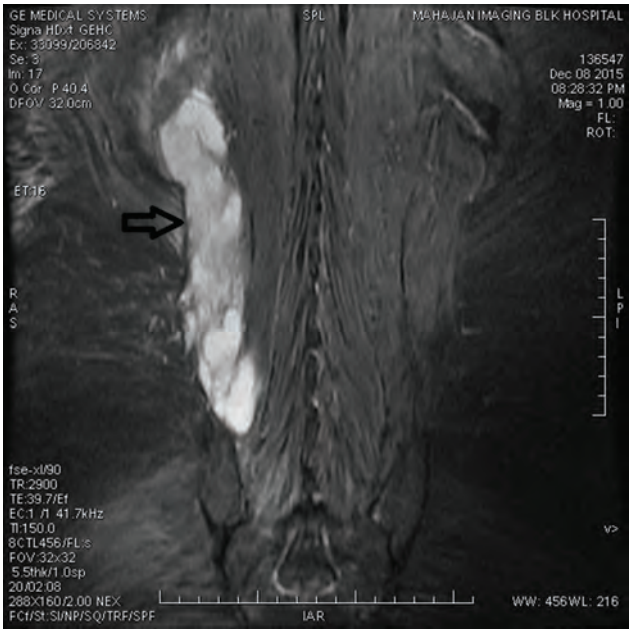
Amit Kumar,[1] Sunil Prakash,[1] Ashwini Goel.[2] *[1]Nephrology, BLK SuperSpeciality Hospital New Delhi, New Delhi, India; [2]Nephrology, BLK Super Speciality Hospital, New Delhi, India.*

Background: Nocardosis is an uncommon but important cause of Infection in renal transplant recipients. There is scarce data regarding Nocardisis from Indian Subcontinent. Here we present spectrum of Nocardia infection from our center in India.

Methods: A retrospective analysis of all transplant performed from July 2012 to June 2017 was performed. Patients with diagnosis of Nocardia infection were identified. Their immunosupressive regimen, clinical presentation and outcome was examined.

Results: During the study period total 346 transplant were performed including Live, cadeveric, ABO-Incompatible. 3 patient (0.86%) developed Nocardia infection. Mean age at diagnosis was 58 years. 2 patients had Diabetes Mellitus and one had chronic Glomerulonephritis as native Kidney disease. All 3 received ATG as Induction and were on Tacrolimus, Mycophenolate and Prednisolone as maintenance immunosupression. Mean duration of presentation was 12 to 48 weeks after transplant. 1 patient was treated for acute cellular rejection in recent past with injection Methylprednisolone, one patient had recurrent infection including episode of CMV disease and tuberculosis in form of subcutaneous cold abscess and 3rd was largely asymptomatic prior to presentation.. One patient presented with Pulmonary Nocardiosis, one with epidural abscess at Dorsal Spine D3-D4 level and 3rd presented with paraspinal intramuscular abscess at lumbo-sacral level. All 3 were treated with combination antibiotic. 2 patients improved and one expired.

Conclusions: Nocardia infection is associated with significant morbidity and mortality. Pre transplant diabetes, treatment of rejection, ATG induction may be risk factor for Nocardia infection. High index of suspicion is essential for diagnosis as presentation is varied and patient may present late after transplant.



PUB787

Pre- and Post-Transplant Albumin Levels and Kidney Transplant Survival

Mita zahra E. Co,[1] Arianne clare C. Agdamag,[2] Michael lawrenz F. Co.[2] *[1]Presence Saint Joseph Hospital, Chicago, IL; [2]Rush University Medical Center, Chicago, IL.*

Background: Survival of ESRD patients continues to be lower than the general population even after kidney transplant (KT). Predictors of outcomes are important guides in the proper referral and postoperative care among KT patients. We examined the association of pre- and post-KT albumin levels on patient survival.

Methods: We retrospectively enrolled patients who underwent KT from 2005 to 2015 in our institution. Demographics, date of transplantation and death, albumin levels and preoperative comorbidities were obtained from medical records and kidney transplant program database. Cox regression, Kaplan Meier and ROC analyses were performed to determine the effect of pre- and post-KT levels on survival. Mean pre- and post-KT albumin levels were also compared using T-test for paired variables.

Results: A total of 705 patients underwent KT during the study period, 589 of which had both pre-KT and post-KT albumin data points. Mean pre-KT and post-KT albumin levels were 3.6±0.7 and 3.9±2.3 g/dL, respectively. Median follow-up time was 3.3 years (IQR 1.2-5.4 years). Cox regression analyses showed that both higher levels of pre-KT albumin (HR 0.67, p=0.01) and post-KT albumin (HR 0.28, p<0.001) were significantly associated with improved survival. KM survival analysis showed that a chosen pre-KT and post-KT albumin cut-off of 3.6 g/dL (log rank p=0.04) and 3.7 g/dL, (log rank p<0.001) were able to predict survival (Figure 1). After KT, 321 (54.6%) patients had improvement in albumin (mean increase of 0.3±2.4 g/dL, p=0.003). Improvement in albumin levels was not associated with improvement in survival (log rank p=0.55)

Conclusions: Our results showed that higher pre- and post-KT albumin levels are associated with improved survival. Although albumin levels imrove slightly after KT, this was not associated with improvements in surival. Optimization of nutrition and proper preoperative selection based on albumin levels may be keys to better risk stratification and improvement in survival of KT recipients.

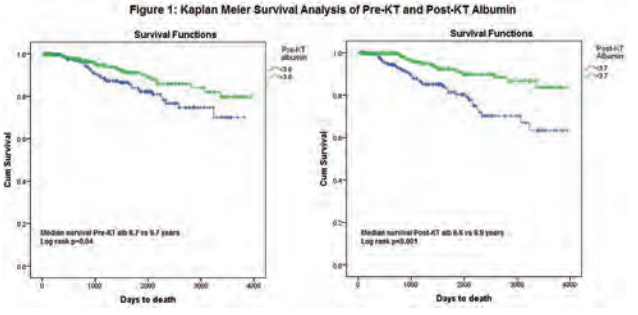


Figure 1: KM Survival analyses for Pre- and Post-KT albumin levels

Advice Given to Moslem Kidney Recipients by Moslem Nephrologists About Potentially Medically Risky Religious Rites

Ziad Arabi,[1] Abdulrahman R. Altheaby,[1] Mahfooz A. Farooqui,[2] Elwaleed A. Elhassan,[2] Mubarak I. Abdalla,[2] Atif A. Mateen,[2] Saleh Kaysi,[3] Syed A. Alam,[4] Saif A. Khan,[5] Abdulla Al sayyari.[2] *[1]Adult Transplant Nephrology, Organ Transplant Center, King Abdulaziz Medical City, Riyadh, Saudi Arabia; [2]Nephrology, Department of Medicine, King Abdulazziz Medical City, Riyadh, Saudi Arabia; [3]CHU Clermont-Ferrand, Saint Pryv/ Saint Mesmin, France; [4]Nephrology Department, Khyber Teaching Hospital, Peshawar, Pakistan; [5]Nephrology, Sultan Qaboos University hospital, Muscat, Oman.*

Background: Moslem patients often ask their nephrologists if performing certain religious obligations may be harmful to their health. Permissibility as advised by an expert Muslim physician religiously acceptable waiving of such rites.

Methods: This is a cross-sectional survey of the nephrologists' advices to posttransplant patients regarding fasting Ramadan, performing pilgrimage, Omrah, marital relations and pregnancy. The survey was sent to Moslem nephrologists in different countries.

Results: Of the respondents (n=58), 78% follow up posttransplant patients; 35% form Saudi Arabia, 19 % from USA and 20 % from Pakistan. 60% of the respondents would let stable patients, fast Ramadan after one year of transplantation whereas just one fifth would not recommend fasting at any time. If the patient is diabetic those who would not recommend fasting at any time increased to 32%. Three quarters would let patients perform Omrah after 6 to 12 months and only 1.7% would not recommend that at any time. Obligatory Hajj, would be allowed by 58% after 1 year after transplantat, additional 22% will allow it after 2 years and 5% would not recommend that at any time. The responses for nonobligatory Hajj were 47%, 23 % and 23% respectively. The majority felt that marital relationship could be resumed once the surgical incision has healed, 6% felt there should a period of one year of abstinence. 61% of the respondents would delay the pregnancy in primigravida with stable renal function for one year, 28% for 2 years, about 2 % would allow it immediately and none

would not recommend it at any time. In multiparous recipients, the respective frequencies were 45%, 25%, 3% and 20% The presence of controlled hypertension in the absence of proteinuria is not a contraindication to pregnancy except in only 3% of, whereas 71% would allow it after one year of transplantation. There was no statistical difference between the advice given by transplant nephrologist and general nephrologist on pregnancy or fasting Ramadan for the recipients or donors.

Conclusions: To our knowledge this the first study exploring the consensus among Moslem nephrologists regarding the advice they would give regarding performing potentially risky religious rites by Moslem posttransplant patients.

PUB789

When to Treat Hepatitis E in Renal Transplant Patients?

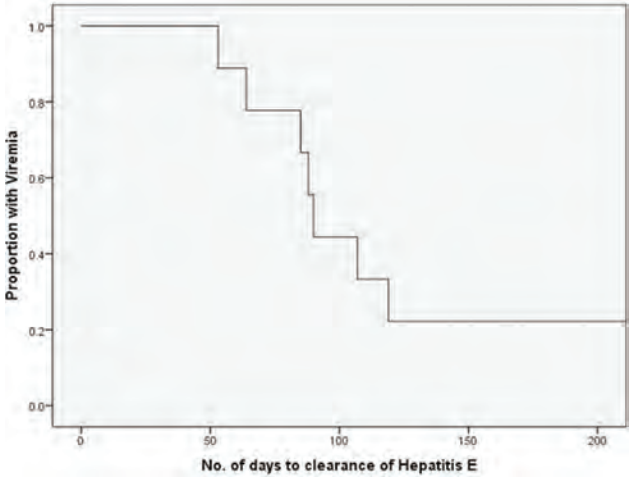
Jia neng Tan,[1] Hersharan Sran,[1] Angeline Goh,[1] Rachel Teo,[1] Anantharaman Vathsala.[2] *[1]National University Hospital, Singapore, Singapore; [2]National University of Singapore, Singapore, Singapore.*

Background: Whereas Hepatitis E (HepE) is a self-limiting illness in the immunocompetent, chronicity is increasingly reported among immunocompromised patients. In the absence of established therapy, current approach is initial monitoring with treatment for viral persistence. We hypothesized that spontaneous resolution is infrequent among immunocompromised renal transplant recipients(RTX), warranting early treatment.

Methods: This single-centre, retrospective study evaluated clinical and laboratory characteristics and outcomes for RTX with HepE.

Results: 10 RTX (90% Male, Median age 55years, 80% Chinese, 20% Indian) were diagnosed with HepE from 2013-2018, yielding a yearly incidence of up to 1,082/100,000 population among RTX, in comparison to 0.92/100,000 in the general population. 2 reported intake of Chinese sausages or raw oysters. 1 Indian male was exposed to plasma products. Diagnosis of HepE was made on viral load (VL) detection in 9 RTX and by serology in 1 RTX at an interval of 111-8,770 days. At diagnosis, median AST was 80IU/mL, ALT 133IU/mL, ALP 102.5IU/mL and VL was 1,140,000IU/ml. Immunosuppression decrease (IsD) alone achieved viral clearance in 1 RTX with low VL of 4,380 copies; another RTX did not achieve clearance despite a 188 day trial of IsD. The remainder could not undergo IsD for clinical reasons and received Ribavirin (Rb) within 50 days of diagnosis. Of 9 treated with Rb, 4(44.4%) developed anaemia, majority requiring erythropoietin. 7 out of 8 (87.5%) achieved viral clearance within 105 days after initiation, 2(22.2%) had relapse/reinfection requiring re-treatment. 1 had treatment failure due to treatment-limiting side effects.

Conclusions: HepE has a high incidence among RTX, presenting with mild transaminitis and responding to Rb in the majority. As viral clearance with IsD is not effective or feasible in the majority, our results advocate for early treatment of HepE among RTX.



PUB790

The Aftermath of Chemotherapy for Burkitt Lymphoma in a Renal Transplant Recipient

Rasika A. Sirsat, Neha Shah. *P. D. Hinduja Hospital and Medical Research Centre, Mumbai, India.*

Introduction: Burkitt lymphoma is a very rare post-transplant lymphoproliferative disorder (PTLD) in adults. It behaves aggressively requiring cessation of conventional immunosuppression and urgent start of combination chemotherapy.

Case Description: A 44 year old man was diagnosed with CKD 5 secondary to ADPKD for which he underwent pre-emptive ABO compatible single haplotype matched live related renal allograft surgery in Jan'11 at our centre. He was on tacrolimus, azathioprine and steroids. He had an uneventful course for 5 years. In Apr'16, he was diagnosed with Burkitt lymphoma of the caecum (CD 20 and Ki67 positive) for which he received 6 cycles of chemotherapy (rituximab, etoposide, vincristine, doxorubicin, cyclophosphamide and prednisolone). He was on 5mg prednisolone daily as maintenance therapy. He was cured of lymphoma in Nov'16 (sr creatinine 0.8 mg%). However, in Dec'16 he developed gross hematuria with graft dysfunction (sr creatinine 3.8 mg%) and pancytopenia. Peripheral smear and bone marrow examination were normal. Blood and urine cultures were negative. Urine TB PCR, geneXpert and culture were negative. Cystoscopy was normal. Serology (ELISA) showed: Parvovirus IgM-negative; EBV VCA IgM and IgG and EBNA IgG positive; HIV, HBsAg and anti HCV negative. Plasma and urine BK viral load, plasma CMV viral load were undetectable. However, his urine was positive for JCV and CMV (by NAAT). Renal biopsy showed acute interstitial nephritis with lymphocytic infiltrate of 10-15% with no tubulitis or peritubular capillaritis and with C4d, SV40 and CMV negative with no chronic changes. Though no strong evidence, we presume that his graft succumbed to JC virus in just three months (contrary to current understanding of JCV nephropathy having a favourable graft outcome). The patient continues to be on hemodialysis. He developed orbito-cerebral mucormycosis in Aug'17 requiring left orbital exenteration and antifungals to which he responded.

Discussion: Despite recovering from Burkitt lymphoma, our patient suffered two opportunistic infections within a year of completion of chemotherapy, though he was not on calcineurin inhibitors and antiproliferative agents. It was tragic that he didnot lose the graft to rejection but to infection highlighting that immunity can remain suppressed as long as 9 -12 months post chemotherapy.

PUB791

Multimodal Individualised Treatment for Recurrent FSGS After a Third Kidney Transplantation Using Rituximab and Belatacept

Dan Hristea,[1,2] Jacques Dantal.[3] *[1]ECHO Nantes, St Herblain, France; [2]Institut de Transplantation Urologie Néphrologie, Nantes, France; [3]Institut de Transplantation Urologie Néphrologie, Nantes, France.*

Introduction: Recurrent nephrotic syndrome due to FSGS is associated with poor transplant outcomes, its optimal management is not yet established.

Case Description: We report the case of a 48 years old patient treated by hemodialysis since 1992 due to ESRD caused by biopsy proven FSGS. A first kidney transplant failed after four months due to severe recurrence of his initial disease. The second transplantation was lost rapidly due to surgical complications. The patient had not developed significant HLA immunization before his well-matched third graft. Immunosuppression consisted of an association of tacrolimus, mycophenolic acid (MA) and steroids at usual doses. Rituximab was injected at day 1 after transplantation and induced a deep depletion in CD19 positive B cells. During the first 2 months kidney function remained stable with GFR levels estimated by CKD-EPI between 35-40 ml/min/1.73 m2 and urine protein/creatinine ratio did not exceed 0.1 g/g while serum-albumin was in the normal range. However during the third month after transplantation positive viremias for BK virus were observed and the patient developed pneumonia and pyelonephritis which required adapted antibiotic treatment. Despite stopping MA and lowering tacrolimus doses BK viremia and viruria remained positive. Proteinuria tended to increase, clinical significant edema developed despite normal serum albumin and kidney function worsened. A kidney biopsy performed at month (M) 7 showed slight signs of calcineurin toxicity and podocyte foot-process fusion. We therefore decided to start plasmapheresis (3 sessions during the first week followed by 1 session every month during 6 months and switch to monthly belatacept injections, while lowering tacrolimus trough levels < 2 ng/l. Under this treatment BK viremia disappeared (M 12), proteinuria could be maintained in the non-nephrotic range and kidney function recovered and is stable at a follow-up of 18 months.

Discussion: This case indicates that Rituximab is able to prevent severe recurrence of FSGS after kidney transplantation but infectious complications are frequent and can have deleterious consequences. Belatacept treatment seems to be a safe in this condition and might permit to lower concomitant immunosuppressive treatment. Further studies and probably individualized strategies are needed to optimize management of recurrent FSGS.

PUB792

The Impact of Hurricane Maria on Transplant Outcomes in Puerto Rico: A Retrospective Chart Review

Melissa L. Swee,[1,2] Jodell Hornickel,[2] Stacey Abel,[2] Roberto S. Kalil.[1,2] *[1]University of Iowa, North Liberty, IA; [2]VA Iowa City, Iowa City, IA.*

Background: On September 20th, 2017, Hurricane Maria made landfall on the island of Puerto Rico, leading to a high number of deaths, destruction of property, and adverse health outcomes. This study aims to characterize the effect of Hurricane Maria on Kidney Transplant Recipients through the Veterans Affairs (VA) Health Care System.

Methods: The electronic health records of all kidney transplant recipients through the Veterans Affairs since 2005 were reviewed. Patients who had lived on Puerto Rico in the year of 2017 were included. All notes and laboratory values were abstracted prior and after the hurricane, including creatinine, urinalysis, urine protein-to-creatinine ratios and drug levels, as well as demographic and historic data on transplant status.

Results: 31 patients were identified Puerto Rico residents in 2017. All 31 were males (100%) and Hispanic/Latino (100%). The mean age was 65.5 ± 7.0 years. 29 were kidney transplants while 2 were kidney-pancreas transplants. The mean time since transplant was 8 ± 3.5 years. End-Stage Renal Disease was most frequently due to diabetes mellitus (11; 35%), hypertension (8; 25.8%), and glomerulonephritis (4; 12.9%). Only 4 patients had proteinuria on urinalysis. Prior to the hurricane, serum creatinine levels were 1.3 mg/dL ± 0.4, urine protein-to-creatinine ratio was 0.45 ± 0.79. Tacrolimus and sirolimus levels were 6.4 ± 1.3 and 11 ± 0.2, respectively. After the hurricane, contact was established with all 31 patients. Serum creatinine levels were 1.4 mg/dL ± 0.55 and UPC were 0.31 ± 0.38, which were not statistically significant (p= 0.33 and 0.38, respectively). Three patients had creatinine elevations greater than 0.3, of which only one had persistent elevations one

month afterwards. Tacrolimus and sirolimus levels three months after the hurricane were 7.3 + 1.3 and 10 ± 0.8, respectively. None was subtherapeutic.

Conclusions: Despite the destruction and degradation of infrastructure in Puerto Rico after Hurricane Maria, the vast majority of kidney transplant recipients through the VA were not adversely affected. Only one recipient had sustained creatinine elevations, which may or may not have been a consequence of disruption of healthcare services after the hurricane.

PUB793

Comparison of Outcomes One Year After Renal Transplant Between Alemtuzumab and Basiliximab for Induction Immunosuppression

Jonathan A. Seaman, Scott G. Westphal, Fang Qiu, Doug Bremers, Diana F. Florescu. *University of Nebraska Medical Center-Nebraska Medicine, Omaha, NE.*

Background: Induction immunosuppression has become increasingly utilized to improve early graft function and decrease rejection rates. The aim of our study was to compare the outcomes one year post-transplant in renal transplant patients who received either alemtuzumab or basiliximab for induction therapy.

Methods: At our center, alemtuzumab is given to all patients with a calculated panel of reactive antibody (CPRA) > 25% and basiliximab is given when CPRA < 25%. We included all patients (N=27) who received induction with alemtuzumab for renal transplant between 2011 and 2016. These were matched 1:2 to basiliximab recipients by age and date of transplant. Continuous variables were compared using t-tests or Wilcoxon rank-sum tests and categorical variables using Fisher's tests or chi-square tests. Binary outcomes were compared using Cochran-Mantel-Haenszel tests. Time-to-event outcomes were plotted using the Kaplan-Meier method and compared between groups using log-rank tests.

Results: Baseline demographics are described in Table 1. Most patients were maintained on tacrolimus, mycophenolate, and prednisone. No statistically significant differences in the following outcomes were detected: delayed graft function (p = 0.76), graft loss (p = 0.99), or rejection (p = 0.2). Opportunistic infection rates were not significantly different at 1-year post-transplant (p = 0.83). Time-to-infection (p = 0.84) and time-to-death (p=0.21) were similar in both groups, but time-to-rejection was longer in the basiliximab group vs alemtuzumab group (p = 0.04).

Conclusions: Despite a difference in immunological risk between the 2 groups, we did not detect any significant differences in outcomes at 1-year post-transplantation between higher immunological risk patients receiving alemtuzumab and lower risk patients receiving basiliximab. Early opportunistic infectious rates were similar.

Low-Dose Mycophenolate Mofetil in Kidney Transplant Recipients and Its Association with Infectious Diseases and Acute Rejection

Jorge Andrade-Sierra,[1,2] Hernesto Hernandez,[2] Enrique Rojas-Campos,[3] Alfonso M. Cueto-Manzano,[2,3] Benjamin Gomez-Navarro,[2] Miguel Medina Pérez,[2] Basilio Jalomo martínez,[2] Petra Martínez,[2] Luis Alberto Evangelista-Carrillo,[2] Jose I. Cerrillos.[2] *[1]Universidad De Guadalajara, CUCS, Guadalajara, Jalisco Mexico, Mexico; [2]Nephrology, HE.CMNO.UMAE.Instituto Mexicano Del Seguro Social, Guadalajara, Mexico; [3]Unidad de Investigacion Medica En Enfermedades Renales, IMSS-UIMER, Guadalajara, Mexico.*

Background: Current immunosuppression schemes have improved the overall kidney transplant (KT) survival; however, the adverse events associated with maintenance of immunosuppressive therapy have not been modified. The use of Mycophenolate mofetil (MMF) has unfavorable dose-related effects (gastrointestinal, hematological and infectious). **OBJECTIVE:** Determinate the incidence of infectious diseases and acute rejection (AR) with two different doses of MMF.

Methods: A prospective cohort (March 1, 2017 - March 1, 2018) in first-time live donor kidney transplant (LDKT) recipients. Patients with low dose of MMF (1.5 gr/day) and standard dose of MMF (2 gr/day) were compared. Anthropometric measures, presence of post-transplant infections, hospitalizations, AR and adverse events associated with MMF were collected.

Results: 81 low risk posttransplant patients were included (31±11 y/o), from which 39 were in the low dose group (LD-G) and 42 in the standard dose group (SD-G), both of them with tacrolimus and prednisone. At the end of follow up, an incidence of infectious diseases was reported (46.2% vs 47.6% p=0.9), [RR=1.06, CI (0.44-2.5)], and AR proved with biopsy of (4.8% vs 2.6% p=0.6), [RR=1.9, CI (0.17-19.6)]. The LD-G had a higher tendency for risk of AR without statistical significance and other complications (gastrointestinal manifestations and hematologic diseases) that required hospitalization, which were more frequent in the SD-G (9.5% vs 56.4% p<0.001) [RR= 2.07, CI (1.43- 3.04)].

Conclusions: The use of low doses of MMF has an adequate safety profile in the Mexican population, without increasing the risk of AR or having a significant impact on infections in the post-transplant period, therefore, reducing the presence of adverse effects that require hospitalization.

PUB795

Characteristics of Long-Term Renal Allograft Survivors

Amgad E. El Agroudy.[1,2] *[1]Medicine, College of Medicine and Medical Sciences, Arabian Gulf University, Manama, Bahrain; [2]Nephrology and Transplantation Unit, Salmaniya Medical Complex, Manama, Bahrain.*

Background: We studied the characteristics and the predictors of survival in Bahraini renal transplant recipients with an allograft that functioned for more than 10 years.

Methods: Seventy-eight patients underwent renal transplantation between 1982 and 2007. Among them, 179 patients maintained functioning allografts for more than 10 years (range 10-35 years). Characteristics of the surviving patients, data on graft survival, and determinants of outcome were obtained by reviewing all medical records.

Results: The mean age at time of renal transplantation was 40.1 ± 14.4 years and 70% were males. The cause of end-stage renal disease was diabetic nephropathy in 24.6% and 84% received dialysis therapy before transplantation. The source of the graft in 119 (66%) recipients was from living related donors with a mean age of 29.8 ± 6.6 years, and it was the first graft in 172 recipients. The primary immunosuppression regimen was cyclosporine (CsA) base in 129 patients, tacrolimus (Tac) based in 46 patients while four patients received steroids and azathioprine only. Induction therapy was administered to 96 patients. Acute rejection episodes occurred in 25 patients (14%), of whom three experienced two episodes. During the last follow-up in January 2018, the mean serum creatinine was 118.3 ±46.5 μmol/L. A history of cancer was noted in two patients, whereas hypertension was encountered in 54% and diabetes mellitus in 24%. We compared the graft functioning group with the graft failure group and found that the independent determinants of long-term graft survival included time of late acute rejection episodes and histopathologic findings of chronic allograft damage, post-transplant hypertension and serum creatinine at one year.

Conclusions: We conclude that renal transplantation even in its earliest years and despite the associated numerous complications has provided a ten-year or more of near-normal life to patients with end-stage renal disease.

PUB796

Serum β2-Microglobulin May Predict the Change of Renal Function After Kidney Transplantation

Yoshifumi Hamasaki,[1] Teruhiko Yoshida,[2,3] Rei Isshiki,[1] Akihiko Matsumoto,[1] Kent Doi,[2] Eisei Noiri,[2] Masaomi Nangaku.[2] *[1]The University of Tokyo Hospital, Tokyo, Japan; [2]The University of Tokyo, Tokyo, Japan; [3]National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD.*

Background: Several perioperative factors including histological findings of allograft biopsy are known to be associated with graft function and graft survival after kidney transplantation (KTx). It is unclear what factors in post-KTx period predict the longitudinal change of renal function.

Methods: The data from post-KTx patients who are followed at The University of Tokyo Hospital were collected retrospectively. Patients followed-up less than 6 months after KTx were excluded. To identify predictors of the longitudinal change of renal function, we analyzed data including clinical parameters measured at each outpatient visit. The primary outcome was determined as the eGFR decline (more than 10% or 2 ml/min/1.72m^2 reduction from baseline) during 12 months period.

Results: A total of 38 post-KTx recipients were analyzed in this study. Age and eGFR at baseline of these patients were 51.0 ± 15.4 years old and 43.0 ± 16.1 ml/min/1.73m^2 (mean ± SD), respectively. The duration from KTx to collection of clinical parameters was 7.9 ± 7.3 years. Estimated GFR changes were evaluated 12 months after. When patients were divided into two groups with (N = 14) and without (N = 24) eGFR decline after 12 months, percentage of male (93% vs 63%), serum uric acid (UA, 7.48 vs 6.18 mg/dl), and β2-microglobulin (β2MG, 5.78 vs 2.85 mg/L) were significantly higher and serum albumin (3.98 vs 4.22 g/dl) was significantly lower in the eGFR decline group. On ROC analysis, β2MG and UA predicted eGFR decline after 12 months (AUC [95%CI] = 0.75 [0.58-0.92] and 0.72 [0.53-0.92], respectively). On multiple regression analysis, logarithm of β2MG was significantly correlated with the relative eGFR changes during 12 months observation period (β = -0.50, p = 0.001).

Conclusions: β2MG and UA measured at outpatient clinic may predict the change of renal function of post-KTx patients.

PUB797

Effects of Late Cyclosporine Withdrawal on Graft Function and Survival

Frederic Bauer,[2] Nikolaos Pagonas,[4] Felix S. Seibert,[3] Richard Viebahn,[4] Nina Babel,[4] Timm H. Westhoff.[1] *[1]Ruhr-University Bochum, Germany, Herne, Germany; [2]Ruhr-University Bochum, Herne, Germany; [3]University Hospital Marien Hospital Herne, Herne, Germany; [4]Ruhr University Bochum, Herne, Germany*.

Background: Attempts to discontinue calcineurin inhibitors (CNI) early after renal transplantation without conversion to an alternative immunosuppressive have failed due to high rates of acute rejections. Data on "late CNI withdrawal" are lacking so far.

Methods: The present work provides a matched case-control study on the effects of CNI withdrawal on graft loss and mortality in 90 patients (1500 screened) with advanced graft dysfunction (serum creatinine > 3.5 mg/dl) and a cyclosporine based triple immunosuppressive regimen at the Charité University Hospital, Berlin.

Results: Cyclosporine was withdrawn at a mean of 54.0±32.8 months posttransplant in 45 subjects. Whereas eGFR did not significantly differ between the groups at this time (12.4±2.7 vs. 14.7±8.9 in the control group, p=0.08), it was significantly higher in subjects undergoing withdrawal after 120 months (D 4.1 ml/min; p<0.001). In a Cox regression analysis adjusted for age, gender and eGFR patients with CNI withdrawal showed better survival rates for the combined endpoint death/graft loss (HR (95% CI): 0.19 (0.12-0.33), p=0.001) compared to matched controls. The survival benefit was significant for the endpoints death (p=0.01) and graft loss (p=0.001).

Conclusions: CNI withdrawal was associated with improved survival rates in patients with advanced graft dysfunction in this retrospective analysis.

PUB798

All That Glitters Is Not Gold: CKD Stage 4 Disguised as CKD Stage 4T

Abhilash Koratala, Amir Kazory. *University of Florida, Gainesville, FL*.

Introduction: Steroid-resistant focal segmental glomerulosclerosis (FSGS) is the primary renal disease in approximately 10% of pediatric renal transplant recipients (RTR). While immunosuppressive medications (ISM) are essential for prevention of allograft rejection, they could also potentially portend salutary impact on the underlying disease of the native kidneys.

Case Description: A 38-year-old African American man referred to nephrology clinic to re-establish care for his transplanted kidney after he was lost to follow up for about 20 years. He had a history of end-stage renal disease secondary to FSGS and received a living-related donor kidney transplant at the age of 10. Although he was on dialysis briefly prior to transplant, he was never anuric. Post-transplant, he received azathioprine and prednisone for about 10 years with a baseline serum creatinine (Scr) of 1.6 mg/dL. Then, the patient stopped taking all ISM and lost follow up. At the time of current presentation (Scr 3.4 mg/dL and urine albumin-creatinine ratio 75 mg/g) he was presumed to have developed allograft rejection leading to chronic kidney disease stage 4T as he was taking no ISM for 2 decades. Surprisingly, ultrasound of the right lower quadrant, performed twice, could not identify any allograft tissue due to its significant atrophy and blending in with the hyperechogenic surrounding fat tissue. Therefore, a radionuclide renogram was obtained which confirmed complete absence of flow to the right lower quadrant allograft while perfusion to the native kidneys was present; his renal function was entirely provided by the native kidneys rather that the allograft. Seven years later, his Scr has remained stable with medical therapy without ISM.

Discussion: This patient received azathioprine and steroids for 10 years after transplant prior to stopping ISM. While he lost his allograft afterwards likely due to rejection, the salutary impact of ISM on underlying FSGS of the native kidneys resulted in partial recovery that has lasted for more than 25 years. The main teaching point in this case is that renal function in RTRs could still be partially (or completely) provided by the native kidneys even decades later, as post-transplant ISM could induce remission in certain underlying diseases. In cases where there is a doubt, complementary studies such as radionuclide renogram could be beneficial.

PUB799

Clinical Phenotype of CAKUT May Predict Clinical Course After Kidney Transplantation

Yasar Caliskan,[1,2] Halil Yazici,[2] Erol Demir,[2] Aydin Turkmen,[2] Mehmet S. Sever,[2] Sanjay Jain.[3] *[1]Division of Nephrology, Yale School of Medicine, New Haven, CT; [2]Division of Nephrology, Department of Internal Medicine, Istanbul School of Medicine, Istanbul, Turkey; [3]Washington University School of Medicine, St. Louis, MO*.

Background: Clinical and pathological differences in transplant (tx) recipients, where the cause of end stage renal disease (ESRD) was vesicoureteral reflux nephropathy (VURN) or other congenital anomalies of the kidney and urinary tract (CAKUT) or biopsy confirmed glomerulonephritis (GN) were compared to test the hypothesis that the tx outcomes may differ among these various groups.

Methods: We compared post-tx outcomes of 150 renal tx recipients with non-syndromic VURN (VURN group, 52% male, mean age:28±9 years), 52 tx recipients with CAKUT other than VURN (CAKUT group, 73.1% male, mean age:30±11 years) and 150 tx recipients with GN as the cause of ESRD (GN group: 55.3% male, mean age:31±10 years). Randomly selected renal allograft indication biopsies in each group [VUR (n=16), CAKUT (n=7) and GN (n=19)] were evaluated. Primary outcome was allograft loss and secondary outcome was biopsy-confirmed rejection.

Results: Demographic characteristics of study groups were similar except higher number of males in CAKUT group (p=0.028). Allograft survival rates by Kaplan-Meier analysis at 10 year for VURN, CAKUT and GN groups were 83%, 77.4% and 71.3%, respectively (p=0.21). Patient survival rates were similar among VURN (100%), CAKUT (96.2%) and GN (98.7%) groups during follow up (p=0.08). There was a trend in CAKUT group to develop post-tx donor specific antibodies (9, 17.3%) compared to VURN group (12, 8%) (p=0.05). Biopsy-proven acute rejection rate (BPAR) in VURN, CAKUT and GN groups were 14%, 26.9% and 16%, respectively (p=0.09). BPAR rate and total inflammation score in biopsy were significantly higher in CAKUT group than VURN group (p=0.03 and p=0.05, respectively). Incidence of post-tx VUR was significantly higher in VURN group (19, 12.7%) compared to CAKUT (2, 3.8%) and GN (4, 2.7%) groups (p=0.002). Recurrent allograft pyelonephritis was significantly higher in VURN group (23, 15.3%) compared to CAKUT (2, 3.8%) and GN (6, 4%) groups (p=0.001).

Conclusions: Primary diagnosis of VURN poses an increased risk of VUR and urinary tract infections in kidney allograft and the sustained infection related inflammation may account for reduced rejection rates compared to non-VURN CAKUT and GN patients.

PUB800

Effects of Different Thymoglobulin (r-ATG) and Mycophenolic Acid (MPA) Dosing Regimens on Acute Rejection and BK and CMV Infections

Samuel A. Younan, Bekir Tanriover, Venkatesh Kumar Ariyamuthu, Malcolm Macconmara. *University of Texas Southwestern Medical Center, Dallas, TX*.

Background: There are no randomized clinical trials comparing outcomes of different r-ATG and MPA dosing regimens, as induction and maintenance immunosuppression agents respectively, in renal transplant recipients maintained on tacrolimus, MPA and prednisone.

Methods: We retrospectively reviewed the charts of all adult kidney transplant recipients at our institution from January 2015 to December 2017. We divided our patient cohort into 2 groups. Group-1 received r-ATG 5 mg/kg (standard dose), MPA 540 mg BID (low dose), standard tacrolimus BID dosing, and a fast taper of prednisone down to 5 mg qd in 1 month (N=49). Group 2 underwent r-ATG 3-4.5 mg/kg (low dose), MPA 720 mg BID (standard dose), standard tacrolimus BID dosing, and a slow taper of prednisone down to 5 mg qd in 3 months (N=46). Plasma BK and CMV PCR were checked monthly within 1 year of transplant. Acute rejection (AR) was defined as biopsy proven and treated rejection within 1 year of transplant.

Results: A total of 95 patients were followed post-transplant with a mean follow up of 10 months. The overall graft survival (graft failure or patient death) for both groups is 100% at 1 year. There was no significant difference in 1 year BK & CMV viremia between both groups (BK Group-1 18 % vs. Group-2 15%, p=0.68; CMV Group-1 4% vs. Group-2 13%, p=0.12). Moreover, AR at 1 year did not differ between groups (Group-1 19.5% vs. Group-2 24%, p=0.36). The mean tacrolimus levels at discharge differed significantly between Group-1 (5.9 ng/ml) and Group-2 (7.15 ng/ml) with p=0.04. Of the patients who were BK positive, CMV positive, and rejection positive, there was no significant difference in their mean tacrolimus levels at the time of their positive tests. Lastly, the mean eGFR at 6 months and 1 year were not significantly different between Group-1 and Group-2.

Conclusions: Overall, the rates of BK/CMV viremia and AR at one year in kidney transplant recipients were not significantly different between the standard dose of r-ATG / low dose MPA and low dose r-ATG / high dose MPA groups.

PUB801

Understanding Barriers to Kidney Transplantation Among Adults on Maintenance Dialysis: A Cross-Sectional Study

Sami A. Alobaidi,[1,2] Ahmed Akl,[1,3] Nada Salem,[4] Naji A. Dwid,[1] Fahtima Mehdawi,[1] Abdullah Kashgary,[4,5] Saad S. Alobaili,[5] Wisam H. Al-Badr,[5] Abdulkareem Alsuwaida,[5] Ibrahim A. Jubran,[5] Hanadi M. Alhozali.[4] *[1]Dr. Soliman Fakeeh Hospital, Jeddah, Saudi Arabia; [2]University of Jeddah, Jeddah, Saudi Arabia; [3]Urology & Nephrology Center, Mansoura University, Mansoura, Egypt; [4]KIng Abdulaziz University, Jeddah, Saudi Arabia; [5]DaVita-Saudi Arabia, Riyadh, Saudi Arabia*.

Background: Kidney transplantation (KT) is the treatment offering the best possible long-term outcomes for patients with end-stage renal disease. In Saudi Arabia, KT accounted for only 4.5% of total renal replacement therapy in 2016; the number of KTs performed outside Saudi Arabia in 2016 is not known. The main objective of this study was to evaluate the barriers to KT experienced by patients in Saudi Arabia.

Methods: This cross-sectional study was conducted during the period of September 2017 to January 2018. Direct interviews using a specifically pre-coded and pre-tested online questionnaire were used to examine reasons for low KT rate and the possible barriers to KT in Saudi Arabia.

Results: A total of 321 adult hemodialysis (HD) patients eligible for KT were selected from 4 HD units in Jeddah, representing 11% of the total HD population in Jeddah. Mean patient age was 49.9 ± 14.9 years, 62.1% were male, and 26% were employed. Most patients were of Saudi nationality, only 38 (11.8%) were non-Saudi. Upon interviewing, 90.7% had been counseled for KT. The majority of counselling (86.5%) was done by nephrologists after the start of HD. 178 (55.5%) were referred for pre-transplant evaluation. Among the cohort, 92 (28.6 %) were on the active transplant list. The most common barrier to KT was lack of donor availability (n=107, 40.5%), followed by misconceptions regarding long-term complications for donors (n=58, 22%), and concerns regarding surgical complications (n=24, 9.1%). Only 17 patients (6.4%) reported financial constraint as the main reason for not having a KT; this occurred more frequently among non-Saudi patients.

Conclusions: Misconceptions about KT still represent a substantial barrier among dialysis patients. Most patients are educated about KT after initiation of dialysis. Initiatives to promote and improve pre-dialysis education and knowledge about KT are needed to improve the low transplant rate in Saudi Arabia.

PUB802

Kidney Transplantation in Patients with Neurogenic Bladder

Zeljka Jurekovic,[1] Mladen Knotek.[2] *[1]University Hospital Merkur, Zagreb, Croatia; [2]University of Zagreb Medical School, Clinical Hospital Merkur, Zagreb, Croatia.*

Background: Neurogenic bladder is a condition associated with high incidence of urinary tract infections (UTI) and is a rare cause of end stage renal disease (ESRD), for which kidney transplantation (KT) is performed. There is lack of data in the recent literature on the outcome of KT in adult recipients with neurogenic bladder.

Methods: During 2009-2018 period, six patients with neurogenic bladder were transplanted at the Merkur Hospital. Their medical records were retrospectively analyzed, with aim to evaluate long-term patient and graft survival, as well as UTI and rejection frequency.

Results: The mean ± SD (range) age of the study cohort was 31.6± 11.0 (20-50) years at the time of transplantation. Cause of neurogenic bladder in three patients was spinal cord injury, meningomyelocele in one patient, detrusor areflexia after bladder surgery in one and neurological disorder in one patient. Mean dialysis vintage was 59 ± 32 (0-96) months. All patients had repeated urinary tract infections before and after transplantation. One-year patient and graft survival was 100%. Five-year patient survival was 67%. One patient died 30 months after transplantation due to squamous cell bladder cancer, with a functioning graft and one kidney graft lost its function 60 months after transplantation due to BKV nephropathy. 5/6 patients required either intermittent, or permanent bladder catheterization after KT. During the mean follow-up of 1206 ± 1106 (102-3092) days, there was a mean number of 14.3±10.4 (5-34) urinary infection episodes requiring antibiotic therapy and mean number of 3.8±1.5 (2-6) urinary tract infections requiring hospitalization and intravenous antibiotic therapy. Two patients had one episode of acute cellular rejection (IA), which was treated by bolus of steroids. Mean serum creatinine in patients with graft function on the last visit was 84.6 ± 21.8 (56-109) μmol/L.

Conclusions: Acceptable long-term patient and graft survival, graft function and serious UTI rates can be achieved in patients with ESRD attributable to neurogenic bladder. The fact that KT can be successfully performed in patients with neurogenic bladder is especially important, because this population often consists of younger patients with longer life expectancy.

PUB803

Adenovirus Infection Case-Series in Kidney Allograft Recipients at Hospital do Rim

Alejandro Zapata,[1] Renato D. Foresto,[1] Maria A. Hazin,[1] Daniel wagner C. Santos.[2] *[1]Nephrology division, Federal University of São Paulo, São Paulo, Benin; [2]Federal University of Sao Paulo, Sao Paulo, Brazil.*

Background: Adenovirus infection is an important cause of complications in renal transplant patients that carries potential risks of loss of graft function and death. Hence, we attempted to describe the main characteristics of the affected patients with such a disease in our population during 2017.

Methods: We described the clinical and laboratory features of renal transplantation recipients coursing with adenovirus infection after kidney transplantation at the time of diagnosis at Hospital do Rim during 2017. These included main symptoms at onset, duration, time from transplantation to disease, time from onset to negative viremia, time to creatinine improvement, time to clinical response, association with other infections and immunosuppression description.

Results: Adenovirus infection occurred in 6 patient transplanted during 2017. All of the patients received 3 mg x kg of rabbit anti-thymocyte globulin as induction, all of them used prednisone and calcineurin inhibitor according to institutional protocols, 4 used azathioprine and 1 received everolimus as third drug. All of the living donor kidney recipients who developed infection did it during the first year(n=3), two of them during the first month, compared with deceased recipients (23rd month, range 17-30 months). The main symptoms at onset where fever (n=6), macroscopic hematuria (n=5) and dysuria (n=5). The mean time to negative viremia from onset of symptoms was 21 days. Interestingly, the duration of the symptoms was 13 days (7-18 days) meanwhile the lowest creatinine value after the event was reached at 26th day (14-39 days). The loss of allograft function was 9 ml/min/1.73m2 (8-32 ml/min/1.73m2) assessed by CKD-Epi formula. Co-infection with CMV happened in 1 case. The mean hospitalization time was 26 days (9-55days). Management of adenovirus infection included adjusting immunosuppression in all the cases. Two patients suspended azathioprine, one suspended everolimus and two patients received IV immunoglobulin. All of the patients survived to infection and one of them developed a new episode subsequently.

Conclusions: Adenovirus infection in transplant patients must be considered as an alternative hypothesis to urinary tract infection, mainly during the first months of transplantation in living donor recipients. Its prompt management could preserve allograft function.

PUB804

Severe Hyponatremia with Intraoperative Desmopressin Use in (Deceased and Living Donor) Renal Transplant Recipients

Mandeep S. Gill,[1] Sarat C. Kuppachi,[1] Christie P. Thomas.[2] *[1]University of Iowa, Iowa City, IA; [2]University of Iowa College of Medicine, Iowa City, IA.*

Background: Desmopressin (DDAVP) is used for hemostasis in patients with factor VIII deficiency, von Willebrand disease and platelet function defects including that seen in patients with chronic kidney disease. A serious consequence of its use is water intoxication with attendant hyponatremia. We studied the incidence of hyponatremia in patients who received desmopressin during kidney transplant (KT) surgery.

Methods: We retrospectively analyzed the incidence of hyponatremia (Na < 135) and severe hyponatremia (Na < 130) in the first 48 hrs following DDAVP used during KT surgery at our center between 2009-2018. We compared the incidence of hyponatremia in the first 48 after surgery with a control group of living and deceased KT recipients who did not receive DDAVP but were administered the same post-operative fluid protocol that the study group received. Relative risk (RR) and Fishers exact t test p values were used to determine the significance of differences between the two groups.

Results: 22 patients met the inclusion criteria. 17 (77.3%) patients developed hyponatremia, and 8 (36.4%) developed severe hyponatremia (Mean 125.3, SD 3.93) (Table 1). In 25 controls (living donor 4; deceased donor 21) hyponatremia was noted in 17 (68%), but no patient developed severe hyponatremia. There was no significant difference between the groups for the incidence of hyponatremia (RR 1.13 [0.7-1.62], p=0.35). However, severe hyponatremia was noted only in patients who received DDAVP; 3 out of 4 living KT recipients (75%) and 4/18 (22.2%) deceased donor recipients (p = 0.0027).

Conclusions: In this retrospective analysis of the incidence of hyponatremia, among KT recipients who were given DDAVP for intraoperative hemostasis, there was a significantly higher incidence of severe hyponatremia (75% of living KT recipients, and 22.2% of deceased recipients) compared to patients who did not receive DDAVP. Although larger retrospective analyses are required to further validate these findings, the risk of severe hyponatremia should be acknowledged and anticipated if patients are administered DDAVP during KT surgery.

Recipients	Na (mEq/L)	DDAVP (%)	No DDAVP (%)
Living Donor	< 135	4/4 (100)	3/4 (75)
	<130	3/4 (75)	0 (0)
Deceased Donor	< 135	13/18(72.2)	14/21 (66.67)
	<130	4/18 (22.22)	0 (0)

Early Evidence of the Association Between Gout and Higher Mortality Rates in the Prevalent Solid Organ Transplant Population

Justin W. Li,[1] Marissa Suh,[1] Herman Sanchez,[1] Jeffrey Kent,[2] Brian Lamoreaux,[2] Richard J. Johnson.[3] *[1]Trinity Partners, Waltham, MA; [2]Horizon Pharma, Lake Forest, IL; [3]University of Colorado Denver, Aurora, CO.*

Background: There is evidence that gout may be associated with higher mortality risk in kidney transplant recipients, though little data is available in other transplant types. Existing literature has focused on the association between new onset gout and mortality in the incident transplant population. Important questions remain regarding the impact of gout on transplant outcomes beyond the initial post-transplant timeframe and on other solid organ transplant (SOT) types. This retrospective patient claims data analysis was performed to determine whether an association between gout and mortality exists in the prevalent SOT population.

Methods: 2015 gout prevalence among the prevalent SOT population was assessed in 2 administrative claims databases: Medicare Fee-For-Service Limited Data Set (5% sample) and a commercial claims sample (IQVIA™ Real-World Data Adjudicated Claims – US). Definitions used were – SOT: a claim with an SOT procedure code OR any claim with a history of SOT status diagnosis code, limited to kidney, liver, and heart; Gout: ≥1 claim with any gout diagnosis code. Univariate analysis included 2016 mortality for patients in the gout / non-gout SOT cohorts identified in calendar year 2015 and still living in 2016.

Results: In the Medicare SOT population, 2016 mortality was higher among kidney transplant patients with gout vs. those without gout (9.6% vs. 7.1%, p=0.013). In the commercially insured SOT population, 2016 mortality was higher among patients with gout for both kidney (3.0% vs. 2.3%, p=0.022) and heart (5.3% vs. 3.2%, p=0.045) recipients. No significant differences in mortality were observed in either population for liver transplant recipients.

Conclusions: The higher mortality risk observed in the surviving kidney transplant population for those with vs. without gout, regardless of insurance provider, reveals an important initial finding and demonstrates a potential unmet need in this population. While gout appears to be associated with a greater risk in this analysis, further risk-adjusted studies are warranted to determine whether gout is an independent driver of mortality, as well as other poor outcomes, in the prevalent SOT population.

PUB806

Impact of Cardiac Function on Allograft Survival in a Cohort of Mexican Transplant Recipients

Viridiana Rodriguez,[4] Priscila B. Villalvazo,[5] Jorge Andrade-Sierra,[2,1] Benjamin Gomez-Navarro,[3] Milagros M. Flores Fonseca.[1] *[1]Centro Medico Nacional de Occidente, Guadalajara, Mexico; [2]Universidad De Guadalajara, CUCS, Guadalajara, Jalisco Mexico, Mexico; [3]IMSS, HECMNO, Zapopan, Jalisco, Mexico; [4]Instituto Mexicano Del Seguro Social, Guadalajara, Mexico; [5]IMSS, Zapopan, Jaliscco, Mexico*.

Background: Cardiovascular disease is a major cause of morbidity and mortality among patients who undergoes kidney transplant (KT). Asymptomatic cardiac changes cause during CKD, could lead to perioperative complications and mortality as well as poor graft and patient survival. The purpose of this study was to evaluate the impact systolic ventricular function and pulmonary arterial pressure in patients with CKD and the outcomes after KT.

Methods: The study included 150 patients over 18 years of age with CKD who had a successful KT. Ventricular function and pulmonary arterial pressure were assessed by echocardiographic standard parameters before and 6 months after transplant.

Results: Mean age was 31.99 ± 11.28 years, and 65% were women. Before transplant, mean ventricular ejection fraction (VEF) was 58% and pulmonary arterial pressure was 32 mmHg. Ventricular dysfunction was associated with unclamping donor renal vessels at 107.8 ± 7.96mmHg, and lower perioperative hemodynamics values. The LVEF group increased from 25% to 72.5%, and serum creatinine decrease from 2.25 ± 3.76 mg/dl to 1.98 ± 2.65 mg/dl ($p<0.001$) by 6 months after kidney transplant. The best set of predictors in multiple regression analysis for renal function were the onset of diuresis and the use of diuretics ($R2 = 0.4$; $p < 0.001$).

Conclusions: Patients with LVEF should not be excluded from KT. These results showed the relationship between ventricular function and lower perioperative vasopressors and diuretics and its association on the graft function. Further studies are needed to determine if after KT there is an improvement as well on cardiac structure.

PUB807

Short-Term Outcomes of Kidney Transplantation in Patients with Preformed DSA: University Malaya Medical Centre Experience

Maisarah Jalalonmuhali,[1] Soo Kun Lim,[2] Kok Peng Ng.[1] *[1]University Malaya Medical Centre, Kuala Lumpur, Malaysia; [2]Univeristy Malaya Medical Centre, Kuala Lumpur, Malaysia*.

Background: The shortage of deceased donors led to an increase of living related renal transplant (LRRT) performed in the presence of donor-specific antibodies (DSAs) or ABO incompatibility (ABOi). Various desensitization protocols have been used in order to reduce the incidence of antibody mediated rejection (ABMR). Here, we described our short-term outcomes in patients with preformed DSAs using our desensitization protocol.

Methods: This is a prospective, cohort study recruiting all kidney transplant recipients from August 2016 till February 2018. Cadaveric, ABO incompatible and those sensitized patients who were not prescribed on our desensitization protocol were excluded. Our desensitization protocol consisted of anti-CD20 (Rituximab) and plasma exchanges post transplantation. However, MFI≥3000 or positive flow cytometry will receive extra cycles of plasma exchanges prior to transplantation. Clinical outcomes: immediate graft function, serum creatinine at 3 months, incidence of acute rejection (borderline, acute T-cell mediated and ABMR), de novo DSAs and infections (CMV and BKV) were documented.

Results: A total of 26 LRRT patients were recruited (11 patients DSAs positive and 15 patients in low risk group). Mean age was 37.45 ± 11.68 and 37.07 ± 12.09 for DSAs' group and low risk group respectively. Both groups had 3 HLA mismatches (median). Immediate post-transplant 1 patient from DSAs' group had slow graft function (prolong warm ischaemic time) and 1 patient from low risk group also had slow graft function (TTP/HUS secondary to CNI). All other patients had immediate graft function. Mean creatinine at 3-month was 109.25 ± 27.28 mmol/L for DSAs' group and 124.47± 40.16mmol/L in low risk group. At 3-month 2 patients (18%) had borderline rejection from DSAs' group and 7 patients (47%) from low risk group, 1 patient from low risk group had acute T-cell mediated rejection and none developed ABMR. Two patients from low risk group had also developed de novo DSA. There was no incidence of BKV. However, 5 patients had CMV viraemia and 1 patient had disease.

Conclusions: We demonstrated favorable short-term allograft survival and function after renal transplantation (immediate graft function, stable serum creatinine and no development of denovo DSA at 3-month) using desensitization with anti-CD20 and plasma exchange in patients with preformed DSA.

PUB808

Intestinal Perforation by Schistosoma mansoni in a Kidney Transplant Patient: Case Report

Saulo J. Feitosa,[1,2] Frederico C. Cavalcanti,[2] Ana C. Souza.[2] *[1]Universidade Federal de Pernambuco, Recife, Brazil; [2]Real Hospital Português de Beneficência em Pernambuco, RECIFE, Brazil*.

Introduction: Schistosomiasis is endemic in several regions of Brazil and is a public health problem. Caused by *Schistosoma mansoni*, it can present with gastrointestinal symptoms in its chronic form; its presentation with colitis and intestinal perforation is rare, even more so among kidney transplant patients.

Case Description: We present the case of a 56-year-old female patient who underwent kidney transplant in October 2013 and developed chronic allograft nephropathy due to chronic rejection. In February 2018 she was hospitalized with complaints of severe abdominal pain and intestinal constipation for 3 days, and had signs of peritonitis on physical exam. Computed tomography of the abdomen showed signs of colitis and pneumoperitoneum. On the same day of hospitalization, the patient was submitted to exploratory laparotomy, with the finding of a rectum-sigmoid perforation. Hartmann's colectomy with biopsy of the lesion were performed. The patient developed septic shock and acute-on-chronic kidney injury requiring hemodialysis in the postoperative period. The patient was treated with Meropenem based on results of peritoneal fluid cultures. Because Cytomegalovirus (CMV) is a more common cause of intestinal perforation among kidney transplant patients, serum PCR for CMV was performed and came back positive with 6656 copies and the patient was treated with intravenous Ganciclovir until a result with zero copies was obtained. The histopathological study showed active peritonitis with active granulomatous colitis associated with serosal perforation and the presence of viable eggs of *Schistosoma mansoni* in the intestinal mucosa. The patient was treated with praziquantel evolving with clinical improvement and partial recovery of kidney graft function, being discharged in April 2018, awaiting reconstruction of the intestinal transit.

Discussion: In endemic regions for schistosomosis, all kidney transplant candidates must be empirically treated with praziquantel for one month before the transplant, and schistosomosis must be included in the differential diagnosis of intestinal perforation in immunossupressed patients.

PUB809

Impact of the Kidney Donor Profile Index (KDPI) on Kidney Transplants Outcomes in a Tertiary Hospital in Brazil

Saulo J. Feitosa,[1,2] Ana C. Souza,[2] Frederico C. Cavalcanti,[2] Lucila Maria Valente.[1] *[1]Universidade Federal de Pernambuco, Recife, Brazil; [2]Real Hospital Português de Beneficência em Pernambuco, RECIFE, Brazil*.

Background: Due to the disproportionate relationship between supply and demand of organs, a more complete analysis of the deceased kidney donor is necessary to avoid organ discard. The KDPI is used to estimate how long a deceased donor kidney is expected to function relative to all of the kidneys recovered in the United States of America during the last year, but there is a lack of data regarding KDPI in Brazil.

Methods: A retrospective analysis of medical records of 73 patients submitted to kidney transplant from deceased donors was performed. The transplants ocurred between January and December 2014 in a referral tertiary hospital in Brazil. Stratified KDPI values (less than 20%, 20-40%, 41-60%, 61-80% and more than 80%) were correlated with recipients glomerular filtration rate (CKD-EPI), biopsy-proven rejection episodes and loss of graft function at 1 and 3 years post transplantation. All statistical analysis were made using StatPlus for Mac version 6.

Results: Kidney recipients mean age was 46.2 (SE +/- 1,3) years and 76.7% were male. They had 6.6 (SE +/- 0,4) years of dialysis prior to transplantation and 83.5% had low immunological risk (PRA: 0%). Mean KDPI value was 48.4% (SE +/- 3,2). The mean GFR distribution at 1 year was: less than 20%: 74.5 (SE +/- 8) ml/min (N = 10), 20-40%: 66.5 (SE +/- 6,7) ml/min (N = 17), 41-60%: 62.9 (SE +/- 8,6) ml/min (N = 13), 61-80%: 49.1 (SE +/- 8,3) ml/min (N = 9) and more than 80%: 42.1 (SE +/- 7,3) ml/min (N = 7), $p = 0.09$. In the 3-year analysis we observed: less than 20%: 68.4 (SE +/- 7,3) ml/min (N = 10), 20-40%: 59.4 (SE +/- 5,3) ml/min (N = 17), 41-60%: 53.6 (SE +/- 6,7) ml/min (N = 13), 61-80%: 42.3 (SE +/- 8,6) ml/min (N = 9) and more than 80%: 33.6 (SE +/- 7,1) ml/min (N = 7), $p = 0.03$. The percentages of biopsy-proven rejection episodes at 3 years were: less than 20%: 16.6%, 20-40%: 15%, 41-60%: 26.6%, 61-80%: 35.7%, more than 80%: 66.6%, and regarding complete loss of graft function at 3 years: less than 20%: 16.6%, 20-40%: 10% 41-60%: 13.3%, 61-80%: 35.7% and more than 80%: 41.6%.

Conclusions: In our study, patients who received kidneys from donors with higher KDPIs did have worse outcomes regarding GFR, biopsy-proven rejection episodes, and loss of the allograft.

PUB810

Clinical Significance of C4d Deposition in ABO-Compatible Renal Allografts Without Histologic or Serologic Evidence of Antibody Mediated Rejection

Esther Park,[1] Meghan Pearl,[2] Sunee Panombualert,[1] Patricia L. Weng,[1] Robert B. Ettenger,[2] Jonathan E. Zuckerman.[1] *[1]UCLA, Los Angeles, CA; [2]Mattel Children's Hospital at UCLA, Los Angeles, CA.*

Background: Antibody-mediated rejection (AMR) is a leading cause of allograft loss in kidney transplant recipients (KTRs). C4d, a product of the classical complement pathway, with morphologic changes on graft biopsy and/or detectable circulating donor specific antibodies (DSAs) is diagnostic of active AMR. The clinical significance of C4d positivity alone is undetermined. We aimed to evaluate clinical outcomes in adult and pediatric ABO-compatible, DSA negative, KTRs with isolated C4d positivity.

Methods: This was a retrospective chart review to identify adult and pediatric KTRs transplanted between 2009-2017 with isolated C4d positivity on biopsy and at least 1 year of post-biopsy follow up. Isolated C4d positivity was defined as C4d + (> 1+ by immunofluorescence in peritubular capillaries) without other findings of AMR and without DSA positivity. Patients with concomitant acute cellular rejection (ACR) were included. Protocol biopsies were performed on pediatric KTRs at 6, 12, and 24 months post-transplant and for clinical suspicion of rejection. Only clinically indicated biopsies were performed in adult KTRs.

Results: 11 patients had isolated C4d positivity. C4d was focal in 7/11 (75%) and diffuse in 4/11 (36%). 4/11 (36%) had ACR and were all treated with steroids, 1 patient received anti-thymocyte globulin (ATG), and 1 patient received IVIG. At 1-year post-biopsy, 6/11 (55%) had repeat biopsies and 6/11 (55%) had DSA testing. None of these patients developed AMR and 2 patients developed DSAs (Figure 1A). The mean change in eGFR between time of biopsy and 1 year post-biopsy was +6.1mL/min/1.73m^2(Figure 2A).

Conclusions: This case series provides preliminary evidence that isolated C4d positivity in ABO-compatible, DSA negative allografts does not correlate with deterioration of renal function, development of DSA, or development of AMR within 1 year following the incident biopsy. Further studies are needed to better understand the impact of isolated C4d positivity on allograft outcomes to better tailor monitoring and treatment.

Patient	C4d	C4d Intensity	ACR	Treatment	AMR in repeat biopsies	DSAs in repeat labs
1	Focal	2+	No	NA	Not tested	No
2	Focal	2+	No	NA	No	No
3	Diffuse	1+	Borderline	Steroids, ATG	No	Yes
4	Focal	3+	Borderline	Steroids	Not tested	Not tested
5	Diffuse	3+	Borderline	Steroids	No	No
6	Focal	1+	No	NA	No	Yes
7	Focal	1+	ACR1A	Steroids	No	No
8	Focal	2+	No	Steroids	Not tested	Not tested
9	Diffuse	1+	No	NA	No	Not tested
10	Diffuse	2+	No	IVIG	Not tested	Not tested
11	Focal	3+	No	NA	Not tested	Not tested

Figure 1A: Patient Biopsy and Clinical Characteristics. Characteristic of C4d positivity, presence or absence of ACR, treatment regimen and presence or absences and AMR and HLA DSA within 1 Year post-biopsy are shown.

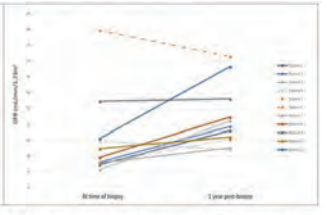

Figure 2A: Renal Function at Time of Biopsy and 1Year Post-Biopsy. GFR was measured at time of biopsy and 1-year post-biopsy to trend renal graft function.

Effect of Linagliptin on Kidney and Cardiovascular Outcomes in Patients with Type 2 Diabetes and Kidney Disease: CARMELINA®

Vlado Perkovic,[1] Robert D. Toto,[2] Mark E. Cooper,[3] Odd Erik Johansen,[4] Julio Rosenstock,[5] Darren K. Mcguire,[6] Steven E. Kahn,[7] Nikolaus Marx,[8] John H. Alexander,[9] Bernard Zinman,[10] David Baanstra,[11] Egon Pfarr,[12] Sven Y. Schnaidt,[12] Thomas Meinicke,[13] Jyothis T. George,[12] Maximilian von Eynatten,[12] Christoph Wanner.[14] *[1]The George Institute for Global Health, Newtown, NSW, Australia; [2]University of Texas Southwestern Medical Center, Dallas, TX; [3]Monash University, Melbourne, VIC, Australia; [4]Boehringer Ingelheim Norway, Asker, Norway; [5]Dallas Diabetes Research Center at Medical City, Dallas, TX; [6]UT Southwestern Medical Center at Dallas, Dallas, TX; [7]University of Washington, Seattle, WA; [8]University Hospital Aachen, Aachen, Germany; [9]Duke Clinical Research Institute, Durham, NC; [10]Mount Sinai Hospital, Toronto, ON, Canada; [11]Boehringer Ingelheim, Alkmaar, Netherlands; [12]Boehringer Ingelheim, Ingelheim, Germany; [13]Boehringer Ingelheim International GmbH, Biberach, Germany; [14]University Hospital, Wuerzburg, Germany*.

Background: Type 2 diabetes (T2D) is a common cause of ESKD so the effects of glucose-lowering therapies on kidney outcomes are of great interest, especially in people with CKD.

Methods: CARMELINA (NCT01897532) randomized people with T2D and prevalent CKD (UACR >30 mg/g with concomitant CV disease, OR eGFR 45-75 ml/min/1.73m^2 and UACR > 200 mg/g OR eGFR 15-45 regardless of UACR) to receive double-blind linagliptin (5 mg, a DPP inhibitor) or placebo QD. The primary CV endpoint was 3P-MACE, with a key secondary kidney endpoint (adjudicated ESKD, renal death, or sustained ≥40% decrease in eGFR from baseline). Other renal outcomes included albuminuria and eGFR slope. Subgroups were assessed by baseline eGFR (≥/<45 and ≥/< 30, 45 or 60 ml/min/1.73m^2).

Results: 6979 participants (mean age 66 yrs, HbA1c 8.0%, eGFR 54.6 ml/min/1.73m^2, 43% eGFR ≤45, and 80% UACR ≥30 mg/g) from 27 countries were followed for median 2.2 yrs. Linagliptin reduced albuminuria progression and albuminuria levels (table), but eGFR-slope was unaffected. Rates of the secondary kidney endpoint (HR 1.04 [0.89, 1.22]) and renal death, or sustained ESKD (0.87 [0.69, 1.10]), as well as 3P-MACE and hospitalization for heart failure (table) were similar between groups. Incidence rates were higher with reduced eGFR, however, results were consistent across subgroups (p heterogeneity >0.1).

Conclusions: Linagliptin slowed progression of albuminuria, without affecting eGFR slope or other kidney outcomes. Linagliptin also demonstrated CV safety including in patients with advanced CKD where clinical evidence has been particularly scarce.

High-Dose Versus Low-Dose Intravenous Iron Therapy in Hemodialysis: The PIVOTAL Trial

Iain C. Macdougall,[1] Claire White,[1] Stefan D. Anker,[7] Sunil Bhandari,[2] Ken Farrington,[3] Philip A. Kalra,[4] John McMurray,[6] Heather M. Murray,[6] Charles Tomson,[8] David C. Wheeler,[5] Christopher G. Winearls,[9] Ian Ford.[6] on behalf of the PIVOTAL Study Group *[1]King's College Hospital, London, United Kingdom; [2]Hull and East Yorkshire Hospitals NHS Trust and Hull York Medical School, East Yorkshire, United Kingdom; [3]Lister Renal Unit, Hitchin, United Kingdom; [4]Salford Royal Hospital NHS Trust, Salford, United Kingdom; [5]University College London, London, United Kingdom; [6]University of Glasgow, Glasgow, United Kingdom; [7]Charité Medical School, Berlin, Germany; [8]Freeman Hospital, Newcastle upon Tyne, United Kingdom; [9]The Churchill Oxford Radcliff Hospital, Oxford, United Kingdom*.

Background: Intravenous (IV) iron is widely used in the management of anemia in hemodialysis (HD) patients, but very little scientific evidence guides its appropriate use. The Proactive IV irOn Therapy in haemodiALysis patients (PIVOTAL) trial (EudraCT 2013-002267-25) was designed to compare the effects of 2 distinct IV iron dosing regimens on "hard" clinical outcomes, including mortality and cardiovascular (CV) events, as well as infection risk among HD patients.

Methods: In this multicenter, open-label, blinded endpoint, controlled trial, 2141 incident HD (<12 mo) patients receiving erythropoiesis-stimulating agents (ESAs) were randomly assigned (1:1) to a proactive, high-dose IV iron regimen (iron sucrose 400 mg monthly unless ferritin >700 µg/L and/or TSAT ≥40%) or a reactive, low-dose IV iron regimen (iron sucrose administered if ferritin <200 µg/L or TSAT <20%). The primary outcome was nonfatal myocardial infarction, nonfatal stroke, hospitalization for heart failure, or death, analyzed as time to first event. The hazard ratio (HR) for noninferiority was set at 1.25. Secondary endpoints included all-cause death, infection, and ESA dose.

Results: The median duration of follow-up was 2.1 years (max: 4.4 yr). Patients in the proactive, high-dose IV iron arm received a median (lower quartile [LQ], upper quartile [UQ]) monthly iron dose of 264 (200, 336) mg compared with 145 (100, 190) mg in the reactive, low-dose arm. Median monthly ESA doses were 19.7% lower in the high-dose arm (P<0.001). The incidence of the primary outcome was numerically lower in the high-dose arm than the low-dose arm (30.5% vs 32.7%; adjusted HR [95% CI]: 0.88 [0.76–1.03]; P<0.001 for noninferiority; P=0.11 for superiority). Rates of all-cause death, hospitalization, and infection were similar between the two arms (Table).

Conclusions: Among HD patients, the use of higher doses of IV iron significantly reduced ESA dose requirements without negatively affecting mortality or the incidence of nonfatal CV endpoints.

Funding: Government Support - Non-U.S.

Selected secondary endpoints

Outcome	Proactive, High-Dose IV Iron (N=1093)	Reactive, Low-Dose IV Iron (N=1048)	Estimated Treatment Effect	P Value
All-cause death	22.5%	25.7%	HR (95% CI): 0.84 (0.71–1.00)	0.054
All-cause hospitalization	59.6%	58.8%	HR (95% CI): 1.01 (0.90–1.12)	0.90
Hospitalization for infection	29.6%	29.3%	HR (95% CI): 0.99 (0.85–1.16)	0.92
All-cause death or myocardial infarction or stroke or hospitalization for heart failure as recurrent events, rate per 100 patient-years	20.63	26.10	Rate Ratio (95% CI): 0.78 (0.66–0.92)	0.003

Safety and Effectiveness of Bexagliflozin in Type 2 Diabetes Mellitus and Stage 3a/3b CKD: A Phase 3 Randomized Clinical Trial

Andrew S. Allegretti,[1] Tara K. Thurber,[1] Wenbin Zhang,[2] Wenjiong Zhou,[3] Mason W. Freeman,[4] Yuan-Di C. Halvorsen.[1] *[1]Massachusetts General Hospital, Boston, MA; [2]Shanghai JiaYue PharmaTech Ltd, Shanghai, China; [3]FMD K&L, Langhorne, PA; [4]Massachusetts General Hospital, Harvard Medical School, Boston, MA*.

Background: Hyperglycemia exacerbates the progression of chronic kidney disease (CKD), but most glucose-lowering therapies seldom address morbidities associated with CKD. Sodium-glucose cotransporter-2 (SGLT2) inhibitors offer potential benefits to diabetics with CKD but their utility may be diminished with impaired renal function.

Methods: A phase 3, double-blind, placebo-controlled, multi-center, multi-national, randomized trial was conducted to evaluate the safety and effectiveness of bexagliflozin, a novel SGLT2 inhibitor, in patients with type 2 diabetes and stage 3a/3b CKD. Patients were randomly assigned to receive bexagliflozin or placebo for 24 weeks. The placebo-adjusted change in hemoglobin A_{1c} was the primary endpoint. Secondary endpoints were changes in body weight, systolic blood pressure, albuminuria, fasting plasma glucose and hemoglobin A_{1c} stratified by CKD 3a/3b status. Efficacy data were analyzed using repeated measures methodology with intent to treat population to demonstrate treatment effects at 24 weeks.

Results: 312 patients across 54 sites were analyzed. Bexagliflozin lowered hemoglobin A_{1c} by 0.37% (95% CI 0.20, 0.54, p <0.0001) compared to placebo. Patients with CKD stage 3a (eGFR 45 to <60) and 3b (eGFR 30 to <45) had reductions in hemoglobin A_{1c} of 0.31% (p = 0.0068) and 0.43% (p = 0.0017), respectively. Bexagliflozin lowered body weight (1.61 kg, p <0.0001), systolic blood pressure (3.8 mmHg, p = 0.02), fasting plasma

Underline represents presenting author/disclosure.

glucose (0.76 mmol/L, p =0.0029) and albuminuria (geometric mean ratio reduction of 20.1%, p = 0.027). Adverse events were comparable between groups.

Conclusions: Bexagliflozin was effective for lowering hemoglobin A_{1c} in diabetic patients with stage 3a/3b CKD and was well tolerated. Additional benefits in this population were reduction in body weight, systolic blood pressure, fasting plasma glucose and albuminuria.

Cardiovascular Safety of Methoxy Polyethylene Glycol-Epoetin Beta in Treatment of Anemia of CKD

Francesco Locatelli,[1] Thierry P. Hannedouche,[2] Steven Fishbane,[3] Zoe Morgan,[4] Delphine Oguey,[4] William B. White.[5] *[1]Alessandro Manzoni Hospital, ASST Lecco, Lecco, Italy; [2]University of Strasbourg School of Medicine, Strasbourg, France; [3]North Shore University Hospital, New York, NY; [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland; [5]University of Connecticut School of Medicine, Farmington, CT.*

Background: Erythropoiesis-stimulating agents (ESAs) may increase the risk of cardiovascular events when used in the treatment of anemia of CKD. We compared cardiovascular outcomes and all-cause mortality for monthly methoxy polyethylene glycol-epoetin beta (continuous erythropoietin receptor activator, C.E.R.A.) with those of reference ESAs epoetin alfa/beta and darbepoetin alfa in the MIRCERA Post-Approval Safety Study (PASS).

Methods: MIRCERA PASS was a prospective, multicenter, open-label, blinded endpoints, non-inferiority trial. CKD patients with anemia were randomized either to start or switch to C.E.R.A., or to a reference ESA for correction or in the maintenance setting. The primary endpoint was the composite of all-cause mortality and non-fatal myocardial infarction or stroke, adjudicated by an independent committee unaware of treatment assignment. Non-inferiority was defined as the two-sided 95% confidence interval (CI) upper boundary of the hazard ratio [HR] <1.2.

Results: 2825 patients were randomized between December 2008 and November 2011 and 2818 were treated for a median of 3.4 years (maximum 8.5 years). The primary endpoint occurred in 640/1409 patients (45.4%) in the C.E.R.A. arm and 644/1409 (45.7%) in the reference ESAs arm (HR 1.03; 95% CI, 0.93–1.15; p=0.0039 for non-inferiority). Subgroup analyses showed no significant differences between treatment groups for patients on dialysis or not, those with or without diabetes, or in the maintenance or correction setting. Similar findings were seen for individual components of the primary endpoint, all-cause mortality (HR 1.06, 95% CI 0.94–1.19), and non-fatal myocardial infarction or stroke (HR 0.91, 95% CI 0.74–1.12). Mean hemoglobin was maintained at 10–12 g/dL throughout the trial and was comparable between treatment arms, as were serum iron parameters. Gastrointestinal bleeding and thromboembolic events were also similar between treatment groups. No patient developed antibody-mediated pure red cell aplasia.

Conclusions: In patients with anemia of CKD, long-term treatment with monthly C.E.R.A. resulted in overall rates of major cardiovascular events and all-cause mortality similar to those associated with reference ESAs administered more frequently. Study registered at clinicaltrials.gov (NCT00773513).

Comparison of Lanthanum Carbonate and Calcium Carbonate in the Cardiovascular Mortality and Morbidity of Hemodialysis Patients

Hiroaki Ogata,[1] Masafumi Fukagawa,[2] Hideki Hirakata,[3] Tatsuo Kagimura,[4] Tadao Akizawa.[1] LANDMARK Study Group *[1]Showa University School of Medicine, Yokohama, Japan; [2]Tokai University School of Medicine, Isehara, Japan; [3]Fukuoka Renal Clinic, Fukuoka City, Japan; [4]Translational Research Center for Medical Innovation, Kobe, Japan.*

Background: The multicenter LANDMARK study (NCT01578200/UMIN000006815) is a randomized, open-label, parallel assignment study comparing the effects of a non-Ca P binder, lanthanum carbonate (LC), with the effects of calcium carbonate (CC) on cardiovascular mortality and morbidity in hemodialysis (HD) patients.

Methods: A total of 2309 hemodialysis patients with at least one risk factor for vascular calcification (VC) (age >65 years, postmenopausal women, type 2 diabetes); intact parathyroid hormone ≤240pg/mL; and life expectancy >1 year were randomly assigned to the LC (n = 1154) or CC (n =1155) group. In the LC group, patients initially received 750 mg/day of LC (or their previous dose) and were titrated up to a maximum of 2250 mg/day to achieve serum P levels of 3.5 to 6.0 mg/dL. In the CC group, patients received 3 g/day of CC (or their previous dose), and were titrated to achieve the same target serum P levels. If these levels were not achieved with the maximum tolerated dose, non-Ca P binders were given to those in the LC group, and P binders other than LC to those in the CC group. The primary endpoint was survival time free of cardiovascular events (CVEs), including cardiovascular death, nonfatal myocardial infarction or stroke, and unstable angina.

Results: A total of 2135 patients (female 40.5%, 68.4 years, diabetes 56.1%) were analyzed in this study. After a median follow-up of 3.16 years, the incident rates of CVEs were 4.80 (/100 patient-years) in the LC group and 4.30 in the CC group, and there was no significant difference in the adjusted hazard ratio (HR) between the two groups (1.11 [95%CI, 0.88–1.41], P = 0.366; log rank test. There is also no significant difference in all-cause death between the LC and CC groups (HR 1.10 [95%CI, 0.88–1.37], P = 0.424).

Conclusions: The non-Ca P binder, LC, did not reduce CVEs as compared with CC among long-term HD patients with high risk of VC.

Effect of a Restrictive Versus Liberal Approach to Red Blood Cell Transfusion on AKI in Patients Undergoing Cardiac Surgery

Amit X. Garg,[1] C. David Mazer.[2] TRICS Investigators *[1]London Health Sciences Centre, London, ON, Canada; [2]St. Michael's Hospital, University of Toronto, Toronto, ON, Canada.*

Background: Safely reducing red blood cell transfusions avoids transfusion-related adverse effects, conserves the blood supply, and reduces healthcare costs. We conducted a prespecified substudy of the Transfusion Requirements in Cardiac Surgery-III (TRICS-III) trial to determine if a restrictive approach to red blood cell transfusion is as safe as a liberal approach on the risk of acute kidney injury [protocol Can J Kid Health Dis 2018 Jan 3; 5].

Methods: This was a randomized trial of 4531 moderate-to-high–risk patients undergoing cardiac surgery with cardiopulmonary bypass from 73 centers in 19 countries between January 2014 and March 2017. Patients were assigned to a restrictive red blood cell transfusion threshold (transfuse if hemoglobin level was <7.5 g/dL, intraoperatively and postoperatively until day 28 or hospital discharge; n=2251) or a liberal threshold (transfuse if hemoglobin level was <9.5 g/dL in the operating room or intensive care unit, or <8.5 g/dL on the non-intensive care ward; n=2280). Acute kidney injury was defined as an increase in the postoperative serum creatinine concentration (from the preoperative value) of ≥0.3 mg/dL (≥26.5 μmol/L) within 48 hrs of surgery, or ≥50% within 7 days of surgery. The prespecified noninferiority margin for the absolute risk difference was 3.5%.

Results: Perioperative acute kidney injury occurred in 27.7% of patients in the restrictive-threshold group and in 27.9% of patients in the liberal-threshold group; absolute risk difference, -0.2% (95% CI, -2.8% to 2.4%). Results were consistent

Underline represents presenting author/disclosure.

with multiple alternative definitions of acute kidney injury, and in the subgroup with preoperative chronic kidney disease (Table).

Conclusions: A restrictive approach to red blood cell transfusion was as safe as a liberal approach on the risk of acute kidney injury in patients undergoing cardiac surgery. Trial Registration: NCT02042898

Funding: Government Support - Non-U.S.

	Number of Events (%)		
	Restrictive (n=2251)	Liberal (n=2280)	Risk difference (95% CI)
AKI (primary outcome)	624 (27.7%)	636 (27.9%)	-0.2% (-2.8% to 2.4%)

Comparative Efficacy of Therapies for Depression for Patients Undergoing Hemodialysis

Rajnish Mehrotra,[1] Daniel Cukor,[2] Mark L. Unruh,[3] Tessa Rue,[1] Patrick J. Heagerty,[1] Scott D. Cohen,[12] Laura M. Dember,[4] Yaminette Diaz-Linhart,[13] Amelia Dubovsky,[1] Tom Greene,[5] Nancy K. Grote,[1] Nancy G. Kutner,[6] Madhukar Trivedi,[7] Davin Quinn,[8] Nisha Ver halen,[2] Steven D. Weisbord,[9] Bessie A. Young,[1] Paul L. Kimmel,[10] Susan Hedayati.[11]
[1]University of Washington, Seattle, WA; [2]SUNY Downstate Medical Center, Brooklyn, NY; [3]University of New Mexico, Los Ranchos, NM; [4]University of Pennsylvania School of Medicine, Philadelphia, PA; [5]University of Utah, Salt Lake City, UT; [6]Emory University School of Medicine, Atlanta, GA; [7]UT Southwestern Medical Center, Dallas, TX; [8]University of New Mexico Health Sciences Center, Albuquerque, NM; [9]University of Pittsburgh Medical Center, Pittsburgh, PA; [10]National Institute of Diabetes and Digestive Kidney Diseases (NIDDK), Bethesda, MD; [11]University of Texas Southwestern, Dallas, TX; [12]George Washington University, Washington, DC; [13]Brandeis University, Cambridge, MA.

Background: Depression is common in patients undergoing hemodialysis but limited data exist on increasing treatment acceptance or efficacy of various anti-depressant therapies. We sought to determine the effect of an engagement interview on treatment acceptance, and compare efficacy of cognitive behavioral therapy (CBT) or sertraline for treating major depressive disorder (MDD) or dysthymia in patients undergoing hemodialysis.

Methods: In a multi-center randomized controlled trial, 2569 patients in 41 dialysis facilities in 3 metropolitan areas were screened with Beck Depression Inventory (BDI). In those who scored ≥ 15, MDD/dysthymia was diagnosed using MINI Neuropsychiatric Interview. Participants were randomized to engagement interview, to increase treatment acceptance, vs. control visit, with proportion starting anti-depressant treatment within 28 days as the primary outcome. Willing individuals were further randomized to 12-weeks of CBT or sertraline, with Quick Inventory of Depressive Symptoms (QIDS-C) at 12 weeks as the primary outcome.

Results: Of 636 patients with BDI score ≥ 15, 310 (49%) eligible subjects were evaluated further, 184 were randomized to engagement vs. control, and 120 subsequently randomized to CBT vs. sertraline. There was no difference in the proportion initiating treatment for depression in engagement arm or control (66% vs. 64%, respectively, p=0.77). Compared with CBT, sertraline resulted in a greater decrease in depressive symptoms (12-week QIDS-C, -1.84, (-3.54, -0.13), p=0.04). There was also greater improvement in 5 of 9 secondary patient-reported outcomes with sertraline (BDI, Sheehan Disability, SF-36 Energy/Vitality, Satsifaction with Life, and Pittsburgh Sleep Quality Index scales). The incidence of serious adverse events was similar but non-serious adverse events were more frequent with sertraline (56 events, 25 patients) than with CBT (17 events, 12 patients).

Conclusions: In participants undergoing hemodialysis, there was no effect of an engagement interview on patients' acceptance of treatment for depression. There was greater improvement in depressive symptoms and other patient-reported outcomes with sertraline compared to CBT.

Interventions to Reduce Early Dialysis Initiation in Canada: A Cluster Randomized Trial

Navdeep Tangri,[1] Thomas W. Ferguson,[1] Amit X. Garg,[3] Braden J. Manns.[2]
[1]Seven Oaks General Hospital, Winnipeg, MB, Canada; [2]Foothills Medical Center, Calgary, AB, Canada; [3]London Health Sciences Centre, London, ON, Canada.

Background: There are higher healthcare costs and poorer outcomes when patients initiate dialysis earlier at a higher level of kidney function compared to when they initiate dialysis later. Despite the publication of The Initiating Dialysis Early and Late (IDEAL) study and concurrent clinical practice guidelines recommending an intent-to-defer dialysis initiation strategy, the estimated glomerular filtration rate (eGFR) at dialysis initiation varies widely.

Methods: We conducted a national cluster randomized controlled trial of a multifaceted knowledge translation intervention in 55 multi-disciplinary advanced chronic kidney disease (CKD) clinics in Canada. The intervention included academic detailing, audit and feedback, and provision of visual aids for patients and providers promoting the intent-to-defer strategy. The primary efficacy outcome was the proportion of patients who started dialysis early (eGFR > 10.5 ml/min/1.73m^2) and the primary safety outcome was the proportion of dialysis starts occurring in the acute inpatient setting. Absolute risk differences were estimated using generalized-estimating-equations analysis of clustered binary data using the difference-in-differences approach.

Results: There were 6,836 patients that started dialysis during the study period, 3,521 people who started in the 1 year before the intervention and 3,314 people who started in the 1 year following the intervention. Prior to the intervention, the proportion of early dialysis starts was 28.1% in the intervention group and 31.1% in the control group, and following the intervention was 30.6% and 31.0% in the intervention and control groups respectively. In unadjusted and analyses adjusted for patient-level characteristics no differences in early initiation were observed (adjusted absolute risk difference 3.7%; 95% confidence interval [CI] -0.07% to 8.1%; p = 0.10). Similarly, no differences in acute inpatient dialysis starts between the intervention and control group were detected (adjusted relative risk 1.11; 95% CI 0.96-1.29; p = 0.17).

Conclusions: A multifaceted knowledge translation intervention did not result in further declines in early dialysis initiation in Canada. Secular trends in dialysis initiation from uptake of the IDEAL trial findings may have limited the impact of this intervention.

Canagliflozin Reduces the Risk of Renal Events in People with Type 2 Diabetes Mellitus and Normoalbuminuria

Vlado Perkovic,[1,6] Brendon L. Neuen,[1] Toshiaki Ohkuma,[1] David R. Matthews,[2] Dick de Zeeuw,[3] Kenneth W. Mahaffey,[4] Greg Fulcher,[6] Qiang Li,[1] Meg J. Jardine,[1,7] Richard Oh,[5] Hiddo J. Lambers Heerspink,[3] Bruce Neal.[1]
[1]The George Institute for Global Health, UNSW Sydney, Sydney, NSW, Australia; [2]Oxford Centre for Diabetes, Endocrinology and Metabolism and Harris Manchester College, University of Oxford, Oxford, United Kingdom; [3]University of Groningen, University Medical Center Groningen, Groningen, Netherlands; [4]Stanford Center for Clinical Research, Department of Medicine, Stanford University School of Medicine, Stanford, CA; [5]Janssen Research & Development, LLC, Raritan, NJ; [6]Royal North Shore Hospital, Sydney, NSW, Australia; [7]Concord Repatriation General Hospital, Sydney, NSW, Australia.

Background: It has been postulated that the renoprotective effect of SGLT2 inhibitors is primarily due to restoration of tubuloglomerular feedback, which ameliorates glomerular hyperfiltration and lowers albuminuria. As a result, these agents might not be as effective in people with type 2 diabetes mellitus (T2DM) and normoalbuminuria (urinary albumin:creatinine ratio [UACR] <30 mg/g). Ongoing renal outcome studies are including participants who mostly or entirely have macroalbuminuria. We therefore sought to determine the renal effects of canagliflozin in people with normoalbuminuria in the CANagliflozin cardioVascular Assessment Study (CANVAS) Program.

Methods: The CANVAS Program randomized people with T2DM and high risk of cardiovascular disease to canagliflozin or placebo. We included participants with normoalbuminuria in this analysis, and further divided them into tertiles according to baseline UACR (low, mid, or high normoalbuminuria), and into subgroups based on estimated glomerular filtration rate (eGFR; <45, 45-<60, 60-<90, and ≥90 mL/min/1.73m^2). We analyzed the effects of canagliflozin on renal outcomes in people with normoalbuminuria overall and across these subgroups.

Results: Among 10,142 CANVAS participants, 7,007 (69%) had normoalbuminuria (mean age 63 years, BP 135/77 mmHg, HbA1c 8.2%, eGFR 78.3 mL/min/1.73m^2). In this population, canagliflozin reduced average UACR by 9% (95% CI 7-12%) compared to placebo over 338 weeks. Mean annual change in eGFR for placebo and canagliflozin treated participants was –0.47 and +0.59 mL/min/1.73m^2, respectively (placebo-subtracted difference 1.06 mL/min/1.73m^2). Canagliflozin reduced the risk of the composite renal outcome of 40% decrease in eGFR, end-stage kidney disease, or renal death by half (HR 0.50, 95% CI 0.33-0.77). The effect on the composite renal outcome appeared broadly consistent across UACR and eGFR subgroups (*P* heterogeneity = 0.16 and 0.10, respectively).

Conclusions: Canagliflozin reduces the risk of eGFR decline and renal outcomes in people with normoalbuminuria despite modest albuminuria reductions. Multiple mechanisms of renal benefit from SGLT2 inhibition might be important in T2DM.

TH-PO1148

Effects of Selonsertib in Patients with Diabetic Kidney Disease (DKD)

Glenn M. Chertow,[1] Pablo E. Pergola,[2] Fang Chen,[3] Brian J. Kirby,[3] John Sundy,[3] Uptal D. Patel.[3] GS-US-223-1015 Investigators
[1]Stanford University School of Medicine, Palo Alto, CA; [2]Renal Associates, PA, San Antonio, TX; [3]Gilead Sciences, Inc., Foster City, CA.

Background: Increased oxidative stress in the kidney and the resulting activation of apoptosis signal-regulating kinase 1 (ASK1) in glomerular and tubular cells has been implicated in progression of acute and chronic kidney diseases. This Phase 2 trial

evaluated the safety and efficacy of selonsertib (SEL), a potent and selective ASK1 inhibitor, in 334 pts with treatment-refractory moderate to advanced DKD.

Methods: Pts were randomized to receive SEL (2, 6, or 18 mg oral daily) or PBO. Primary outcome was change from baseline eGFR with SEL compared with PBO at 48 wks.

Results: SEL appeared safe with no dose-dependent adverse effects over 48 wks. Although there was no significant difference in SEL group mean (±SE) eGFR compared with PBO (0.38±1.21, 0.84±1.22, and -0.87±1.23 mL/min/1.73m^2 in the 2-, 6-, and 18-mg groups, respectively; p>0.4 for all pairwise comparisons; n=333 dosed; full analysis set [FAS]), differences in eGFR at 48 wks were confounded by acute effects related to SEL's inhibition of creatinine secretion. To account for this unanticipated effect, we used piecewise linear regression and found two dose-dependent effects: an acute, more pronounced decline in eGFR from 0-4 wks (creatinine secretion effect) and an attenuated decline in eGFR between 4-48 wks (therapeutic effect) seen with higher doses of SEL. Between 4-48 wks, rate of eGFR decline was reduced 71% for the 18-mg group relative to PBO (difference 3.11±1.53 mL/min/1.73m^2 annualized over 1 year, 95% CI, 0.10-6.13; nominal p=0.043; n=313; FAS excluding data from 2 sites with GCP compliance findings).

Conclusions: Although the trial did not meet its primary pre-specified endpoint, post-hoc analyses indicate that SEL appears to slow the progression of DKD (ClinicalTrials.gov: NCT02177786).

Primary Results of the Quality of Life in Peritoneal Dialysis and Conventional In-Center Hemodialysis (China Q) Study: A Prospective, Randomized, Open-Label, Multicenter, Noninferiority Trial

Xueqing Yu,[1] Li Fan,[1] Mark R. Marshall.[2] the China Q study investigators
[1]Department of Nephrology, The First Affiliated Hospital, Sun Yat-sen University, Guangzhou, China; [2]Middlemore Hospital, Auckland, New Zealand.

Background: There may be differences in health-related quality of life between hemodialysis (HD) and peritoneal dialysis (PD) for incident end-stage renal disease (ESRD) patients, but this hypothesis has not been adequately tested.

Methods: Open-label clinical trial from 21 centers in China, in adults diagnosed with new ESRD requiring maintenance dialysis, randomized 1:1 to receive in-center HD (≥3 x 4 hour sessions/week) or PD (3-5 exchanges/day). Primary end-point was burden of kidney disease score from the KDQoL-SF at 48 weeks; main secondary endpoint was all-cause mortality at 48 weeks. This dataset was supplemented by 235 patients (142 PD, 93 HD) from the previously terminated SURinD trial, who had complete measures of burden of kidney disease at both baseline and 48 weeks. The primary endpoint was assessed in the per protocol (PP) population, with a sensitivity analysis in the intention-to-treat (ITT) population. The treatment effect between arms was represented by the geometric mean (GM) ratio, and non-inferiority defined by the lower bound of 1-side 95% CI of GM ratio > 0.9 after 48 weeks follow-up. The main secondary end-point was assessed only in the China Q ITT population (NCT02378350, NCT01413074).

Results: 336 incident patients allocated to HD (237 per protocol), 332 to PD (253 per protocol) between Apr 2014 to Jun 2016. Patients were representative of those in China, with a pooled mean (SD) age of 49.5 (14.7) years, and 370 females (41.0%). For the primary endpoint, the GM ratio (95% CI) of PD *vs.* HD was 1.06 (0.91, 1.24), exceeding the limit for non-inferiority (p=0.43). The result of the sensitivity analysis was similar. There were 13 deaths in the PD group, and 19 deaths in the HD group, with no difference between groups (p=0.94).

Conclusions: In this study, burden of kidney disease was not inferior with PD *vs.* in-center HD, suggesting comparable perceptions of frustration and interference of kidney disease in one's life. Mortality risk was not different, although the study was not powered for this end-point. Analysis of other KDQoL-SF endpoints, clinical endpoints, and hospitalization are ongoing.

A Randomized Trial of Magnesium Oxide for Coronary Artery Calcification in Pre-Dialysis CKD

Yusuke Sakaguchi,[1] Takayuki Hamano,[1] Tatsufumi Oka,[2] Satoshi Yamaguchi,[2] Isao Matsui,[2] Nobuhiro Hashimoto,[2] Ayumi Matsumoto,[2] Karin Shimada,[2] Yoshitsugu Takabatake,[2] Atsushi Takahashi,[2] Jun-Ya Kaimori,[4] Masaru Horio,[5] Ryohei Yamamoto,[3] Toshiki Moriyama,[3] Yoshitaka Isaka.[2] *[1]Department of Inter-Organ Communication Research in Kidney Disease, Osaka University Graduate School of Medicine, Suita, Japan; [2]Department of Nephrology, Osaka University Graduate School of Medicine, Suita, Japan; [3]Osaka University Health Care Center, Toyonaka, Japan; [4]Department of Advanced Technology of Transplantation, Osaka University Graduate School of Medicine, Suita, Japan; [5]Department of Functional Diagnostic Science, Osaka University Graduate School of Medicine, Suita, Japan.*

Background: Although coronary artery calcification (CAC) predicts cardiovascular events among patients with CKD, effective therapeutic strategies for CAC have not yet been established. Animal studies have revealed that magnesium inhibits vascular calcification whereas indoxyl sulfate aggravates it. We explored whether magnesium supplementation or oral carbon adsorbent (AST-120) mitigates the progression of CAC in CKD.

Methods: In this 2-year, open-label, randomized controlled trial with a 2 by 2 factorial design, the efficacy of magnesium oxide and AST-120 for the progression of CAC was separately evaluated. We enrolled stages 3-4 CKD patients with known risk factors of CAC (diabetes mellitus, prior history of cardiovascular disease, hyper-low-density lipoprotein cholesterolemia, or current smoking). These patients were randomly assigned to magnesium oxide or control group and to AST-120 or control group. The primary outcome was a percent change in CAC score (Agatston score).

Results: The study was terminated prematurely after a planned interim analysis of the first 125 enrolled patients, showing that the percent change in CAC score in the magnesium oxide group was lower than that in the control group (median: 11.3% vs 39.5%; P<0.001). The proportion of patients whose annual percent change in CAC score over 15% was significantly lower in the magnesium oxide group (23.9% vs 62.0%; P<0.001). Magnesium supplementation increased serum magnesium levels from 2.0 to 2.3 mg/dL (P<0.001; vs control group) but did not alter serum calcium, phosphate, or parathyroid hormone levels. The progression rate of CAC was not significantly different between patients in the AST-120 and control groups (23.1% and 31.9%, respectively; P=0.57).

Conclusions: Oral magnesium oxide retards the progression of CAC among pre-dialysis CKD patients with a high risk of vascular calcification.

TH-PO1151

Phase 3, Randomized, Double-Blind, Active-Comparator (Darbepoetin Alfa) Conversion Study of Oral Roxadustat in CKD Patients with Anemia on Hemodialysis in Japan

Tadao Akizawa,[1] Manabu Iwasaki,[4] Yusuke Yamaguchi,[3] Yoshikatsu Majikawa,[3] Michael Reusch.[2] *[1]Showa University School of Medicine, Tokyo, Japan; [2]Astellas Pharma Europe B.V., Leiden, Netherlands; [3]Astellas Pharma Inc., Tokyo, Japan; [4]Yokohama City University, Yokohama, Japan.*

Background: Roxadustat, an oral HIF-PHI, is in late-stage development for treatment of CKD anemia. This phase 3 study evaluated non-inferiority of roxadustat efficacy to darbepoetin alfa (DA) as treatment of CKD anemia on hemodialysis (HD).

Methods: Multicenter, 24-week, Japanese study of CKD anemia patients on HD for ≥12 weeks and treated with ESA. Patients were randomized to roxadustat (70mg and 100mg) three times weekly or DA (10-60μg) once weekly; dose was adjusted to maintain Hb at 10-12g/dL. Primary endpoint was change of average Hb from baseline to Weeks 18-24 (ΔHb_{18-24}). Roxadustat efficacy was confirmed if the 95% CI of average Hb at Weeks 18-24 was within 10-12g/dL; non-inferiority to DA was confirmed if the lower limit of the 95% CI of the difference between roxadustat and DA was above –0.75g/dL. Secondary endpoints were average Hb at Weeks 18-24, proportion of patients with Hb of 10-12g/dL at Weeks 18-24 (maintenance rate), and iron parameters (ie, serum iron, ferritin, TSAT, transferrin, and TIBC). Safety was assessed as occurrence of adverse events (AEs) including ophthalmological examination (color fundus photography and optical coherence tomography [OCT]).

Results: 303 patients were randomized to roxadustat (n=151) or DA (n=152). The average Hb at Weeks 18-24 was 10.99 g/dL (95% CI: 10.88, 11.10) with roxadustat,

Underline represents presenting author/disclosure.

confirming its efficacy. The difference between roxadustat and DA in $\Delta Hb_{18\text{-}24}$ was –0.02g/dL (95% CI: –0.18, 0.15), confirming non-inferiority of roxadustat to DA. Maintenance rate of target Hb in patients with ≥1 Hb value at Weeks 18-24 was 95.2% (roxadustat) and 91.3% (DA). With roxadustat, serum iron, ferritin, and TSAT showed no remarkable change; transferrin and TIBC increased through Week 4 and then remained stable. No remarkable changes in iron parameters occurred with DA. The most common AEs in both groups were nasopharyngitis, shunt stenosis, diarrhea, contusion, and vomiting. New/worsening retinal hemorrhage occurred in 32.4% (roxadustat) and 36.6% (DA) of patients; no clinically meaningful change in retinal thickness by OCT were observed over time between groups.

Conclusions: Roxadustat maintained target Hb in HD patients and its efficacy was non-inferior to DA. AEs were consistent with previous reports.

Background: Roxadustat is an oral hypoxia–inducible factor prolyl hydroxylase inhibitor that regulates erythropoiesis and iron metabolism.

Methods: In this phase 3 trial, Chinese pts (hemoglobin-Hb 9-12g/dL) on hemo/peritoneal dialysis with previous erythropoiesis stimulating agent (ESA) therapy for >6 weeks were randomized 2:1 to roxadustat or epoetin-alfa thrice-weekly for 26 wks; IV iron was withheld except for rescue. Primary endpoint was the average Hb change from baseline to wks 23-27 ($deltaHb_{23\text{-}27}$) tested for non-inferiority vs epoetin-alfa. Both arms were titrated to maintain/achieve Hb 10-12g/dL. All randomized subjects who received ≥2 weeks of study treatment with baseline and post-baseline Hbs w/o rescue therapy 6 wks prior to assessment and w/o important protocol deviation comprised the per protocol set (PPS); all randomized subjects with baseline and post baseline Hbs comprised the full analysis set (FAS) population.

Results: The safety population consisted of 304 pts (204 roxadustat, 100 epoetin-alfa); 256 pts (162 roxadustat, 94 epoetin-alfa) completed the 26-week treatment period. Average baseline Hb overall was 10.4g/dL. Roxadustat produced a numerically greater mean $deltaHb_{23\text{-}27}$ of .8g/dL(±1.1) than epoetin-alfa, (.5 g/dL±1.0) and was noninferior and superior (p=.037) to ESA in the PPS population and non-inferior but not superior in the FAS population. The Hb change in the roxadustat group wasn't clinically affected by baseline CRP. Roxadustat increased transferrin, maintained serum iron, and attenuated decreases in TSAT versus epoetin-alfa (all p<0.01). At wk 27, the decline from baseline in both total and LDL cholesterol was greater with roxadustat (both p<0.0001). Roxadustat reduced hepcidin from baseline by a mean of 30.21ng/ml (p=.0028) compared to 2.28ng/ml in the epoetin-alfa group (p=.1228). Roxadustat was well tolerated.

Conclusions: Roxadustat was efficacious as oral anemia therapy in Chinese pts receiving dialysis. Roxadustat's reduction in hepcidin levels with iron mobilization likely contributes to its efficacy in erythropoiesis irrespective of inflammation.

Background: Roxadustat (FG-4592) is an oral hypoxia–inducible factor prolyl hydroxylase inhibitor that stimulates erythropoiesis and regulates iron metabolism.

Methods: In this phase 3 trial, Chinese patients with hemoglobin (Hb) between 7.0-10.0 g/dL and CKD not requiring dialysis were randomized and treated in a double-blind manner to roxadustat thrice-weekly or placebo (2:1) for 8-weeks; parenteral iron was withheld except for rescue. The primary endpoint was the average change in Hb from baseline to week 7-9. Following, all patients were offered open-label roxadustat for 18-weeks.

Results: The safety population included 152 patients (101=roxadustat, 51=placebo) in the initial 8-weeks, during which subjects in the roxadustat arm had a greater mean (±SD) change from baseline in hemoglobin of 1.90 g/dL (±1.175)(mean baseline Hb 8.87 ±0.81 g/dL), as compared to placebo -0.39 g/dL (±0.786)(mean baseline 8.93 ±0.73 g/dL) (p<0.000000000000001). At week 9, patients randomized to roxadustat had a greater mean reduction in hepcidin at -56.14 (±63.40)(p<0.00001) vs. -15.10 (±48.06) ng/ml (p=0.172) in the placebo group (p<0.00001 between groups). At week 9, the decline from baseline was greater for lipid fractions (total cholesterol and LDL cholesterol) in the roxadustat arm (p<0.00001). The most frequent treatment-emergent adverse events were typical for this population and without trend in individual or composite events. Ninety-eight subjects completed the 18-week open-label period. Roxadustat performed similarly in the open-label as in the initial treatment period with respect to correction and maintenance of hemoglobin.

Conclusions: Roxadustat was well tolerated in patients with CKD not requiring dialysis in China and superior to placebo in correcting anemia and maintaining Hb levels.

TH-PO1154

A Phase 3, Multicenter, Randomized, Double-Blind, Placebo-Controlled Trial to Treat Metabolic Acidosis in CKD Patients with TRC101, a Novel, Non-Absorbed, Hydrochloric Acid Binder

Donald E. Wesson,[1] Vandana S. Mathur,[5] Yuri Stasiv,[4] Dawn Parsell,[2] Gerrit Klaerner,[4] David A. Bushinsky.[3] *[1]Baylor Scott and White Health and Wellness Center, Dallas, TX; [2]Parsell and Otto Consulting, Inc., Cedar Park, TX; [3]University of Rochester Medical Center, Rochester, NY; [4]Tricida, Inc., South San Francisco, CA; [5]Mathur Consulting, Woodside, CA.*

Background: Metabolic acidosis increases risk of chronic kidney disease (CKD) progression and adversely affects muscle and bone. TRC101, a non-absorbed, sodium-free polymeric drug that selectively binds and removes hydrochloric acid from the gastrointestinal tract, is being developed for the treatment of metabolic acidosis in CKD and slowing CKD progression.

Methods: 217 CKD patients (eGFR 20 - 40 mL/min/1.73m^2) with metabolic acidosis (serum bicarbonate [HCO_3] 12 - 20 mEq/L) were randomized 4:3 to TRC101 (6 g) or placebo once-daily for 12 weeks. Algorithmic dose titration was performed to achieve a normal serum HCO_3 (22 - 29 mEq/L). The primary endpoint was the between-group comparison of the proportion of patients with a ≥4 mEq/L increase in serum HCO_3 or a normal serum HCO_3 at Week 12. The secondary endpoint evaluated the change from baseline in serum HCO_3. Two exploratory endpoints evaluated effects of acidosis correction on physical functioning using the Kidney Disease Quality of Life Short Form-36 Physical Functioning subscale and a timed repeated chair stand test.

Underline represents presenting author/disclosure.

Results: The mean (SD) baseline serum HCO3 and eGFR were 17.3 (1.5) mEq/L and 28.6 (6.0) mL/min/1.73m2, respectively. 96% of patients completed treatment. Comorbidities included hypertension (97%), diabetes (65%), left ventricular hypertrophy (44%), and congestive heart failure (31%). More TRC101 (59.2%) than placebo (22.5%) patients met the primary endpoint response definition ($p<0.0001$). From baseline to Week 12, mean serum HCO3 increased +4.5 mEq/L (TRC101) vs. +1.7 mEq/L (placebo), $p<0.0001$. More TRC101 compared with placebo patients had improvement in self-reported physical functioning ($p = 0.012$) and there was a trend toward improvement in standardized chair stand time ($p=0.063$). There were no effects of TRC101 on creatinine or other electrolytes. Overall treatment-related adverse events occurred in 9.7% of placebo and 13.7% of TRC101 patients, most of which were gastrointestinal (e.g., diarrhea, flatulence, nausea and constipation).

Conclusions: TRC101 effectively and safely treated metabolic acidosis and improved self-reported physical functioning in CKD patients.

Effect of Everolimus with Reduced-Exposure Calcineurin Inhibitor in De Novo Kidney Transplant Recipients: 24-Month Results from the US Cohort of the TRANSFORM Study

Yasir A. Qazi,[1] Dean Y. Kim,[2] Alexander C. Wiseman,[3] V. Ram Peddi,[4] Steven M. Steinberg,[5] Fuad S. Shihab,[6] Mitchell L. Henry,[7] Kevin M. Mccague,[8] Peter Bernhardt,[9] Shamkant P. Mulgaonkar.[10] *[1]University of Southern California, Los Angeles, CA; [2]Henry Ford Hospital, Detroit, MI; [3]University of Colorado at Denver and Health Sciences Center, Denver, CO; [4]California Pacific Medical Center, San Francisco, CA; [5]Balboa Nephrology Medical Group, San Diego, CA; [6]University of Utah Health Science Center, Salt Lake City, UT; [7]Ohio State University, Columbus, OH; [8]Novartis Pharmaceuticals Corp., E. Hanover, NJ; [9]Novartis Pharma AG, Basel, Switzerland; [10]St. Barnabas Medical Center, Livingston, NJ.*

Background: To present 24-month (M) efficacy and safety data from the US cohort of the TRANSFORM study (NCT01950819).

Methods: In this 24M, multicenter, open-label study, *de novo* kidney transplant recipients (KTxRs) were randomized to receive either everolimus + reduced-exposure calcineurin inhibitor (EVR+rCNI: 1022) or mycophenolic acid + standard-exposure CNI (MPA+sCNI: 1015) with induction and steroids. The binary composite of tBPAR or eGFR <50 mL/min/1.73 m^2, composite efficacy failure (CEF: tBPAR/graft loss/death) and individual components, eGFR (MDRD4), and safety were assessed at M24.

Results: Of 2037 KTxRs in overall study, 352 (EVR+rCNI: 173; MPA+sCNI: 179) were included in the US cohort. Except for younger donors and lower proportion of extended criteria donors (ECD) in the US cohort, other characteristics were similar for both populations. Similar to the overall population, CNI trough levels (C0) were towards the upper limit/above the target C0 throughout the study. In contrast to overall population, the incidence of binary composite efficacy was significantly higher in the EVR+rCNI vs MPA+sCNI arm in the US cohort at M24. The CEF and individual components were comparable between arms in both populations (**Table**). Mean eGFR was higher in the US cohort vs overall population for both arms. Incidence of viral infections were lower in EVR+rCNI vs MPA+sCNI.

Conclusions: Similar to 24M data from the TRANSFORM study, US cohort showed comparable efficacy and safety with lower viral infection rates in the EVR+rCNI vs MPA+sCNI arm; higher mean eGFRs in the US cohort may be attributed to differences in donor type and age in the population.

Funding: Commercial Support - Novartis

Effect of Adding Dapagliflozin as an Adjunct to Insulin on Urinary Albumin-to-Creatinine Ratio over 52 Weeks in Adults with Type 1 Diabetes

Steven Edelman,[1] Johan Jendle,[2] Paresh Dandona,[3] Chantal Mathieu,[4] Diethelm Tschoepe,[5] Fredrik A. Thorén,[6] Markus F. Scheerer,[6] John Xu,[6] Anna Maria Langkilde.[6] DEPICT-1 and -2 Investigators *[1]Division of Endocrinology and Metabolism, University of California, San Diego, CA; [2]Orebro University, Örebro, Sweden; [3]State University of New York at Buffalo, Buffalo, NY; [4]KULeuven, Leuven, Belgium; [5]Herz- und Diabeteszentrum NRW, Ruhr-Universitaet Bochum, Bad Oeynhausen, Germany; [6]AstraZeneca, Gothenburg, Sweden.*

Background: DEPICT-1 and DEPICT-2 studies, where dapagliflozin (DAPA) was added as adjunct to insulin in adults with inadequately controlled type 1 diabetes (T1D) (glycated hemoglobin: 7.5%–10.5%), reported improvements in glycemic control and weight, and was well tolerated.

Methods: In this pooled post hoc analysis of the DEPICT-1 and -2 studies, we evaluated the effect of dapagliflozin on Urinary Albumin to Creatinine Ratio (UACR) in individuals with T1D with baseline albuminuria.

Results: In total, 548 individuals treated with DAPA 5 mg, 565 with DAPA 10 mg, and 532 with placebo had UACR recorded at baseline. Albuminuria at baseline was found in 80, 84, and 87 individuals in the DAPA 5 mg, 10 mg, and placebo arms, respectively. Of these 251 individuals, baseline renal function measured as estimated glomerular filtration rate (eGFR) was normal in 93 individuals (eGFR ≥90 mL/min/1.73 m^2), mildly impaired in 131 individuals (eGFR ≥60 or <90 mL/min/1.73 m^2), and moderately impaired in 27 individuals (eGFR <60 mL/min/1.73 m^2). Changes in eGFR appeared similar across the treatment arms (data not shown). However, treatment with DAPA resulted in a dose-dependent reduction in UACR at weeks 12, 18, 24, and 52 (Figure). The difference in UACR between DAPA 10 mg vs placebo was significant from weeks 18 to 52. At week 52, the differences in UACR between DAPA 10 mg and placebo and DAPA 5 mg and placebo were –31.12% (95% CI: –49.94, –5.22) and –13.30 (95% CI: –37.24, 19.79), respectively.

Conclusions: Treatment with DAPA appears to provide a dose-dependent benefit in reducing UACR, suggesting renoprotective effects in individuals with T1D with baseline albuminuria.

Funding: Commercial Support - AstraZeneca, Gaithersburg, MD, USA.

Underline represents presenting author/disclosure.

Correction of Serum Potassium with Sodium Zirconium Cyclosilicate in Japanese Patients with Hyperkalemia: A Dose-Finding Study

Naoki Kashihara,[1] Toshiki Nishio,[8] Takeshi Osonoi,[4] Yosuke Saka,[6] Toshiyuki Imasawa,[7] Takayasu Ohtake,[2] Hiroshi Mizuno,[9] Yugo Shibagaki,[3] Hyosung Kim,[5] Toshitaka Yajima,[5] Nobuaki Sarai.[5] *[1]Kawasaki Medical School, Okayama, Japan; [2]Shonankamakura General Hospital, Kanagawa, Japan; [3]St. Marianna University School of Medicine Hospital, Kanagawa, Japan; [4]Nakakinen Clinic, Ibaraki, Japan; [5]AstraZeneca K.K., Osaka, Japan; [6]Kasugai Municipal Hospital, Aichi, Japan; [7]Chiba-East-Hospital, Chiba, Japan; [8]Kusatsu General Hospital, Shiga, Japan; [9]Inage Hospital, Chiba, Japan.*

Background: Sodium zirconium cyclosilicate (SZC) is an oral potassium (K) binder approved to treat hyperkalemia (HK) in adults in the US and EU. We evaluated SZC doses for correcting serum K (sK) in Japanese patients (pts) with HK in a multicenter, double-blind, placebo-controlled phase 2/3 trial.

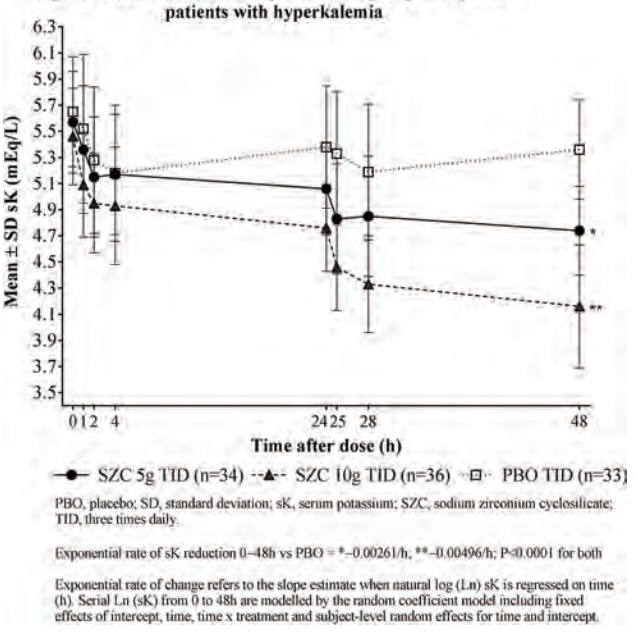
Methods: Pts aged ≥18y with sK ≥5.1–≤6.5mEql/L were randomized 1:1:1 to SZC 5g, SZC 10g, or placebo (PBO) administered (as powder in water) thrice daily for 48h. Primary endpoint was exponential rate of change in sK over 48h. Pts (%) with normokalemia (sK 3.5–5.0mEq/L) at 48h (secondary endpoint), multiple time points (1, 2, 4, 24, 25, 28, and 48h), and adverse events (AEs) were evaluated.

Results: At baseline, the 103 randomized pts (mean age 73y; 75% male) had mean sK of 5.6 mEq/L, mean eGFR of 26.1 mL/min/1.73m^2 (29%, 40%, 28%, and 3% had eGFR <15, 15–<30, 30–<60, and ≥60, respectively). All pts (34 on SZC 5g; 36 on SZC 10g; 33 on PBO) completed the study except 2 PBO pts discontinued due to HK. Exponential rate of sK change from 0–48h vs PBO was –0.00261/h with SZC 5g and –0.00496/h for SZC10g (Figure; both P<0.0001). At 48h, 85% of pts had normokalemia with SZC 5g, 92% with SZC 10g, and 15% with PBO. More pts had normokalemia with SZC 5g vs PBO at 4h through 48h and with SZC 10g vs PBO at every time point. AEs occurred in 4, 5, and 1 pt in the SZC 5g, 10g, and PBO groups; all AEs were mild and single occurrences in individual patients. sK <3.5 mEq/L occurred in 2 pts in the SZC 10g group, and none in the SZC 5g or PBO groups.

Conclusions: SZC 5g and 10g were well tolerated and corrected HK in most Japanese pts within 48h; SZC 10g had the most rapid sK reduction and highest response rate.

Funding: Commercial Support - AstraZeneca

Figure. Mean sK over time by treatment group in Japanese patients with hyperkalemia



PBO, placebo; SD, standard deviation; sK, serum potassium; SZC, sodium zirconium cyclosilicate; TID, three times daily.

Exponential rate of sK reduction 0–48h vs PBO = *–0.00261/h, **–0.00496/h; P<0.0001 for both

Exponential rate of change refers to the slope estimate when natural log (Ln) sK is regressed on time (h). Serial Ln (sK) from 0 to 48h are modelled by the random coefficient model including fixed effects of intercept, time, time x treatment and subject-level random effects for time and intercept.

TH-PO1158

Sodium Zirconium Cyclosilicate for Hyperkalemia: Results of the Randomized, Placebo-Controlled, Multi-Dose HARMONIZE-GLOBAL Study

Faiez Zannad,[1] Bang-Gee Hsu,[2] Yoshitaka Maeda,[3] Sug kyun Shin,[4] Elena M. Vishneva,[5] Martin Rensfeldt,[6] Stefan Eklund,[6] June Zhao.[7] *[1]Inserm, centre d'Investigation Clinique 1433, Université de Lorraine and Centre Hospitalier Universitaire, Nancy, France; [2]Buddhist Tzu Chi General Hospital, Hualien, Taiwan; [3]JA Toride Medical Center, Ibaraki, Japan; [4]NHIS Medical Center, Ilsan Hospital, Goyangshi, Gyeonggi–do, Republic of Korea; [5]City Clinical Hospital No14, Ekaterinburg, Russian Federation; [6]AstraZeneca Gothenburg, Mölndal, Sweden; [7]AstraZeneca, Gaithersburg, MD.*

Background: Sodium zirconium cyclosilicate (SZC) is an odorless, tasteless, inorganic, oral, potassium (K) binder approved for the treatment of hyperkalemia in adults in the US and Europe. In the HARMONIZE trial (Kosiborod, JAMA 2015), SZC rapidly corrected and maintained control for 28 days in Caucasian patients with few dose-related adverse events (AEs). Presented here is the HARMONIZE Global study; a 28-day, multicenter, randomized, double-blind, placebo-controlled phase 3 study that evaluated the efficacy and safety of SZC for hyperkalemia in primarily Asian patients.

Methods: Outpatients (≥18 yrs) with K ≥5.1mEq/L (measured by the point-of-care device iSTAT) were enrolled from sites in Japan, South Korea, Russia and Taiwan. During the open-label correction phase (CP), patients received SZC 10 g thrice daily for 48 hours (**Figure**), changes in serum K (sK) were evaluated serially. Patients with K 3.5–5.0 mEq/L in the CP entered the 28-day maintenance phase (MP) and were randomized 2:2:1 to receive 5 g SZC, 10 g SZC, or placebo once daily. Background renin angiotensin aldosterone system inhibitors and diuretic use were kept stable. The primary endpoint was the mean serum K (measured by central laboratory) during days 8–29 in MP. Secondary endpoints included changes in sK, proportion of patients who achieved normokalemia (sK 3.5–5.0 mEq/L) in CP and those who maintained normokalemia in MP, quality of life (assessed using EuroQol-5D questionnaire), and changes in aldosterone and renin. Safety parameters included adverse events, vital signs, ECG, and clinical laboratory evaluations.

Results: Efficacy and safety data will be available for presentation.

Conclusions: A randomized, controlled trial of two doses of SZC for hyperkalemia versus placebo was conducted over 28 days in a population of primarily Asian patients; the results will be important for the use of this potassium binder in this population.

Funding: Commercial Support - AstraZeneca

Kidney Injury Biomarkers and Contrast-Associated AKI: A Substudy of the PRESERVE Trial

Chirag R. Parikh,[1] Paul M. Palevsky,[2] James S. Kaufman,[3] Heather Thiessen Philbrook,[1] Steven D. Weisbord.[2] PRESERVE Trial Study Group *[1]Johns Hopkins University, Baltimore, MD; [2]University of Pittsburgh/VA Pittsburgh Healthcare System, Pittsburgh, PA; [3]VA New York Harbor Healthcare System, New York, NY.*

Background: The utility of novel biomarkers in contrast-associated AKI (CA-AKI) is unknown. Among PRESERVE trial participants, we evaluated novel proteins of kidney injury and repair to risk stratify post-angiography CA-AKI and 90-day major adverse kidney events and death (MAKE-D); predict pharmacodynamic response to the trial interventions (bicarbonate and acetylcysteine) and; inform clinical trial design.

Methods: We collected plasma and urine 1-2 hours pre- and 2-4 hours post-angiography and measured injury (KIM-1, NGAL, IL-18) and repair (MCP-1, UMOD, and YKL-40) proteins at both time points. We analyzed the association of pre-, post-, and delta (Δ) biomarker levels with 90-day MAKE-D (dialysis, persistent kidney impairment, death) and with CA-AKI. We also evaluated the association of the trial interventions with Δ biomarker levels, and examined whether biomarkers could enrich the primary MAKE-D event rate to improve trial efficiency.

Results: Among 860 PRESERVE participants, pre-angiography levels of four plasma and four urine biomarkers were significantly associated with MAKE-D (Table). Absolute and relative Δ in biomarker levels were modest and were not associated with MAKE-D or CA-AKI. None of the biomarkers demonstrated significant changes with trial interventions. Incorporating the 50th percentile pre-angiography plasma KIM-1 or YKL-40 value into patient screening would have enriched the MAKE-D event rate and reduced the required sample size by ~2000 (30%) participants (prognosticenrichment.com).

Conclusions: Pre-angiography levels of injury and repair biomarkers predict the development of post-angiography MAKE-D outcomes and could improve efficiency of future CA-AKI trials. Changes in biomarker levels did not predict MAKE-D, CA-AKI, or pharmacodynamic response to the trial interventions. The modest change in biomarker levels following angiography suggests that most cases of CA-AKI reflect hemodynamic effects rather than intrinsic kidney damage.

Alemtuzumab for Relapsing and Refractory Primary Systemic Vasculitis: A Trial of Efficacy and Safety (ALEVIATE)

Seerapani Gopaluni,[1] Rona M. Smith,[2] Donna Goymer,[6] Elizabeth Broadhurst,[4] Mark E. Mcclure,[5] Hugh C. Cahill,[2] David R. Jayne.[3] *[1]Department of Medicine, University of Cambridge, Cambridge, United Kingdom; [2]Cambridge University Hospitals, Cambridge, United Kingdom; [3]University of Cambridge, Cambridge, United Kingdom; [4]Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; [5]Department of Medicine, University of Cambridge, Cambridge, United Kingdom; [6]Cambridge University Trust Foundation Hospitals, Cambridge, United Kingdom.*

Background: Primary systemic vasculitis encompassing ANCA associated vasculitis (AAV) and Behcet's Disease (BD) has considerable morbidity & mortality. Inadequate response and relapses are common. There is an unmet need for safer therapy that leads to sustained remission in patients with relapsing or refractory disease (RD). Alemtuzumab(ALZ), an anti-CD52 mAb depletes lymphocytes for prolonged periods and was shown in observational studies to induce remission in RD. This trial's aim is to determine the efficacy and safety of ALZ in patients with RD.

Methods: Randomized, prospective, open label, dose ranging clinical trial. 24 patients with RD randomized to receive either 60mg or 30mg of ALZ. Eligible patients were required to have failed to respond to standard therapies (cyclophosphamide/rituximab in AAV or anti-TNF therapy in BD). Patients > 60 yrs, creatinine >150umol/L, requiring intensive care unit support were excluded. Treatment was repeated at 6 months(M) or earlier where clinically appropriate. Each patient was followed up for 12M or until withdrawal. Co-trimoxazole and acyclovir prophylaxis was administered. Primary end-points: Proportion of patients with treatment response at 6M(Complete remission-CR: BVAS/WG of 0 for > 1M. Partial remission-PR: No severe BVAS/WG items and >=50% fall in BVAS/WG from entry) & proportion with a severe adverse event(SAE; CTCAE grade >=3).

Results: Evaluable patients:23. Mean age 36.8(10.9) yrs; M:F=9:15; AAV:12; BD:11; withdrawals:6/23(26%)-all due to progressive disease. Response(CR/PR) at 6M:15/23(65.2%; 95%CI: 0.43-0.84); 5/23(22%; 95%CI: 0.08-0.44) had remission that lasted to 12M. 10/15 (66.6%, 95% CI: 0.38-0.88) achieving remission had a relapse during the follow-up period. Of the 8 SAEs in 6 patients(26%), 5 were treatment related (1 CMV colitis, 1 viral gastroenteritis, 1 c.difficile infection; 2 infusion related reactions) and the other 3 were due to relapse. Small sample size precluded dose comparison analysis.

Conclusions: In this small phase II RCT testing the efficacy and safety of ALZ to treat RD, 65% of the patients achieved clinical remission at 6M. Even though relapses were common, 22% achieved sustained remission. SAEs were seen in 26% of the patients. This study indicates that ALZ is a safe therapy in a select group of patients.

Insulin Therapy for the Prevention of Posttransplantation Diabetes Mellitus: Preliminary Results from an International Multicenter Study (ITP-NODAT)

Elisabeth Schwaiger,[5] Leon Bergfeld,[8] Klemens Budde,[1] Julio Pascual,[2] Kathrin Eller,[7] Alexander R. Rosenkranz,[3] Marcus D. Saemann,[4] Manfred Hecking.[6] *[1]Charite Universitatsmedizin Berlin, Berlin, Germany; [2]Hospital del Mar, Parc de Salut Mar, Barcelona, Spain; [3]Medizinische Universität Graz, Graz, Austria; [4]Wilhelminen Hospital, Vienna, Austria; [5]Medical University Vienna, Vienna, Austria; [6]Medical University of Vienna, Nephrology & Dialysis, Vienna, Austria; [7]Graz Medical University, Graz, Austria; [8]Charité Universitätsmedizin Berlin, Berlin, Germany.*

Background: In our previous proof-of-concept trial, basal insulin therapy early after kidney transplantation significantly reduced the odds of posttransplantation diabetes mellitus (PTDM) throughout 1 year of follow-up (PMID22343119). The ITP-NODAT study aimed at reproducing these findings (NCT03507829).

Methods: Kidney transplant recipients without diabetes history were randomized to receive immediate insulin isophane treatment for pre-dinner glucose ≥140 mg/dL, or short-acting insulin and/or oral antidiabetics for fasting glucose ≥200 mg/dL. Primary endpoint: PTDM incidence at 12 months.

Results: Of 263 patients enrolled at 4 centers, N=205 completed month 24 by 5/2018. 119 of 133 treatment patients received insulin for a median duration of 49 days while 18 of 130 control patients received insulin and/or oral antidiabetics for a median duration of 730 days (Figure: A/B). We observed 17 versus 1 episodes of hypoglycemia in treatment versus control patients (none clinically concerning). While results from oral glucose tolerance tests are currently being evaluated, fasting glucose and HbA1c data indicate that treatment and control patients did not separate well in terms of glycemic control (Figure: C/D). Based on HbA1c (≥6.5 %) and antidiabetic treatment, 13 patients in each group classified as diabetics at 12 months.

Conclusions: (1) Exogenous insulin therapy was relatively safe; (2) treatment and control patients had a similarly low PTDM incidence and a low rise in HbA1c over follow-up; (3) there were more control group than treatment group patients who required prolonged antidiabetic therapy. Result (2) differs from our previous trial, where PTDM incidence had been higher, and significantly different between groups. The lower glucocorticoid regimen in ITP-NODAT and increased PTDM awareness likely contributed to this difference.

RITUXILUP: An Open-Label Randomised Multicentre Controlled Trial of Rituximab and Mycophenolate Mofetil (MMF) Without Oral Steroids for the Treatment of Lupus Nephritis

Liz Lightstone,[1] Hannah R. Wilson,[1] Matyas Szigeti,[1] Daphne Babalis,[1] H. Terence Cook,[1] Ian N. Bruce,[8] Tom Cairns,[4] David D'Cruz,[6] Paul Emery,[9] Megan Griffith,[4] Peter Hewins,[2] Richard Hull,[5] David Isenberg,[3] David R. Jayne,[7] Jeremy B. Levy,[4] Stephen D. Marks,[13] Philip D. Mason,[11] Alan D. Salama,[3] Peter S. Topham,[12] Diane J. Wessels.[10] on behalf of the RITUXILUP Trial Study Group *[1]Imperial College London, London, United Kingdom; [2]University Hospital Birmingham, West Midlands, United Kingdom; [3]University College London, London, United Kingdom; [4]Imperial College Healthcare NHS Trust, London, United Kingdom; [5]King's College Hospital NHS Foundation Trust, London, United Kingdom; [6]Guy's and St. Thomas' Hospitals NHS Foundation Trust, London, United Kingdom; [7]University of Cambridge, Cambridge, United Kingdom; [8]University of Manchester, Manchester, United Kingdom; [9]Leeds Institute Rheumatic and Musculoskeletal Medicine, University of Leeds, Leeds, United Kingdom; [10]Renal, Royal Stoke University Hospital, Stoke, United Kingdom; [11]Oxford Kidney Unit, Oxford, United Kingdom; [12]University Hospitals of Leicester NHS Trust, Leicester, United Kingdom; [13]Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom.*

Background: A key challenge in lupus nephritis (LN) is to treat effectively whilst minimising treatment related toxicity. The investigator led RITUXILUP trial hypothesised that rituximab (RTX), methyl prednisolone (MP) & mycophenolate mofetil (MMF) but without oral steroids (OS) would be non-inferior to standard of care (MP, MMF & OS) in inducing complete remission (CR) at 1yr.

Methods: The trial primary objective was CR at 1yr defined by urine protein/creatinine ratio (uPCR) of ≤50mg/mmol, eGFR (CKD-Epi) ≥60mls/min, or without a fall of >20% if baseline <60mls/min, & without extra steroids above a strictly defined limit. Inclusion criteria: age 12-75yrs, renal biopsy within 8 weeks (ISN/RPS Class III or IV, (A or A/C) or class V), uPCR ≥100mg/mmol & not on maintenance OS. Patients randomised 1:1 all received MP 500mg d1+d15 & MMF with (SoC arm) tapering OS (from 0.5mg/kg) or (RTX arm) RTX 1g d1+d15 & no OS

Results: We needed to recruit minimum 210 patients for 80% power. However, over 2 yrs only 25 (13 RTX, 12 SoC; Female 88%; Non white 68%) were enrolled as the majority of otherwise eligible patients were on longterm OS. The trial terminated early due to slow recruitment & withdrawal of funding. **Median (IQR) days follow up (f/up) for primary endpoint**: RTX arm 336(253,356); SoC arm 354.5(306,365). **Key results n (%): CR at 1 yr or latest f/up if <1yr: RTX** 6 (**46**) vs **SoC** 4 (**33**) (1 randomised to SoC, withdrew & received RTX) **CR (+steroid deviation): RTX** 2 (**15**) vs **SoC** 1 (**8**) **PR: RTX** 3 (**23**) vs **SoC** 6 (**50**) **Non response: RTX** 2 (15) vs **SoC** 1 (8) **Significant difference in median total OS exposure over trial : 0mg in RTX vs 3570mg in SoC & equivalent daily dose including the MP 3.6mg/day in RTX vs 13.7mg in SoC SAEs: RTX** 4 in 3 pts & **SoC** 2

Conclusions: Doing trials in LN remains challenging. Whilst limited, RITUXILUP provides the first RCT data ever to support our hypothesis that LN can be effectively treated without oral steroids. The RTX arm CR is superior to that in most trials despite minimal steroids. A pragmatic future trial will include patients on longterm low dose OS with no dose increase in RTX arm

TH-PO1163

Failure of Regulatory B Cells to Repopulate After Rituximab Associates with Lack of Efficacy in Renal Transplant Patients with CAMR: Evidence from the RituxiCAN-C4 Trial

Anthony Dorling,[1] Kin Y. Shiu,[2] Laura Mclaughlin,[1] Dominic Stringer,[1] Tjir-Li Tsui,[3] Olivia Shaw,[4] Paul Brookes,[5] Hannah M. Burton,[1] Hannah E. Wilkinson,[1] Hatty A. Douthwaite,[3] Adam Mclean,[6] Rachel Hilton,[3] Sian V. Griffin,[7] Simon T. Ball,[8] Richard J. Baker,[9] Candice A. Roufosse,[5] Catherine J. Horsfield.[3] *[1]King's College London, London, United Kingdom; [2]Royal Free Hospital, London, United Kingdom; [3]Guy's & St Thomas' NHS Foundation Trust, London, United Kingdom; [4]Viapath, Guys Hospital, London, United Kingdom; [5]Imperial College Healthcare NHS Trust, London, United Kingdom; [6]Imperial College Kidney & Transplant Institute, London, United Kingdom; [7]Heath Hospital Cardiff, Cardiff, United Kingdom; [8]University Hospital Birmingham, Edgbaston, United Kingdom; [9]SJUH, Leeds, United Kingdom.*

Background: Immune-mediated late failure of kidney allografts is a significant problem, usually presenting as progressive dysfunction with histological features of chronic antibody-mediated rejection (CAMR). RituxiCAN-C4 was an open-labelled randomised controlled phase IV clinical trial running in 13 UK centres from 2007-2017, to assess efficacy of Rituximab in stabilising graft function after failure of optimised oral immunosuppression.

Methods: Of 59 patients meeting eligibility criteria who underwent optimisation, 23 consented to randomisation, 11 to no additional treatment (control), and 12 to Rituximab. In the pre-specified second interim (per protocol) analysis of the 9 who received rituximab vs. 11 controls, there was no significant difference in the primary endpoint (short-term stability of function), so recruitment was halted in 2015. Follow-up ended in 2017.

Results: The median reduction in circulating B cells post Rituximab was 98.2% (IQR 3.8%), with no significant recovery in circulating B cells over 3 years. Analysis of remaining B cells showed normalisation of the proportions of different subpopulations, except for transitional cells expressing higher levels of CD24 and CD38, which remained disproportionately low compared to controls. ELISPOT analysis of indirect alloresponses to donor proteins in all 59 patients confirmed that B dependent CD4+ IFNγ production associated with greater decline in eGFR. Optimisation of immunosuppression that resulted in conversion to non-responsiveness or to anti-donor responses regulated by CD19+ or CD25+ cells was associated with slower decline in eGFR. Regulation by CD19+ cells associated with higher proportions of the same transitional B cells that failed to repopulate in Rituximab-treated patients, none of whom showed this pattern of ELISPOT responsiveness.

Conclusions: This analysis illustrates the importance of B cells and indirect alloresponses in CAMR, confirms the functional heterogeneity of B cells and association with eGFR decline in these patients, and suggests an explanation for the lack of efficacy of Rituximab in CAMR.

Funding: Commercial Support - Roche provided the rituximab free of charge, Government Support - Non-U.S.

A Randomized Trial of Mild Hypothermia and Machine Perfusion in Deceased Organ Donors for Protection Against Delayed Graft Function in Kidney Transplant Recipients

Darren Malinoski,[2] Sharon L. Swain,[3] Tahnee Groat,[4] Alex Garza,[5] Claus Niemann.[1] Donor Management Research Initiative *[1]UCSF School of Medicine, San Francisco, CA; [2]Oregon Health & Science University, Portland, OR; [3]Donor Network West, San Ramon, CA; [4]Oregon Health and Science University, Portland, OR; [5]UNOS, Richmond, VA.*

Background: Machine perfusion (MP) of kidneys from deceased donors has been increasingly adopted by many centers even though clinical and cost effectiveness studies remain uncertain in the United States. We investigate the effectiveness of MP compared to mild hypothermia which recently has been shown to be protective against DGF (1).

Methods: The trial was approved by the IRB of UCSF (# 17-21768). Donors are not considered human subjects under federal regulations. A waiver of informed consent for recipients is acceptable based on the same federal regulations. A pragmatic multi-site randomized controlled trial that bases enrollment on each Organ Procurement Organization (OPO) current pumping criteria. There are two main groups of deceased donors (DNDDs), (1) those that are "pump eligible" based on current practice and (2) those that are lower risk and whose kidneys do not receive MP ("not pump eligible"). In this trial, "pump eligible" DNDDs are randomized to one of three groups : (1) normothermia (36.5-37.5 C) plus MP of both kidneys (standard of practice control group), (2) mild hypothermia (34-35 C) plus MP of the left kidney only, and (3) mild hypothermia plus MP of the right kidney only. In this manner, the same number of kidneys are randomized to each of the three treatment strategies (MP alone, mild hypothermia alone, or MP+hypothermia). NCT02525510

Results: Three OPOs joined the trial within the first 12 months and 709 donors were screened for eligibility, 559 (78.8%) had research authorization. 353 were excluded with DCD, age the most common reason for exclusion. 203 DNDDs were enrolled in the trial. There were 2 reportable events (bradycardia and ectopy with low BP) with no adverse events that required intervention. In 40 kidneys randomized to pump-eligibility, intended pump assignment could not be followed. Notably, 28 kidneys (22.5% of pump eligble) could not be pumped when supposed to, mainly because of anatomy and logistics.

Underline represents presenting author/disclosure.

Conclusions: Additional OPOs will join within the next 6 months allowing enrollment to increase above 10/week. Importantly, a significant portion of pump eligble kidneys could not be pumped which demonstrates the need to identify additional protective strategies for kidneys at risk for DGF and poor function. 1. Enteric-Coated Mycophenolate Sodium Versus Mycophenolate Mofetil in Combination with Calcineurin Inhibitors in Chinese Renal Transplant Recipients: An Observational Phase 4 Study

Bingyi Shi,[1] Changxi Wang,[2] Tao Lin,[3] Aimin Zhang,[4] Tongyi Men,[5] Jianlin Yuan,[6] Guanghui Pan,[7] Da Xu,[8] Xiaotong Wu,[9] Jinliang Xie,[10] Jianghua Chen,[11] Chunbai Mo,[12] Ke Cheng,[13] Hongxin Guo,[14] Xiaodong Zhang,[15] Xiaowen Gu,[16] Matthias Meier.[17] *[1]309th Hospital of PLA, Beijing, China; [2]The First Affiliated Hospital of Sun Yat-Sen University, Guangzhou, China; [3]West China Hospital, Sichuan University, Chengdu, Sichuan Province, China; [4]General Hospital of Jinan Military Region of PLA, Jinan, China; [5]Shandong Qianfoshan Hospital, China, Xian, China; [6]Xijing Hospital affiliated to Fourth Military Medical University, China, Xi'an, China; [7]The Second Affiliated Hospital of GuangZhou Medical College, China, Guangzhou, China; [8]Ruijin Hospital affiliated to Shanghai Jiao Tong University, China, Shanghai, China; [9]The Second People's Hospital of Shanxi Province, China, Taiyuan, China; [10]XiangYa Hospital Central-South University, Changsha, China; [11]The First Affiliated Hospital of Medical School of Zhejiang, Zhejiang University, Hangzhou, China; [12]Tianjin First Center Hospital, China, Tianjin, China; [13]The Third Xiangya Hospital of Central South University, China, Changsha, China; [14]463rd Hospital of PLA, China, Shenyang, China; [15]Beijing Chao-Yang Hospital, China, Beijing, China; [16]Novartis China, Shanghai, China; [17]Novartis Pharma, Basel, Switzerland.*

Background: This phase IV observational study (ERL080A2424) compared efficacy and safety of enteric coated mycophenolate sodium (EC-MPS; myfortic®) vs mycophenolate mofetil (MMF; Cellcept®) in Chinese renal transplant recipients (RTxR).

Methods: In this 12-month (M) study, 600 adult RTxR received EC-MPS (N=401) or MMF (N=199) + cyclosporine(CsA)/tacrolimus(TAC) + steroids post-Tx. Usage of mycophenolic acid (MPA) dosing regimen, efficacy, and safety at M12, and MPA exposure ($AUC_{0\text{-}12h}$; EC-MPS) in a pharmacokinetic (PK) subset at days 14 and 90 post-Tx were assessed.

Results: Most patients in EC-MPS (78.4%) and MMF (87.8%) cohorts received a starting daily dose ±25% of recommended dose (EC-MPS: 1440 mg/day; MMF: 2000 mg/day). Efficacy events were similar in both cohorts (**Table 1**). Patients receiving lowest range of starting daily doses (EC-MPS: 360-<720 mg; MMF: 500-<1000 mg) had numerically higher acute rejection (AR) rates than patients with higher MPA exposure (EC-MPS, *P*=0.200; MMF, *P*=0.670). MPA exposure ($AUC_{0\text{-}12h}$; EC-MPS) increased in CsA subset from days 14 to 90, but was similar in TAC subset (**Table 2**). Probability of developing serious infections was low with starting doses ±25% of recommended dose for both cohorts.

Conclusions: EC-MPS and MMF cohorts showed similar efficacy and safety at M12; lowest dose ranges, but not higher, were associated with AR rates in EC-MPS cohort. These results will facilitate informed decision-making for EC-MPS-based regimen in China and for patients of Chinese ethnicity in the US.

Funding: Commercial Support - Novartis

Table 1. Tolerability, efficacy, and safety of EC-MPS vs MMF at M12

Parameters	EC-MPS group	MMF group
Tolerability – PPS	**N = 399**	**N = 197**
Duration of use in days, mean (SD)	344.2 (73.53)	338.6 (90.97)
Mean dose in CsA patients*, mg, n (mean±SD)	112 (977.1±207.44)	43 (1255.8±338.45)
Mean dose in TAC patients*, mg, n (mean±SD)	190 (910.9±207.66)	117 (1237.2±262.30)
Number of dose reductions, n (mean±SD)	322 (2.2±1.21)	162 (2.5±1.30)
Time to first dose reductions*, days, n (mean±SD)	322 (39.2±56.20)	162 (49.7±71.71)
Patients switched from EC-MPS to MMF and vice versa, n (%)	72 (18.0)	17 (8.6)
Efficacy – PPS		
eGFR (mL/min/1.73 m² by MDRD4), mean±SD	65.0±16.65	70.2±17.65
BPAR, n (%)	12 (3.0)	7 (3.6)
Suspected or confirmed AR episodes (at least 1), n (%)	40 (10.1)	18 (9.1)
Graft loss, n (%)	1 (0.25)	1 (0.50)
Death, n (%)	3 (0.75)	6 (3.04)
Safety – FAS/SAF	**N = 401**	**N = 199**
Overall AEs, n (%)	322 (80.3)	172 (86.4)
Infections and infestations	182 (45.4)	76 (38.2)
Gastrointestinal disorders	91 (22.7)	55 (27.6)
Overall SAEs, n (%)	149 (37.2)	66 (33.2)
Discontinuation of study	36 (9.0)	17 (8.5)
AEs leading to study discontinuation	1 (0.2)	2 (1.0)

*At M12, total number of patients in the CsA arm were 139 (EC-MPS cohort) and 48 (MMF cohort); total patients in the TAC arm were 228 (EC-MPS cohort) and 137 (MMF cohort).
AE, adverse event; BPAR, biopsy-proven acute rejections; CsA, cyclosporine; EC-MPS, enteric coated mycophenolate sodium; eGFR, estimated glomerular filtration rate; FAS, full analysis set; M, month; MDRD4, 4-variable modification of diet in renal function disease; MMF, mycophenolate mofetil; PPS, per-protocol set; SAE, serious AE; SAF, safety analysis set; SD, standard deviation.

Table 2. Pharmacokinetics of MPA at Days 14 and 90 post-Tx

Parameters	EC-MPS (MPA) in CsA subset				EC-MPS (MPA) in TAC subset

TH-PO1166

Is High-Dose Telmisartan for Proteinuria Better and Safe?

Arpita Roychowdhury,[1] Umesh Dubey,[3] Smita S. Divyaveer.[1,2] *[1]IPGMER, Kolkata, India; [2]Nephrology, R G Kar Medical College, Kolkata, India; [3]Ipgmer and sskm hospital, Kolkata, India.*

Background: Renal and CV outcomes correlate with proteinuria(PU) reduction with ARB therapy in diabetic(DN) and non diabetic(non DN) proteinuric diseases. Combining ACEI with ARB for maximal RAAS blockade and PU reduction failed to meet safety criteria. This trial aims to compare benefit [of PU reduction] vs risk (rising creatinine, declining eGFR or hyperkalemia)of using **high dose Telmisartan(hT) 160 mg/d** i.e. Gr. A versus **conventional dose Telmisartan 80mg/d(cT)** i.e. Gr. B in treatment of DN and non DN proteinuric patients(pts).

Methods: This is hospital based RCT. Pts with persistent PU ≥1 gram/day, due to DN and non DN disease, neither on any disease specific therapy nor on RAAS blockers for prior 6 wks were screened. Fig 1 shows protocol of study. Furosemide 20mg/day was given in both groups. End point: completion of 6 mo. of follow up or discontinuation of therapy (K>5.5, Sr. Cr rise >30%, eGFR <30). Primary outcome: % change in PU within and between groups. Secondary outcomes:change in Sr.Cr,eGFR by MDRD,BP and occurrence of adverse effects. Intention to treat analysis was done.

Results: No. of pts after randomization and subsequent incidence of adverse effects has been shown in table 1. Dose-related adverse events eg.K+ > 5.5 mEq/L were comparable in both groups but decline in eGFR to <30 ml/min/1.73 m² was more in Gr.A compared to Gr.B (6 vs 2).

Conclusions: Effectiveness of **cT** versus **hT** for PU reduction is comparable in proteinuric diseases. Adverse effects like hyperkalemia were similar, however higher events of dose related decline in eGFR occurred with hT.

Funding: Government Support - Non-U.S.

PHYOX: A Safety and Tolerability Study of DCR-PHXC in Primary Hyperoxaluria Types 1 and 2

Bernd Hoppe,[1] Pierre Cochat,[2] Graham Lipkin,[3] Amanda M. Gentile,[4] Bob D. Brown,[4] Ralf Rosskamp,[4] Sally Hulton,[5] Jaap W. Groothoff,[7] Michelle A. Baum.[6] *[1]University Hospital Bonn, Bonn, Germany; [2]Université ClaudeBernard Lyon1-, Bron, France; [3]Queen Elizabeth Hospital, Birmingham, United Kingdom; [4]Dicerna Pharmaceuticals, Cambridge, MA; [5]Birmingham Children's Hospital, Birmingham, United Kingdom; [6]Boston Children's Hospital, Boston, MA; [7]Emma Children's Hospital AMC, Amsterdam, Netherlands.*

Background: Primary Hyperoxaluria (PH) is a family of rare diseases characterized by hepatic overproduction of oxalate due to 3 distinct genetic mutations. Clinical manifestations include nephrocalcinosis, recurrent kidney stones, progressive renal impairment, and systemic oxalosis (primarily PH1). DCR-PHXC is an investigational RNAi therapeutic targeting LDHA enzyme, which is involved in the ultimate step of hepatic oxalate production and has the potential to treat all 3 known genetic forms of PH.

Underline represents presenting author/disclosure.

Methods: This abstract includes preliminary data from the ongoing PHYOX study (ClinicalTrials.gov: NCT03392896), a two-part, single-ascending dose study conducted in 25 normal healthy volunteers (NHVs, Group A) and 16 PH patients (Group B). Eligible PH patients have PH1 or PH2, urinary oxalate (Uox) ≥0.7 mmol/24Hr, and eGFR ≥30 mL/min/1.73m^2. Group A is randomized including placebo with 5 cohorts dosed at 0.3, 1.5, 3, 6, and 12 mg/kg DCR-PHXC or placebo. Group B is open label and has 3 PH1 Cohorts dosed at 1.5, 3, and 6 mg/kg DCR-PHXC and a 4th PH2-only cohort. The primary objective is safety and secondary endpoints include change in 24Hr Uox from baseline defined as the mean of two 24Hr urine collections during screening.

Results: Group A is complete with no observed safety or tolerability issues and no serious adverse events (SAEs). Two mild injection site reactions (ISRs) occurred and resolved within 48Hrs. Dosing is complete in Group B Cohorts 1 (1.5 mg/kg, n=4) and 2 (3.0 mg/kg, n=4) and in the Cohort 4 sentinel PH2 subject (1.5 mg/kg). To date, only adults have been dosed. No SAEs have occurred in Group B. Two mild ISRs resolved within 48Hrs. Preliminary results following a single administration of 1.5 mg/kg DCR-PHXC in Cohorts 1 and 4 shows maximum 24Hr Uox reductions from baseline between 39%-57% between postdose Days 43 and 95. Cohort 2 has shown 40-62% reductions in Uox between Days 15 and 43 and 2/4 patients have 24Hr Uox values in the normal range. Follow-up in all Cohorts is ongoing.

Conclusions: Preliminary PHYOX data show DCR-PHXC is safe and well-tolerated in this ongoing study. Observed reduction of 24Hr Uox following a single administration of DCR-PHXC in both PH1 and PH2 patients is a promising sign of DCR-PHXC's potential potency and duration of action.

Short-Term Medium-Chain Triglycerides Supplementation on the Nutritional Status and Muscle Strength of Patients on Chronic Dialysis

Vincent Wu,[1] Chih-Hsiang Chang.[2] *[1]National Taiwan University Hospital, Taipei, Taiwan; [2]Chang Gung Memorial Hospital, Taoyuan, Taiwan.*

Background: One of the major risk factors for cardiovascular disease is lipid abnormalities among hemodialysis patients. We prospectively evaluated the effects of medium chain triglycerides (MCT) supplementation on the nutritional status, muscle strength and anthropometrics of patients on chronic dialysis.

Methods: This study was randomized, double-blind comparison of placebo and active treatment for dialysis patients with MCT. In this full scale of the evaluation study, chronic dialysis patients who have malnutrition (serum albumin less than <3.8 g/DL) and did not have the active infection disease were included. Dietary supply with MCT and by daily dietary record review, we estimated the amount of dietary components in participants. Patients were supplied with the powder of MCT, 9.1g, (100kcal) daily while the control group received start (100 kcal) daily. The biochemical data, nutritional status, muscle power and anthropometrics were evaluated at baseline and 4 months later.

Results: Totally 84 patients (male, 43.8%; mean age, 62.7 years) of chronic dialysis with malnutrition (albumin 3.42± 0.32 g/dL) were included. Forty-two patients received MCT treatment (100 kcal daily) and another fourth-two patients received starch 100 kcal daily. After MCT treatment, the SGA 7-point nutritional score (5.22± 1.53 to 6.19 ± 1.36, p=0.001) and the estimated carbohydrate amount (127.7± 69.8 to 165.9± 42.5g, p=0.004) augmented. Additionally, the hand-grip strength (18.0± 6.8 to 19.2± 7.5kg, p =0.048) as well as the middle arm circumference (25.4 ± 2.72 to 26.9 ± 3.7 cm, p= 0.025) improved. However the patients received starch supplement did not improve muscle power or nutritional score.

Conclusions: In chronic dialysis patients with malnutrition, short- term daily oral MCT supply could improve the nutritional status in term of nutritional score and carbohydrate amount. It will contribute to the positive effect of muscle thickness and muscle power.

Effect of Hemodiafiltration (HDFIT) on Physical Activity and Self-Reported Outcomes: Primary Results of the Brazilian HDFIT Trial

Roberto Pecoits-Filho,[1] John W. Larkin,[1,2] Priscila B. Gonçalves,[1] Shimul Sheth,[3] Hao Han,[2] Carlos E. Poli de Figueiredo,[4] Americo L. Cuvello neto,[5] Ana Beatriz L. Barra,[6] Jochen G. Raimann,[3] Maria Eugenia F. Canziani.[7] HDFIT Study Investigators *[1]Pontificia Universidade Catolica do Parana, Curitiba, Brazil; [2]Fresenius Medical Care North America, Waltham, MA; [3]Renal Research Institute, New York, NY; [4]Pontificia Universidade Catolica do Rio Grande do Sul, Porto Alegre, Brazil; [5]Hospital Alemão Oswaldo Cruz, Sao Paulo, Brazil; [6]Fresenius Medical Care, Rio de Janeiro, Brazil; [7]Universidade Federal de Sao Paulo, Sao Paulo, Brazil.*

Background: Advantages of hemodiafiltration (HDF) in solute removal and clinical outcomes compared to hemodialysis have been reported. HDFIT investigated the effects of HDF on physical activity (PA), quality of life (QOL) and other outcomes.

Methods: HDFIT (NCT02787161) is a multicenter RCT conducted in 13 clinics in Brazil that studied if HDF effects PA measured by accelerometry (ActiGraph, Pensacola, USA), self-reported QOL as per SF-36, and laboratories. Stable HD patients (vintage 3-24 months) were randomized to either high-volume online HDF or high-flux HD (control). We compared differences in changes from baseline (BL) at months 3 and 6 for 1) step counts and moderate-to-vigorous PA (MVPA) over 24 hrs after HD (primary outcome) and 2) self-reported SF-36 vitality scores and post-dialysis recovery time (secondary outcome), and 3) laboratory parameters. Linear mixed-effects models (LMM; adjusted for age, sex, and baseline values) quantified effect sizes of switching to HDF. Data are reported as percentage of the effect size to the BL mean value (control) with 95% CIs.

Results: We randomized 195 patients (age 53±15 yrs; 71% male; 29% diabetes) from Aug/16 to Oct/17. Exchangeability at BL was achieved for the primary outcomes (BL step count 5184±3374 (HDF) vs 5050±4262 (HD), P=0.69; min of MVPA 27±32 (HDF) vs 27±42 (HD), P=0.95). HDF tended to increase the step count by 3.0% (95%CI -2.3 to 8.3) and the min of MVPA by 2.3% (95%CI -6.9 to 11.5; Figure 1A), and reduce the recovery time by 15% (-31 to 2) vs HD (Figure 1B). SF-36 Vitality scores were not affected by HDF. Effect sizes of HDF on laboratories are consistent with increased solute clearance (Figure 1C).

Conclusions: HDF produces higher clearance of solutes compared to HD. Despite borderline significance, HDF has a positive absolute effect on increasing step counts and minutes of MVPA, and reducing post-dialysis recovery time compared to HD.

Funding: Commercial Support - Fresenius Medical Care and Pontificia Universidade Catolica do Parana

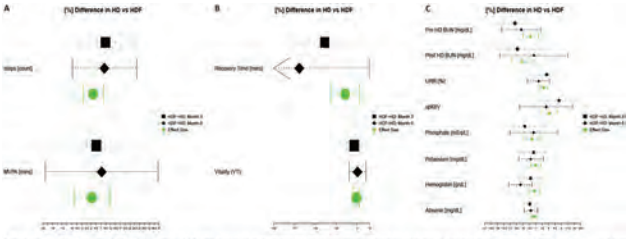

Figure 1: Forest plots depicting the differences in change between HDF versus HD from baseline (reference) to months 3 (black square) and 6 (black diamond). Data are presented as the percentage of the effect size in reference to the baseline mean value in the control group . Linear mixed effects models estimate the effect size of HDF compared to HD adjusted for baseline value, age and sex (green circle). A) step counts and mins of MVPA during 24 hours after the treatment. B) post-dialysis recovery time and SF-36 vitality scores. C) selected laboratory parameters.
